*Treatment Source Skin Distance (SSD).* Does any part of the patient's anatomy, or do the available applicator sizes, prevent the treatment being given at the standard treatment distance (nominal SSD) on the central axis? This nominal SSD is generally 100 cm, which implies a gap of 50 mm between the applicator and the skin surface for many models of linear accelerator\*. However, with Elekta linacs, it is a common practice to treat in skin apposition at 95 cm SSD.

*Oblivity.* If electrons are to enter any part of the patient with significant obliquity, then additional considerations apply, as described in [Section 34.4.4](#).

*Surface Irregularities.* If surface irregularities are present in the area to be treated, side-scatter bolus may be required. Alternatively, bolus may be required to fill the irregularities and present a flat surface perpendicular to the beam.

*Choice of Energy.* The beam energy is determined, along with the amount of surface bolus, by considering both the required surface dose and the required depth of the treatment isodose beneath the surface.

*Field Size.* The decrease in dose near the field edges must be taken into account.

*Calculation of Monitor Units (MU).* The isodose to which the treatment is prescribed must be carefully specified (it should be 100% of the maximum dose) and the monitor unit calculation must take into account any field shaping or modification to the applicator.

*Vulnerable Organs.* Organs-at-risk may need to be shielded during treatment.

---

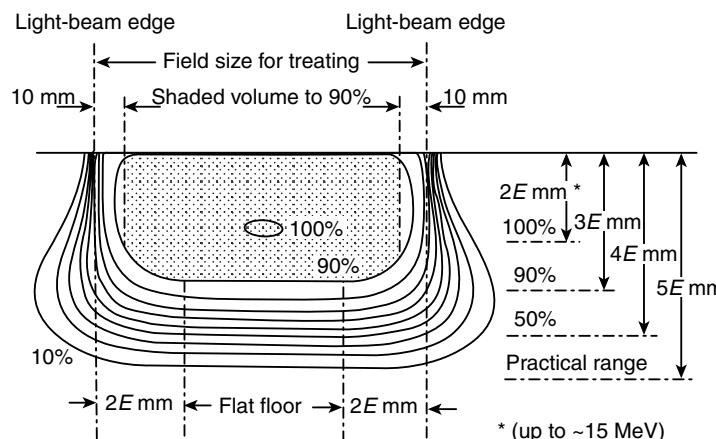

\* This SSD is a nominal value, generally equal to the Source Axis Distance where the wall mounted lasers intersect, dictated by the geometry of the machine. The effective SSD will be variable with energy and field size as discussed in [Section 24.2.6](#).

### 34.3 FIELD SIZE AND COVERAGE OF THE TARGET VOLUME

Electron applicator sizes, or insert (cut-out) sizes if the applicator carries an insert with an aperture cut in it, are generally quoted in terms of the geometrical size found by measuring the extent of the light beam projected through the applicator (or insert) onto the skin at the normal treatment distance. This will also be, to a close approximation, the size of the field defined by the 50% isodose at the skin surface.

The International Commission on Radiation Units and Measurements (ICRU 1993) recommends that planning target volumes should be covered by the 95% isodose or better, but to insist on this same criterion in electron therapy will often mean unacceptably large margins around the planning target volume. This difficulty is recognised and addressed by ICRU (2004). For electron therapy, the International Atomic Energy Agency (IAEA 1987) recommends an 85% coverage, and the American Association of Physicists in Medicine (AAPM 1991) recommends 90% coverage. Pragmatically, in electron planning, it is common practice to aim to cover the planning target volume with the 90% isodose. In some instances lower-value isodoses may be chosen, as for example, in chest wall irradiation, in which the 80% isodose may be chosen to lie at the lung surface in order to reduce penetration into the lung and hence overall lung dose. If any critical structure, such as cord, lies beneath the target volume, then the relative doses, both at the inner limit of the target and at this structure, must be carefully considered to make an appropriate clinical choice of the optimum beam energy.

As illustrated by Figure 34.1, the width of the *flat floor* of the 90% isodose surface is considerably less than the 50% field width at the tissue surface. The 90% isodose surface generally begins to flatten out at a distance of about  $2E$  mm inside the 50% isodose (see Figure 34.1), where  $E$  is in MeV. Hence, to guarantee that a target volume is treated uniformly to the same 90% depth as the central axis, one would need to use a field size about  $4E$  mm larger than the width of the target volume. In clinical practice, this is too large a margin, and, instead, the addition of 10 mm around the target volume is commonly used, which allows for some rounding of the bottom edges of the target volume. However, the significance of the  $4E$  mm

**FIGURE 34.1**

The flat floor of the 90% isodose curve is smaller than the field width by a margin of  $4E$  mm, where  $E$  is the incident energy in MeV. In practice, a margin of 10 mm is commonly used, which will treat a target volume with rounded edges (shown shaded). Approximate depths of key percentage doses are also illustrated. Isodose values are shown in intervals of 10%.

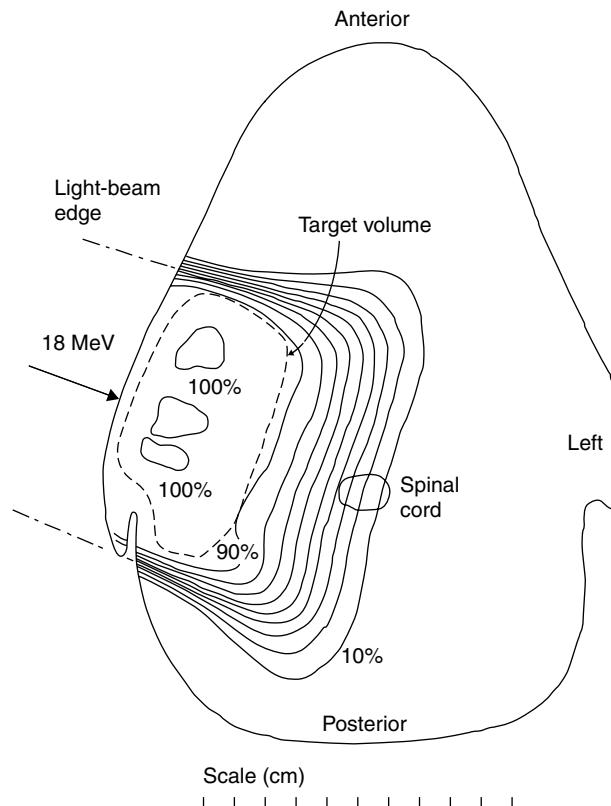

dimension is that, for applicators smaller than  $4E$  mm, there can be no flat floor to the 90% isodose surface. This means that the depth of the 90% isodose for applicators less than  $4E$  mm wide is less than that achieved with a larger applicator, and great care should be exercised when planning with these relatively small applicators, or where any dimensions of a shaped field approach this critical value. [Figure 34.1](#) also illustrates the 2, 3, 4, 5 rule as discussed in [Section 24.2.2](#) to estimate the depths of various isodose parameters from the beam energy.

Rules should not be applied blindly, and it is always incumbent upon the treatment planner to take into account the clinical requirements for target coverage. Attention must be given to the dose outside the geometric beam edge, particularly when the beam is to be placed close to a critical structure (organ at risk). In this situation, some compromise on field size and positioning may be necessary.

## 34.4 EXAMPLES OF ELECTRON PLANNING

### 34.4.1 EXAMPLE A: SINGLE-ELECTRON FIELD WITH NO COMPLICATIONS

As an example of the application of the checklist to a relatively simple plan, consider the treatment of a parotid tumour ([Figure 34.2](#)) which is to be treated with 20 fractions of 2.75 Gy

**FIGURE 34.2**

In this example of treating the parotid, a 90 mm wide field is sufficient to treat a target volume measuring 80 mm across. Isodose values are normalised to the maximum dose on the beam axis (at depth  $d_{\max}$ ) and shown in intervals of 10%.

in four weeks. The target volume measures 80 mm in the anterior-posterior direction, 80 mm in the superior-inferior direction and extends 49 mm beneath the skin surface.

Considering the checklist, no issues are raised by the need for special techniques, treatment SSD or obliquity. Other items on the checklist include:

*Surface Irregularities.* Because it is not the primary intention to treat the ear, it is unnecessary to provide side-scatter bolus, and the ear is merely taped as flat as possible. However, a wax ear-plug is required to prevent electrons tunnelling down the external auditory meatus.

*Choice of Energy.* The depth of the planning target volume is 49 mm, which will be reached by an 18 MeV beam, for which the 90% isodose is at 55 mm deep with a 200 mm  $\times$  200 mm applicator (see Table 34.1) and 53 mm for a 100 mm  $\times$  100 mm applicator. The surface dose of an 18 MeV beam is 88%, from Table 34.1. However, it is not the intention to treat to the skin surface, and the target volume does not come closer to the skin surface than 4 mm, which, from Table 34.1, is more than the 1 mm required to raise the dose to 90%.

*Field Size.* Using the criterion of a 10 mm margin around the planning target volume, the field size should be 100 mm  $\times$  100 mm. However, because the target volume has been drawn with rounded corners at depth, it may be treated with a 90 mm  $\times$  90 mm field in this case.

*Calculation of Monitor Units.* The dose prescription point is on the central axis of the treatment beam, at the depth of  $d_{\max}$ , i.e. 22 mm for this linear accelerator. This means that a dose of 2.75 Gy will be given to 100% on the central axis, 22 mm deep.

If a 90 mm  $\times$  90 mm insert is not available, one may be produced by attaching lead strips onto the edges of a 100 mm  $\times$  100 mm insert to reduce the field size appropriately. The output (in Gy per monitor unit) of the newly fashioned insert should be measured, although experience shows that where the field edges are brought in only minimally, the measured output may not show significant change from that for the unmodified applicator.

*Vulnerable Organs.* The ear plug mentioned above is used to protect the external auditory meatus. The dose to the spinal cord is clinically acceptable.

#### 34.4.2 EXAMPLE B: USE OF INTERNAL SHIELDING

A basal cell carcinoma on the cheek is to be treated with electrons using a circular applicator 40 mm in diameter. The full thickness of the cheek is to be treated; it measures 20 mm from the surface of the lesion to the inner surface of the cheek (Figure 34.3).

*Surface Irregularities.* The lesion itself is raised from the normal skin surrounding it. Wax bolus will be applied, which will eliminate the effects of the irregular surface (Figure 34.3).

*Choice of Energy.* From Table 34.1, it will be seen that, at normal incidence, the 90% depth dose of a 9 MeV beam is 27 mm. The surface of the lesion must be covered with 5 mm bolus (using Table 34.1) in order to raise the dose there to 90%. With this arrangement, 9 MeV is adequate for the purpose.

*Field Size.* Using the 4E rule, the minimum field size without affecting the central axis depth doses is  $4 \times 9 = 36$  mm. Hence, the 4 cm diameter applicator should be appropriate, provided that the radiation oncologist accepts the rounded edges of the treatment volume at depth.

*Vulnerable Organs.* It is decided to protect the gums with a lead shield. However, because of backscatter from the lead, which would raise the dose on the inner mucosal surfaces of the

**TABLE 34.1**

## Parameters for Electron Planning

Incident Beam Energy	6 MeV	9 MeV	12 MeV	15 MeV	18 MeV	22 MeV
Surface dose, $D_{0,s}$ , at normal incidence relative to dose at $d_{\max}$ at normal incidence, 100 cm SSD	75%	86%	83%	87%	88%	88%
Surface dose, $D_{45,s}$ , at 45° incidence, 105 cm SSD, relative to dose at $d_{\max}$ at normal incidence, 100 cm SSD	83%	85%	87%	89%	90%	90%
Surface build-up (i.e. bolus thickness) at normal incidence (in mm), 100 cm SSD, required to raise skin surface to 90% of dose at $d_{\max}$ , at normal incidence	6 mm	5 mm	4 mm	1 mm	1 mm	1 mm
Surface build-up at 45° incidence, 105 cm SSD, required to raise skin surface to 90% of dose at $d_{\max}$ at normal incidence, 100 cm SSD	2 mm	2 mm	1 mm	1 mm	0 mm	0 mm
Depth, $d_{0,90\%}$ , of dose at normal incidence, 100 cm SSD, which is 90% of dose at $d_{\max}$ at normal incidence	17 mm	27 mm	38 mm	45 mm	55 mm	63 mm
Depth, $d_{45,90\%}$ , of dose at 45° incidence, 105 cm SSD, which is 90% of dose at $d_{\max}$ at normal incidence, 100 cm SSD	7 mm	11 mm	17 mm	23 mm	26 mm	30 mm
Depth of dose beneath skin surface, covered with build-up as in row 4, at 45° incidence, 105 cm SSD, which is 90% of dose at $d_{\max}$ at normal incidence, 100 cm SSD	5 mm	9 mm	16 mm	22 mm	26 mm	30 mm

For each energy shown, these data relate the skin surface dose and depth of the 90% isodose (at 45° incidence and 105 cm SSD), to the maximum dose (i.e. at  $d_{\max}$ ) measured at normal incidence and 100 cm SSD using a 200 mm×200 mm applicator (see [Figure 34.6](#)). The bolus thicknesses required to bring the surface doses up to 90% have been included. While the parameters for individual machines and different angles of obliquity may vary from those listed above, the table serves as a first approach to designing a treatment plan.

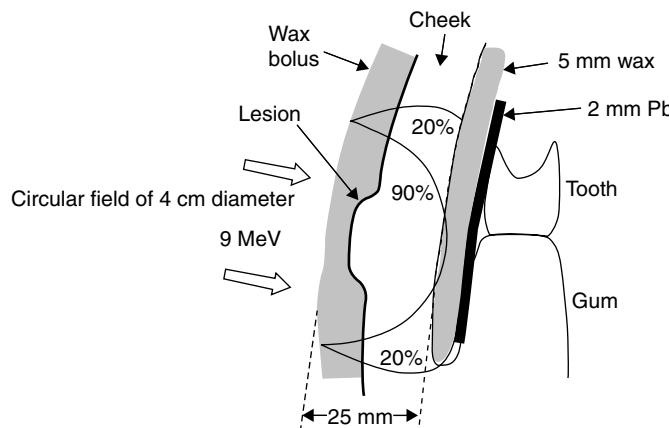

**FIGURE 34.3**

Illustration of the irradiation situation for the use of an internal shield behind the cheek as described in the example.

cheek, a layer of wax is needed between the lead and the cheek. Saunders and Peters (1974) have suggested that a lead shield covered with 5 mm wax to *dampen* the backscattering is sufficient for electrons with residual energy of 3.5 MeV or less at the lead interface. In practice, this arrangement is suitable for most applications, bearing in mind that internal lead shields will not generally be used for beams of incident energy much above 9 MeV.

A calculation for the combination of lead with 5 mm of wax is instructive. With the 5 mm wax protection, plus the 20 mm thickness of cheek and the 5 mm bolus on top, the lead is at a depth of 30 mm. For this rough calculation, it is sufficiently accurate to suppose a linear decrease of energy from the surface downwards. Thus, the energy of the electron beam when it hits the lead shield is  $9(1 - 30/45)$  where the range of the electron beam is estimated to be 45 mm from the relation: practical range (mm) =  $5 \times$  incident energy (MeV) (see Figure 34.1). Hence, the electron energy at the lead shield is about 3 MeV.

Using the relation given by Klevenhagen et al. (1982), the electron backscatter factor (EBF) is

$$\text{EBF}_{(\text{at shield})} = 1 + 0.735e^{-0.052E_s} = 1 + 0.735e^{-0.052 \times 3} = 1.63 \quad (34.1)$$

where  $E_s$  is the energy in MeV of the electrons at the shield. In other words, the backscatter fluence is 63% of the incident fluence at the lead surface. For energies at the shield of between 1 MeV and 9 MeV, Lambert and Klevenhagen (1982) give an exponential expression for the electron backscatter *upstream* from the shield

$$\text{EBF}_{(\text{at } t \text{ mm upstream})} = e^{(-kt)}$$

where  $k$  is given by the relation

$$k = 0.61E_s^{-0.62}$$

Hence, in this case,  $k = 0.31$  and the backscatter 5 mm upstream from the shield is  $e^{-0.31 \times 5} = 0.21$ , that is, 21% of the backscatter found at the shield itself. Hence, the backscatter 5 mm upstream is, finally, 21% of 63%, or 13% of the incident fluence at the shield. Since the incident fluence at the shield (at a depth of 30 mm) is 80% (from depth-dose curves), the mucosal surface of the cheek will experience  $13\% \times 80\% = 10\%$  backscatter. However, the dose from the direct incident beam (at the depth of 25 mm) is 95% (from depth-dose tables), and so the total dose to the mucosa, with the lead shield plus 5 mm wax in place, is 105%, which is quite acceptable.

In general, incident beams will be of this energy or lower when shields need to be used, so that the 5 mm wax protection over the lead shield will usually be adequate. A 2 mm thickness of lead, by the same token, will also normally provide adequate shielding (in this case, it is perfectly able to absorb the residual 3 MeV energy).

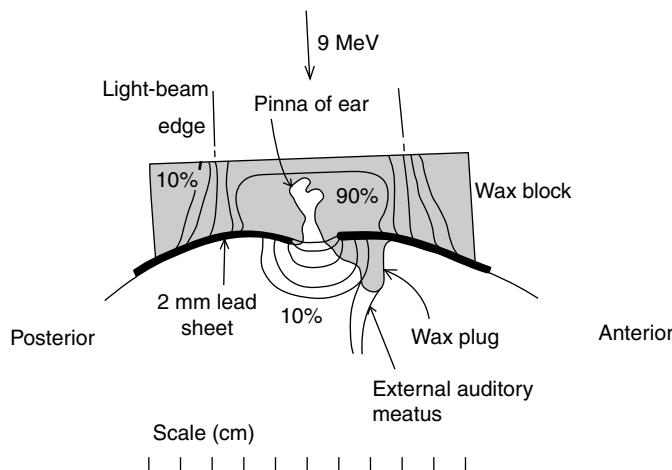

### 34.4.3 EXAMPLE C: SINGLE-ELECTRON FIELD WITH SURFACE INHOMOGENEITIES

Figure 34.4 illustrates the treatment of the pinna of the ear. Referring to the check-list, there is no need for a special technique and there are no problems with SSD or obliquity. Other items on the list include:

*Surface Irregularities.* To avoid the problems of inhomogeneous dose distribution that would arise from irradiating the protruding pinna, a well-fitting wax block is fashioned to enclose the pinna on both the anterior and posterior surfaces. In practice, this may be arranged by producing the wax block in two halves so that the pinna is sandwiched between them. Vaseline helps to eliminate any remaining air gaps, but some centres prefer not to use it because it is messy.

*Choice of Energy.* The pinna extends 20 mm from the tip to the root. From Table 34.1, the minimum appropriate energy is 9 MeV, which has a 90% depth of 27 mm, and so the wax block must extend 7 mm beyond the tip of the pinna. This is also greater than the 5 mm required, from Table 34.1, to build up the dose to 90% on the tip of the pinna.

*Field Size.* The anterior-posterior dimension of the pinna to be treated is of the order of only 10 mm. However, from the  $4E$  rule, a flat 90% isodose is only achieved in this case with surface field sizes of  $4 \times 9 \text{ mm} + 10 \text{ mm} = 46 \text{ mm}$ . In practice, a  $60 \text{ mm} \times 60 \text{ mm}$  applicator is used, and the pre- and post-auricular areas are shielded by lead. Since the lead is placed at the depth of the 90% isodose, the small aperture in the lead does not affect the 90% isodose itself, although it will constrain the lower-value isodoses of electrons transmitted through the aperture to take an almost semi-circular shape as shown in Figure 34.4.

**FIGURE 34.4**

With the pinna in this position, the necessary side scatter is provided by a well-fitted wax plug. Lead sheet protects the surrounding skin, but a plug in the external auditory meatus is still necessary to prevent the possible electron tunnelling. Shown isodose values (both above and beneath the lead shielding) are 10%, 20%, 50%, 80%, and 90%.

*Vulnerable Organs.* Although lead has been used to shield tissue from the incident electron beam, it will be noticed in Figure 34.4 that electrons can leak through the aperture under the lead. It is therefore sensible to place a plug in the external auditory meatus to prevent possible tunnelling. The plug may be made from wax, or it could be produced by soaking cotton wool in olive oil. A thickness of 2 mm of lead will afford sufficient protection in this instance, because the overlying thickness of the wax block will have reduced the energy of the electrons to less than half that of the incident 9 MeV beam. In general, the thickness (in millimetres) of lead shielding required is given by half of the energy (in MeV) of the electrons incident upon the shielding.

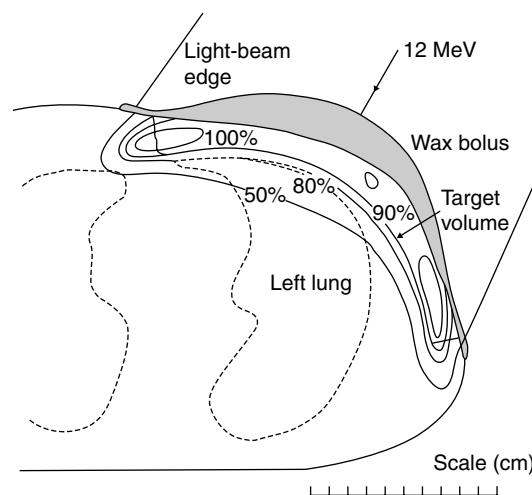

#### 34.4.4 EXAMPLE D: SINGLE-ELECTRON FIELD WITH OBLIQUITY

Consider now the treatment of the chest-wall after mastectomy. In Figure 34.5, the posterior surface of the planning target volume has not been extended as far as the surface of the lung in order to minimise the lung dose as discussed below. The lung extends relatively close to the skin surface, and the target volume extends considerably to the posterior of the patient, so that the technique of treating the chest wall with an opposed pair of tangential photon fields would mean that an unacceptably large portion of lung would be treated to a high dose, with the risk of radiation pneumonitis.

As before, we consider the points in the checklist in turn, and use them to illustrate general principles where appropriate. There are no surface irregularities.

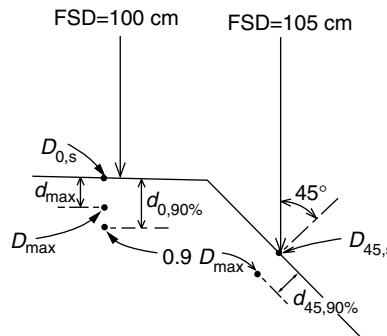

*Special Techniques.* Ideally, this would be treated using electron arc therapy, although the varying radius of curvature of the breast does require complex planning (see Section 34.6). However, for reasons discussed later, this technique is not available in many centres, and so the simplest approach—a static beam—is considered in this case.

*Treatment SSD.* The applicator may be used at the standard distance of 50 mm on the central axis of the field. However, the curvature of the area means that the skin at the periphery of the field may lie considerably further from the applicator than the standard distance (see next point). In practice, it is the bolus applied over the skin surface that is placed at the standard distance of 50 mm.

**FIGURE 34.5**

To treat a curved chest wall with a single-electron field, it is generally necessary to provide a bolus that is thick near the central axis of the field and tapers to the minimum required for surface build-up at the field edges. Shown isodose values, normalised to the maximum dose on the beam axis, are 50%, 80%, 90% and 100%. The maximum dose within the two *islands* defined by 100% isodoses at either edge of the field is 105%.

**FIGURE 34.6**

This illustrates the geometry used to construct Table 34.1. Measurements were made with a Varian Clinac 2500 linear accelerator using a 200 mm  $\times$  200 mm applicator, and the data in Table 34.1 must be regarded only as a guide when applied to other linear accelerators.

**Obliquity.** The curvature of the area means that electrons at the edges of the field will enter with considerable obliquity, that is, at an angle that is significantly removed from the local perpendicular. Because the problems of obliquity become greater as the angle of obliquity increases (McKenzie 1979), it is nearly always best to arrange the angle of incidence of the central axis so that the angles of obliquity at the two extreme edges of the field, as shown in the transverse plane, are about equal, provided that this does not conflict with other clinical considerations. In this case, a gantry angle of 30° is appropriate, and the beam may be said to be *in apposition* to the skin.

Table 34.1 gives some representative data which are useful in a manual first pass approach to treatment planning with oblique fields. Figure 34.6 shows the geometry for those data.

**Choice of Energy.** In oblique incidence, it is generally the depth of the planning target volume beneath the skin at the edges of the field (16 mm in this case at the lateral edge of the field) that determines the required incident energy. The penetration of a 45° oblique beam at 12 MeV (bottom row of Table 34.1) is 16 mm from the skin to the 90% depth dose, and so this energy is used, together with 1 mm build up on the skin surface to raise the skin dose from 87% to 90% (again, using Table 34.1). At the central axis, the thickness of bolus needed is determined from Table 34.1 by subtracting the depth of the target volume on the central axis (16 mm) from the 90% penetration depth at normal incidence (38 mm from Table 34.1).

Using a treatment planning computer, and with these constraints on the bolus, it becomes a relatively easy matter to design the exact shape of the bolus required to shape the isodoses to conform more closely to the target volume, using perhaps one or two trial shapes. The shape of bolus in Figure 34.5 gives rise to the computed isodose distribution shown, which leaves an acceptably low incursion of high-value isodoses into the lung. Notice that the maximum dose at the field edges is 105%. If the increased distance from the source had not mitigated the effect of obliquity, this value would have been nearer 120%.

**Field Size.** At 107 cm SSD at the field edges, the geometric (50%) coverage afforded by a 200 mm  $\times$  200 mm applicator is 214 mm. This is sufficient to provide the 200 mm coverage required between the 90% isodoses at the medial and lateral field edges.

**Calculation of Monitor Units.** It would normally be unnecessary to calculate the monitor units required to deliver the prescribed dose for this treatment because this should be computed automatically by the treatment planning system when producing the isodose distribution. Nevertheless, at 100 cm SSD to the surface of the bolus\* on the central axis, the

\* It may be easier to perform the SSD patient setup without bolus and to add the bolus afterwards. The monitor unit setting would then be slightly lower to compensate for the inverse square variation according to the effective source-bolus distance (typically -1% for a 5mm thick bolus at 100 cm SSD).

monitor unit setting will be given simply by that determined locally for the 200 mm  $\times$  200 mm applicator at the standard distance of 100 cm SSD. This setting may not agree exactly with that produced by the computer (because of the influence of the curved surface) but it will be acceptably close.

*Vulnerable Organs.* The lung inhomogeneities do not significantly influence the distribution of the isodoses that lie above them, but the low density of lung nevertheless plays a part in the design of the treatment plan. In this plan, a margin has been left between the target volume and the lung surface so that the 70% or 80% isodose is coincident with the lung surface rather than the 90%. If the 90% isodose were to lie only a few millimetres closer to the surface of the lung, this would push the 80% isodose considerably further into the lung volume, leaving little room for error and an increased risk of radiation pneumonitis.

---

## 34.5 FIELD MATCHING

Occasionally, situations arise in which adjacent fields must be matched in order to avoid an over- or under-dose. Examples of situations in which such beam matching may be required include:

- Providing varying penetration by using different energy electron beams for adjoining areas
- Treating a larger area than standard applicators allow
- Treating an area adjacent to a previously-treated area
- Reducing the extreme effects of obliquity when treating a curved surface

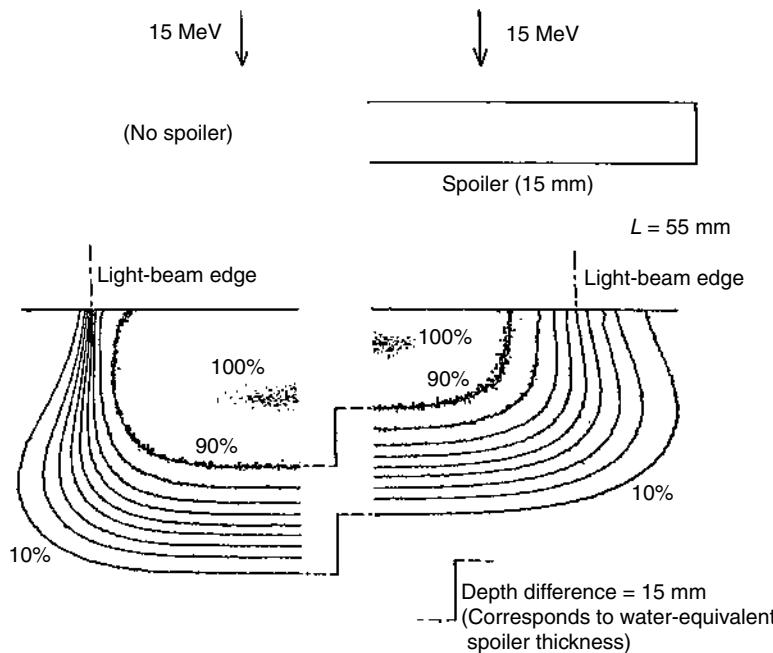

In beam matching, the join should be positioned away from critical areas. Staggered joins (i.e. shifting joins at different treatment fractions) may be considered if this is practical. One method of improving the matching is to utilise the broadened penumbra regions produced by extended SSD. This necessitates on-surface shaping of the other field edges to restore a sharp penumbra, and may well lead to a loss of beam flatness. Several solutions to the problem have emerged over the years, for example, Kalend et al. (1985), Kurup et al. (1992, 1993), and Feygelman (1994).

Ulinin and Palisca (1996) and Lachance et al. (1997) proposed techniques that broaden the penumbra on the edge to be matched. However, the applicator design modifications depend upon the applicator cones, and the overlap or gap that must be left between matching fields is again dependent upon the detail of the design. Furthermore, measurements are required for a range of applicator sizes and energies if computer treatment planning is to be used.

A simple alternative solution is to add a slab of material such as polymethylmethacrylate (PMMA) to cover completely the end of the electron applicator (McKenzie 1998). Such a slab is called a *spoiler* because it spoils the originally narrow penumbra by broadening it. With a spoiler:

- There is no dependence of the properties of the spoiler design upon the applicator cone, provided that the spoiler is large enough to cover the aperture completely.
- No design-dependent overlap or gap is required between adjacent fields, as matching is always to the light beam edge regardless of applicator size or SSD.
- Computer treatment planning programs can be used without modification or extra beam measurement to calculate the effect of the spoiler.

Figure 34.7 illustrates two important characteristics of the dose distribution in tissue irradiated with an electron beam through a spoiler. These characteristics are general in that they are independent of SSD, applicator size, electron energy incident upon the spoiler and spoiler thickness (provided that the thickness is not so great that the electron beam becomes totally diffuse, which is avoided in practice). In summary, these characteristics are:

**FIGURE 34.7**

An illustration of characteristics of the isodose distribution under an electron beam spoiler. The light-beam edge marks the position of the 50% isodose at the surface, and depths of the flat portions of isodose surfaces are given by subtracting the effective thickness of the spoiler from the depths of corresponding isodoses in a beam with no spoiler. The dimension  $L$  is defined in Figure 34.8. Isodoses, normalised to the maximum dose on the beam axis, are shown at 10% intervals. (Note that the step indicated in the middle of the figure does not represent a continuous isodose line - the two halves of the figure are separate.) (From McKenzie, A. L., *Phys. Med. Biol.*, 43, 3456–3478, 1998. With permission.)

- The light-beam edge closely coincides with the 50% isodose at the tissue surface.
- The depths of the isodoses in the flat portion of the distribution in tissue irradiated through a spoiler may be found by subtracting the thickness of the spoiler from the depths of the corresponding isodoses in tissue irradiated without a spoiler.

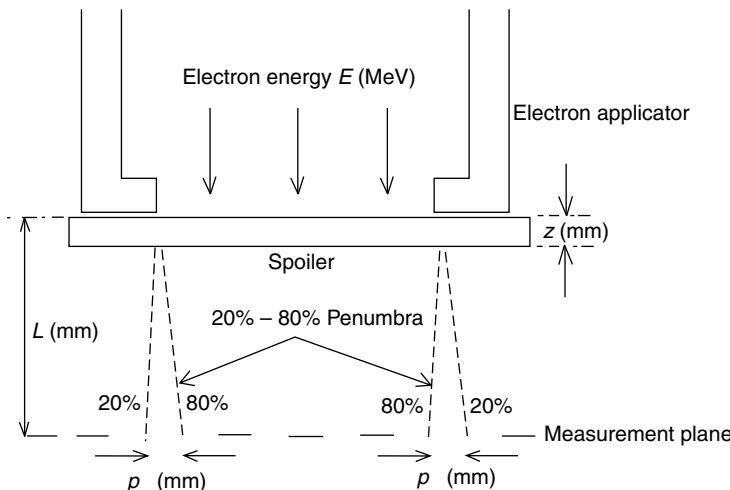

**FIGURE 34.8**

Illustration of the geometry used for beam-spoiler treatment in field matching and of the dimensions used in Equation 34.2. (From McKenzie, A. L., *Phys. Med. Biol.*, 43, 3456–3478, 1998.)

These simple features are particularly useful in planning electron therapy with spoilers. One direct consequence of the first characteristic is that electron beams should be matched by ensuring that the light-beam edges coincide at the tissue surface.

Another feature of using spoilers is that, in general, they increase the surface dose so that additional skin bolus may be unnecessary. A further advantage is that the number of monitor units required to deliver a given dose to the tissue is the same as that calculated for a treatment without a spoiler, except for a small inverse-square decrease to allow for the fact that the point of maximum dose within the tissue has moved closer to the surface by an amount equal to the thickness of the spoiler.

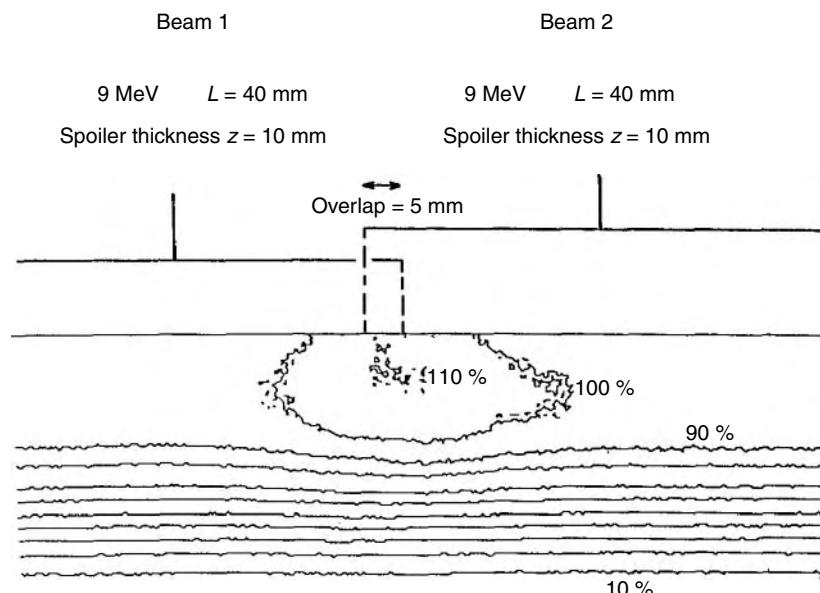

McKenzie (1998) has shown that the 20%–80% penumbra width,  $p$ , is given by

$$p = 1.2Lz^{1/2}E^{-1} \quad (34.2)$$

where  $p$  is in mm,  $L$  is the distance in mm from the inner face of the spoiler (the one nearer the electron source) to the point where the penumbra is measured (see Figure 34.8),  $z$  is the thickness of the spoiler in mm and  $E$  is the energy (in MeV) of the electrons incident upon the front face of the spoiler. This dependence on  $L$ ,  $z$ , and  $E$  is in accordance with theory predicting the broadening of pencil beams through thick absorbers. This equation can be used to indicate the tolerance of abutting fields to an inadvertent overlap or gap.

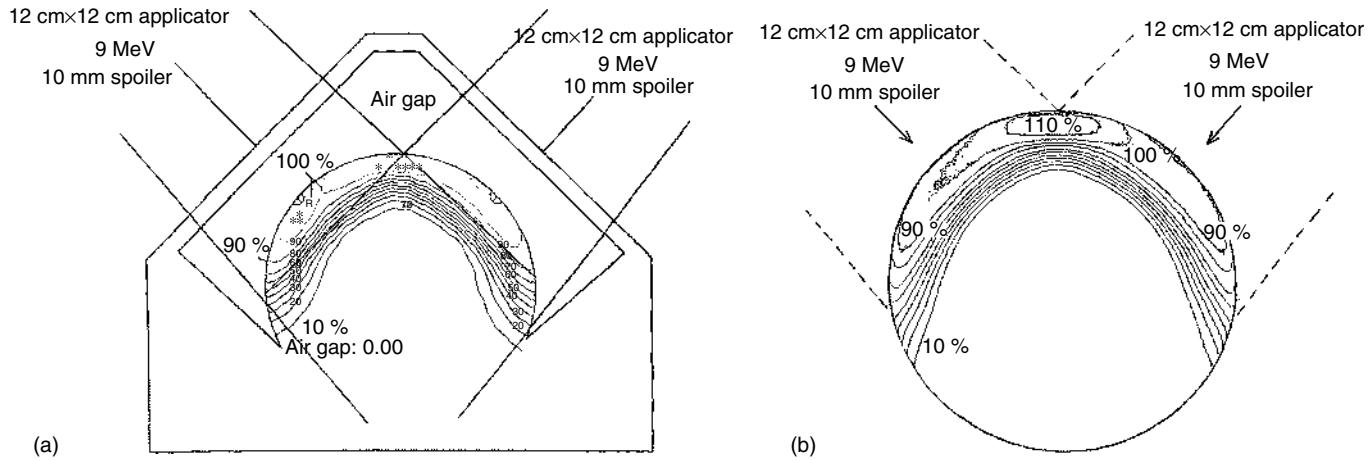

Figure 34.9 shows the isodose distribution at the junction of two 9 MeV beams transmitted through a 10 mm spoiler with a hinge angle of 0°. Although the two beams have been made to overlap by 5 mm, the measured hot spot is only 110%.

An advantage of using spoilers for matching is that the facilities required for treatment planning with spoiler beams, at least in two dimensions, are already available on planning computers that use the Fermi-Eyges theory (Hogstrom et al. 1981) or more recent variants (see Chapter 27). If the computer treatment planning program allows beam modifiers, then planning is straightforward with spoiler beams. If the beam modifier facility is not available,

**FIGURE 34.9**

Even when two beams with a zero hinge angle are made to overlap (in this case by 5 mm), the overdosing is slight, because of the penumbra broadening introduced by the spoiler. Isodoses are normalised to the maximum dose on the beam axis and shown at 10% intervals. (From McKenzie, A. L., *Phys. Med. Biol.*, 43, 3456–3478, 1998. With permission.)

**FIGURE 34.10**

If the treatment planning computer does not have the facility to introduce beam modifiers, it is still possible to model the spoiler by the simple expedient of creating an air gap under a thickness of tissue equal to that of the beam spoiler. (a) This shows the distribution computed using the air-gap technique with a 160 mm diameter cylindrical phantom and the extremely large hinge angle of 90°. The maximum dose is 110%, just beneath the intersection of the two beam edges. (b) This shows the distribution obtained by measuring the arrangement in (a). The maximum dose (inside the 110% isodose curve) is 116%. Isodoses in both cases are normalised to the maximum dose on the beam axis and shown at 10% intervals. (From McKenzie, A. L., *Phys. Med. Biol.*, 43, 3456–3478, 1998. With permission.)

then it is nearly as simple to digitise an air gap under a thickness of tissue corresponding to that of the spoiler. This has been done in Figure 34.10a to predict the effect of two beams incident through 10 mm spoilers at the extreme hinge angle of 90°, treating a cylindrical phantom. The phantom diameter was 160 mm, taken to be typical of that of a scalp.

For comparison, Figure 34.10b shows the measured dose distribution for the arrangement in Figure 34.10a. Even at this extreme angle, it is noteworthy that the maximum dose measured in the phantom is only 116% (at a point inside the 110% isodose curve) and that the computer treatment plan is a relatively faithful representation of the measured dose.

If field matching is used in electron irradiation of the chest wall, the overdose at the matching point will generally be lower, partly because the hinge angles involved will be smaller, and partly because the larger radius of curvature of the chest wall means that matching points are further from the electron source, which reduces the overdose compared to the maximum dose on the central axes of the beams. However, in cases of field matching on curved surfaces, it is always important either to test the predicted doses in a phantom before treatment, or on the patient during treatment, because of the possibility that electrons from one field will be scattered well into the middle of the abutting field, contributing to the total dose.

When using spoilers, only the minimum thickness of spoiler necessary to produce an adequately wide penumbra should be used, and if that leads to too great a depth for the 90% dose, then skin bolus should be applied as well. A 10 mm spoiler works well with 9 MeV for chest wall irradiation. Since a spoiler broadens penumbrae at all edges of the field, consideration should be given to shielding tissue beyond field borders that are not involved in the matching.

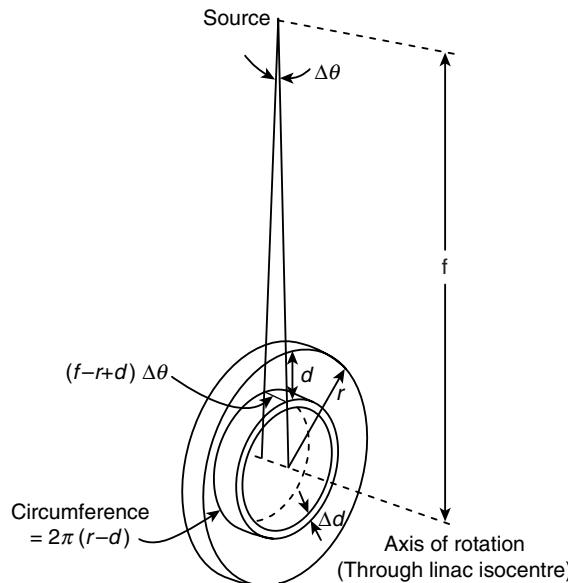

## 34.6 ELECTRON ARC THERAPY

The problems of dose inhomogeneity associated with obliquity and beam matching in the electron treatment of curved surfaces are effectively eliminated with the use of narrow-beam electron arcing techniques. However, these techniques are not standard in every radiotherapy centre and, unlike other techniques that have been discussed earlier in this section, commissioning an electron arc therapy service requires considerably more preparation, starting from the technology, through data gathering to implementation of a system for dose computation. In view of these considerations, it is not practicable to provide enough information here to cover the topic completely, but only to highlight the key points to be considered in establishing electron arc therapy in a radiotherapy centre. Reviews of electron arc therapy can be found in Leavitt et al. (1985) and Leavitt (1996).

In electron arc therapy, it is important to try to minimise the variation in source-skin distance over the treatment arc, and this is achieved by placing the linear accelerator isocentre as close as possible to the centre of curvature of the arc of the patient's surface. The depth of the centre of curvature beneath the patient's surface should be at least  $R_p$ , the electron range, and preferably around twice this distance, in order to avoid possible overdosing from superposition of doses in the region of beam *crossfire*. In the treatment of surfaces with relatively large radii of curvature, such as the chest wall, it is clear that the treatment cannot be delivered through the electron applicator normally used to provide secondary collimation in stationary-beam therapy, because there would not be adequate clearance for the patient.

Secondary collimation\* of the arc therapy beam therefore generally has to be positioned at a significant distance from the patient's skin, so that the beam profile in the plane of the arc extends well beyond the limits indicated by the light field (Leavitt et al. 1985; Lam et al. 1987).

\* The term *primary beam collimation* is reserved here for that imposed upon the electron beam by the x-ray collimators.

**FIGURE 34.11**

Schematic representation of a patient cross section (radius of curvature  $r$ ) used to interpret its influence on the dose delivered during arc therapy. In a complete rotation, the dose delivered at depth  $d$  is proportional to  $(r-d)^{-1}(f-r+d)^{-1}$  (see text).

Because of this beam spread, the aim, at least for the middle sections of the arc, is for the complete beam profile to pass over any given point, so that the dose received by the point is integrated over the whole beam profile. This is more practicable with narrower beams, of around 5 cm width when projected to the isocentre, which will also minimise problems of obliquity at the edges of the beam profile.

To see the effect of the radius of surface curvature upon the dose delivered by arc therapy at a given depth,  $d$ , consider the irradiation of a cylindrical phantom of radius  $r$ . In particular, consider the disk-shaped volume (containing the central treatment plane) defined by a sector of the beam that extends an angle  $\Delta\theta$  in the direction perpendicular to the plane of rotation (see Figure 34.11). At depth  $d$ , the electron energy delivered to an incremental depth  $\Delta d$  through the sector of angle  $\Delta\theta$  during one complete rotation will be spread evenly within the volume  $2\pi(r-d)(f-r+d)\Delta d\Delta\theta$ . Because the dose will depend upon the reciprocal of the mass, and, hence, the volume throughout which the energy is distributed, the variation of dose  $D(r,d)$  at depth  $d$  beneath a surface of radius  $r$  will be given by:

$$D(r,d) \propto (r-d)^{-1}(f-r+d)^{-1} \quad (34.3)$$

It will be seen from this dependence of the dose upon the radius that, in the competing effects of the decrease in radius of curvature and the consequent increase in distance from the source, the former effect wins. In summary, a decrease in the radius of curvature leads to an increase in dose.

It may well be necessary to arrange for a treatment to be based on more than one centre of curvature, in order to accommodate the different skin curvatures in the central plane. In planes parallel to the central plane, lying superior or inferior to it, the skin curvature may again be different. The solution is, rather than use a rectangular treatment beam, to use a beam that varies in width at different distances superior or inferior to the central plane, depending upon how the skin curvature varies away from the central plane. The resultant beam shape may be fixed, and is generally trapezoidal in shape, or it may vary during treatment using multileaf collimators (Leavitt et al. 1989; Klein et al. 1996). Such field shaping with secondary

collimation, whether static or dynamic, may also be used to neutralise the relatively poor beam profile in the superior–inferior direction (Leavitt et al. 1985).

The dose distribution at the ends of the arc is naturally compromised because of incomplete integration across the dose profile. The dose distribution may be sharpened by placing tertiary collimating lead or low-melting-point alloy shaped to the treatment field on the patient's skin and extending the treatment arc some 10° to 15° over the tertiary collimator. Alternatively, dynamic collimation may be used (Swalec et al. 1994), in which the jaws in the plane of the arc are progressively opened and closed at the beginning and end of the arc respectively, which mimics the effect of tertiary shielding.

Determination of the dose distribution in electron arc therapy treatment planning should be done using an appropriate pencil-beam or Monte-Carlo based computer algorithm. It is characteristic of electron arc therapy that the depth–dose curves tend to display a lower surface dose, a greater depth of maximum dose,  $d_{\max}$ , and higher percentage depth–doses at given depths beyond  $d_{\max}$  than they do for stationary electron beams of the same incident energy. This can largely be explained using the same reasoning underlying Equation 34.3: at greater treatment depths in arc therapy, the electrons are distributed over diminishing lengths of arc and so the fractional depth dose is greater than that for stationary beams.

The low surface doses in arc therapy can be an obstacle to achieving dose homogeneity, and Leavitt et al. (1990) have suggested combining electron energies, including using build-up on the lowest energy, to achieve a more uniform depth dose distribution.

In arc therapy, it is always important to remember that the bremsstrahlung contribution is additive around the isocentre (Kase and Bjärngard 1979). Clearly, as the angle of the treatment arc increases, so will the relative bremsstrahlung contribution, which may become a significant fraction of the treatment dose, particularly at higher incident electron energies.

---

## 34.7 INHOMOGENEITIES AND ELECTRON PLANNING ALGORITHMS

Inhomogeneities in composition and in shape modify dose distributions in two ways, both of which need to be considered in clinical situations. The first is the effect on absorption and the consequent shift in isodose lines, and is most pronounced through and beyond large inhomogeneities. The second is due to scatter differences between different materials (interface or edge effects) and is most pronounced for small inhomogeneities or near the edges of larger heterogeneities. The physics of the latter and some basic effects were discussed in [Section 24.6](#). The resultant distribution depends on the size, shape and composition (atomic number and electron density) of the inhomogeneity, as well as on the energy and field size of the beam. In current practice they are best considered by using pencil beam algorithms, as available on most modern treatment planning systems. However, increasingly, Monte Carlo techniques are being applied to these problems. Simple manual methods can be used to provide initial rough estimates of the effects or approximate checks of more sophisticated approaches (e.g. see Klevenhagen 1985; Thwaites 2000).

Pencil beam algorithms are discussed and reviewed in [Chapter 27](#) and Monte Carlo methods in [Chapter 28](#). Other comprehensive reviews of the development of electron beam algorithms can be found in Jette (1996) and of Monte Carlo modelling of electron beams in Ma and Jiang (1999). A concise summary of electron beam algorithms is given in Thwaites (2000), along with a brief review of their accuracy (see also Chapter 28). The pencil-beam algorithms currently implemented have generally been shown to be accurate to within around  $\pm 5\%$  or  $\pm 5$  mm over a range of applications, with the more recent algorithms showing improved performance. In simpler situations, accuracies of  $\pm 2\%$  or  $\pm 2$  mm are achievable in accordance with the requirements laid down for photon algorithms (ICRU 1987). However, larger discrepancies on the order of 10% (and with the potential to be significantly larger) have

been observed at larger depths for narrow inhomogeneities with long edges parallel to the beam. Pencil-beam algorithms are still currently the most widely implemented approach for electron treatment planning on commercial planning systems, although they are now beginning to be supplemented or replaced by Monte Carlo approaches (Kawrakow 2001; Cygler et al. 2004). There are a number of different pencil-beam algorithms and implementations in use and the user must ensure that the system is well tested locally and that any limitations are clearly understood. Commissioning recommendations and test methods are provided in Shiu et al. (1992), van Dyk et al. (1993), IPEMB (1994), AAPM (1998), IPEM (1999) and IAEA (2004).

---

## 34.8 TREATMENT PRESCRIPTION

Prescription depends on clinical requirements but is generally to the position of dose maximum, although other levels may be used. It should be noted that, in some circumstances, low-energy scatter components may give a dose maximum quite close to the surface, which may influence the position of the dose prescription. Electron prescription recording and reporting is dealt with in ICRU Report 29 (1978); this has been superseded by ICRU Report 71 (2004), in which newer recommendations for electron beams complement the recommendations included in ICRU 50 (1993) and ICRU 62 (1999). It is still recommended that the ICRU reference point used for reporting is the point of dose maximum on the beam axis. However, whereas for photon beams ICRU recommends that the dose variation within the Planning Target Volume should be constrained within +7% and -5% of the reference point dose, for electron beams -10% or -15% is acceptable as the 100% reference is by definition at the depth of dose maximum.

---

## 34.9 CURRENT AND FUTURE DEVELOPMENTS

Electron therapy is set to benefit from the same developments that are currently adding to the power of megavoltage photon therapy. Inverse treatment planning will increasingly be used to design solutions to difficult problems, and these solutions will be implemented in clinical practice using electron-beam shaping with multileaf collimators both in static and in dynamic mode, e.g. Klein (1998) and Korevaar et al. (1998). This same technology also offers the possibility of mixing the modalities of photon and electron beams, or different energy electron beams, to design individually tailored beam characteristics of depth dose, flatness, penumbra width and skin dose, e.g. Karlsson and Zackrisson (1997) and Korevaar et al. (1998).

Whilst pencil-beam based treatment planning algorithms will continue to develop, Monte Carlo programs that will handle complex dose distributions in acceptable times are now available commercially; these will be especially useful for dealing with the effects of inhomogeneities. [Figure 34.4](#) was drawn freehand with an eye to the physics of backscattering from lead and diffusion through a narrow aperture. Monte Carlo programs will underpin the art of prediction in cases like this and will add significantly to the confidence placed in calculated distributions. This in turn will lead to an increase in the use of intensity-modulated electron beams and their combination with photon beams to tailor dose distributions in appropriate clinical situations.

## 35.1 INTRODUCTION

The ideal radiotherapy treatment plan produces a uniform coverage of the target volume without giving a significant dose to surrounding normal tissue. The use of CT and MR in treatment planning, and fast computer hardware (for both planning and treatment delivery) has meant that 3D planning is a realistic option. More degrees of freedom in the use of noncoplanar beam arrangements and the introduction of intensity modulation both make plans more

difficult to compare and evaluate. Good, fast plan evaluation tools are essential to simplify this process. Several such tools have been designed, and will be discussed in this chapter.

---

## 35.2 ISODOSE DISPLAY

Isodose information can be displayed on a 3D treatment plan as surfaces of equal dose, which correspond to the familiar isodose lines shown in a 2D display. Isodose surfaces can be labelled in terms of absolute dose (if the dose prescription has been incorporated into the treatment plan), or relative dose (where the dose is expressed as a percentage of a reference dose). One advantage of relative dose displays is that they are valid for any prescription dose, but this is less useful with computerised plans, as it is easy to change the prescription dose with rapid recalculation of the full dose distribution in terms of absolute dose. The type of display chosen depends on local protocols and may depend on whether more than one phase of radiotherapy treatment is to be delivered.

The calculation of a dose distribution requires a lattice of points, spread over the volume in which dosimetric information is required. These points are contained within the external surface of the patient and their number and spatial resolution are the result of a trade-off between the accuracy required and the speed of calculation, which also depends on the dose calculation algorithm used. The  $X$  and  $Y$  coordinates of these points are within the transverse planes, but the  $Z$  coordinate may require some interpretation since the information is limited by the spacing between slices\*. The isodose contours in a given calculation plane or the isodose surfaces are usually produced by linear interpolation between this matrix of points. The separation of the points should therefore be small enough to allow accurate linear interpolation. If the dose calculation algorithm is too slow for quasi-real-time display, a low resolution may be used for rapid display during plan optimisation. A high resolution is then set for the final dose calculation. In this case, the final plan may be printed out and used to scrutinize the isodose curve chosen to cover the planning target volume (PTV), the isodoses through critical organs and the location of hot or cold spots in the dose distribution.

Although it is possible to display the dose distribution in terms of total absolute dose over the whole treatment course, some form of normalisation may be employed. The beam weights can be adjusted to give 100% to a predefined point, such as the ICRU reference point (ICRU 1993 and see [Section 37.6](#)). Independently of the method used to specify the weights or to combine the beams, the dose may be renormalized to the ICRU reference point at the end of the calculation. This facilitates the assessment of the dose uniformity within the PTV on the basis of a permitted percentage deviation from the prescribed dose (e.g. between 95% and 107%).

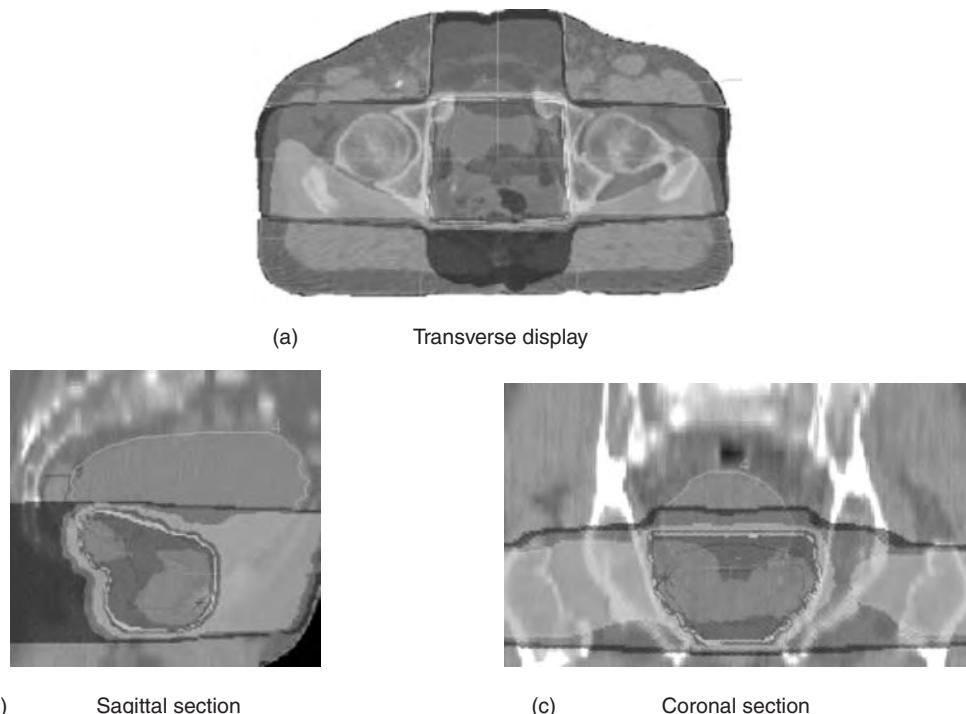

The dose distribution can be displayed in multiplanar views, as shown in [Figure 35.1](#), particularly in transverse (a), sagittal (b), and coronal (c) sections. It can also be displayed as a 3D representation of anatomy and isodose surfaces (see [Figure 35.2](#)).

The possibility of choosing between different display methods for dose distribution and anatomical information should be a feature of any modern treatment planning system (Drzymala et al. 1994). Some useful features are listed as follows:

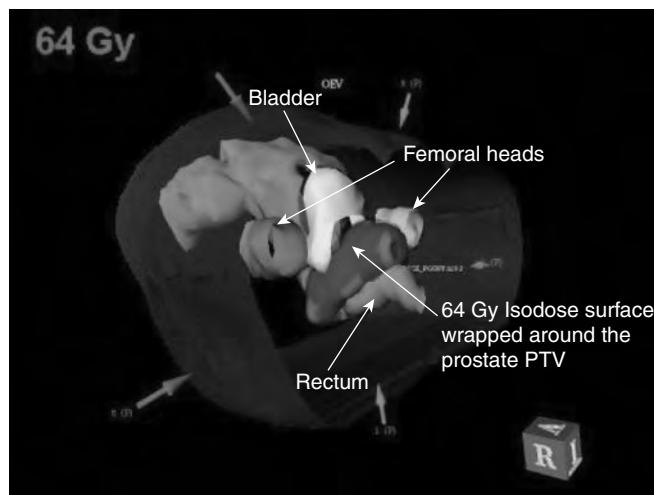

- Opaque *colour-wash* displays, which should be interchangeable with conventional isodose lines, as although they can give a good overall impression of the dose distribution, they can also obscure the target volume.

---

\* The coordinate system used here is that used in the DICOM (Digital Imaging and Communications in Medicine) standard ([Chapter 42](#)) rather than that recommended by the International Electrotechnical Commission (see [Section 11.5.4](#)).

**FIGURE 35.1**  
**(See colour insert following page 590.)** Planar colour-wash representation of the dose distribution in three different calculation planes through the patient: each colour corresponds to a range of dose according to a predefined scale. The corresponding isodose lines can be seen at the frontier of adjacent colours. This display may be easier to understand than the standard isodose line representation.

**FIGURE 35.2**  
**(See colour insert following page 590.)** 3D surface rendering of anatomical structures and 64 Gy isodose surface for a five-beam prostate treatment plan.

- Translucent colour wash displays superimposed on CT grey-scale information which can be windowed.
- Zoom and pan facilities, with variable calculation resolution over the zoomed areas.
- 3D surface rendering of isodose surfaces, for instance as wire frames or translucent rendered surfaces, superimposed on organ volume surface displays, on a graphics device capable of real-time image manipulation (see [Figure 35.2](#)).
- *Volume of regret* representation, which is a dose-reduction technique applied to the dose distribution using surface displays: An acceptable window of dose level is chosen and portions of organs outside this window are highlighted. For critical organs this is a one-sided test, in which regions of dose above the acceptable level are displayed. For target volumes, regions of either excessive or insufficient dose can be shown. This is particularly useful when checking the coverage of PTV when using arcing beams, such as for stereotactic radiotherapy.

Ideally, plan evaluation should be done using real-time displays of the dose distribution. It is useful to display the transverse, sagittal, and coronal planes simultaneously on an interactive console to help overcome the limitations of a 3D display on a 2D medium. This requires special graphics hardware in which all of the images are loaded in graphics memory and rapidly accessed. The real-time capability gives the illusion of the user moving through the 3D display (Emami et al. 1991b). Other possibilities have been explored, such as real-time use of beam's-eye-views (BEVs) with the dose contour displayed (McShan et al. 1990) or colour wash surface dose display. It is also advantageous to be able to make visual comparisons between the dose distributions of rival plans using side-by-side display or other forms of graphical comparisons (i.e. dose difference displays).

## 35.3 DOSE VOLUME ANALYSIS

### 35.3.1 DEFINITION AND APPLICATION OF DOSE VOLUME HISTOGRAM

Volume calculations performed by 3D treatment planning systems provide a large quantity of dose information, which can be difficult to interpret and evaluate when it is displayed as isodose curves on several transverse, sagittal and coronal planes. It is much simpler to condense the 3D dose distribution data to a graph, which displays the radiation distribution within a specifically defined volume of interest, so that summarising and analysing the 3D data is possible (Chen 1988). Such a graphical representation is called a dose volume histogram (DVH).

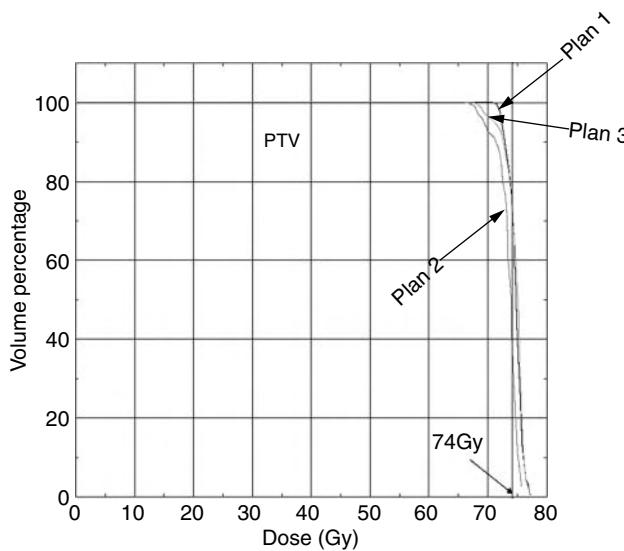

The DVH can be expressed as

The summed volume of elements receiving dose in a specified dose interval, against a set of equally spaced dose intervals.

This is a *differential* DVH and shows the absolute or relative volume in each dose interval (bin) directly.

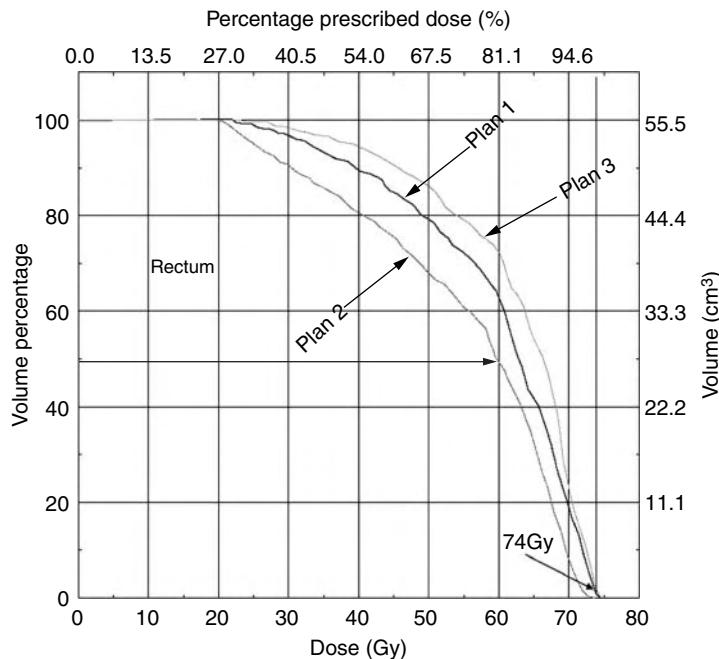

More frequently used, however are *cumulative* dose volume frequency distributions, which are plots of the volume receiving a dose greater than, or equal to, a given dose, against dose. The volume accumulates starting at the highest dose bin continuing towards zero dose, eventually reaching 100% of the total volume (see [Figure 35.3](#) and [Figure 35.4](#)). Normally volumes are expressed as a percentage of the total volume; however, in some situations the absolute volume may be more appropriate.

DVHs can be used during the planning process to check whether the dose is adequate and uniform throughout the target volume, and the extent and value of any hot spots in adjacent normal tissue. However, because they do not display positional information, they should not be the only method used. Their main use is as a plan evaluation tool. They can be used as a method of comparing different treatment plans on a single graph, for specifically identified structures and target volumes. For the PTV, DVHs should show a uniformly high dose

**FIGURE 35.3**

Dose volume histograms (DVHs) from 3 different plans for a prostate planning target volume (PTV where the prescribed dose is 74 Gy). Plan 1 provides a better PTV coverage than Plan 3 or Plan 2.

throughout the volume. The shape approximates to a step function and a steep slope shows that a large percentage of the volume has a similar dose. An ideal curve would show this step around the prescription dose, as in Figure 35.3, in which the DVHs for the PTV in three different treatment beam configurations are compared.

**FIGURE 35.4**

Dose volume histograms (DVHs) for the rectum for the same plans as shown in Figure 35.3. Plan 2 provides a better protection of the rectum than Plan 1 or Plan 3 but, as seen on Figure 35.3, this is at the detriment of the PTV coverage.

DVHs for organs-at-risk which are intended to be protected should preferably have a concave appearance: it may be acceptable either to deliver a relatively high dose to a small volume or a small dose to a large volume. [Figure 35.4](#) shows comparative DVHs for a rectal volume for a prostate treatment where the prescribed dose is 74 Gy. It can be seen for example that 50% of the rectal volume is receiving more than 60 Gy, 63 Gy, or 66 Gy, depending on the treatment plan. It is also useful to display both the absolute dose and the absolute volume, together with normalised values, on the same graph. For the analysis of small differences in DVHs, it can be beneficial to use a non-linear volume axis.

DVHs were used originally for analysis of the effect of sophisticated treatment equipment (Chin et al. 1981) or for charged particle therapy (Goitein and Miller 1983; Chen et al. 1984; Austin-Seymour et al. 1986). They are now a method of choice in the evaluation and optimisation of all external-beam conformal plans (see also [Chapter 43](#)).

### 35.3.2 METHODS FOR DOSE VOLUME HISTOGRAM CALCULATION

#### 35.3.2.1 Sampling Methods

There are essentially two approaches to calculate a DVH, depending on which method is used to sample the points within the structure of interest. These are the grid sampling method and the random sampling method (see Niemierko and Goitein 1990).

The grid method (Chen et al. 1984; Drzymala et al. 1991) consists of systematically calculating the dose at each point of a three dimensional grid of appropriate resolution that covers the structure of interest. This grid is normally derived from a sequence of CT scans in which cubic volume elements are equally spaced in the  $X$  and  $Y$  directions, but not necessarily in the  $Z$  direction. The volume of the voxel can then be defined by the product of the  $X$  and  $Y$  grid spacing and the slice thickness. To calculate the total volume of a particular structure, the volume elements (voxels) lying within the structure are summed. A reasonable resolution for sampling the volume of typical anatomical structures is a grid spacing of between 2 mm and 3 mm. The grid method is the natural extension of the dose calculation performed for isodose representation (see [Section 35.2](#)).

The random sampling method (Niemierko and Goitein 1990; Kooy et al. 1993) consists of setting a parallelepiped of dimensions around the structure of interest, large enough to cover the structure, and picking points randomly within this parallelepiped (i.e.  $X$ ,  $Y$ ,  $Z$  coordinates within the preset limits above). If  $N$  points have been picked with a uniform probability, each of them is representative of an elementary volume  $\Delta V = V/N$ , where  $V$  is the total volume of the parallelepiped (i.e.  $V = (X_{\max} - X_{\min}) \times (Y_{\max} - Y_{\min}) \times (Z_{\max} - Z_{\min})$ ). If, among these  $N$  points,  $N'$  points have been found within the structure, the volume of the structure may be approximated by  $N' \times \Delta V$ . By calculating the dose at each of these  $N'$  points, a DVH may be obtained and plotted.

The advantages and disadvantages of these two methods have been the subject of controversy in the literature (Jackson et al. 1993; Lu and Chin 1993; Niemierko and Goitein 1993c). It is now clear that the random sampling technique is more efficient (i.e. a smaller number of calculation points\*) is required to reach the same level of representativity in the dose volume distribution). It is subject to less variability due to the shape or orientation of the structure. It is more flexible because it can be disconnected from the isodose calculation and launched *on the fly*<sup>†</sup>. For both methods, an indication of the validity of the calculation can be obtained from the comparison between the structure volume calculated from pure geometrical

\* The number of dose calculation points required to reach a reasonable accuracy for a given structure is typically around 400. It should be increased to at least 1000 or 2000 if there are high gradient regions within the structure (for instance at the beam edge), especially for large complex volumes (e.g. lungs).

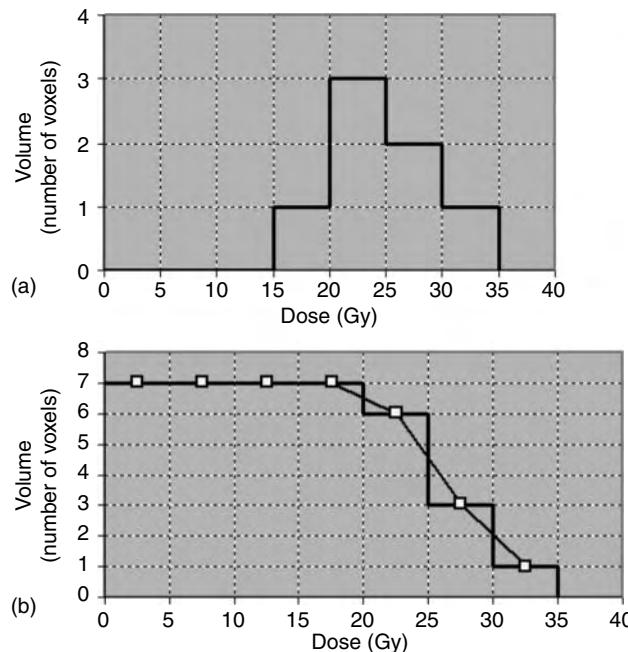

<sup>†</sup> Real-time dose volume histogram (DVH) calculation can be followed, and interrupted when it is stable.

considerations and the summation of the elementary volumes used in the DVH calculation, respectively.

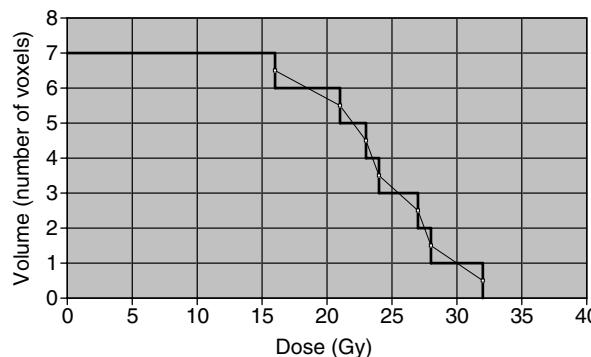

### 35.3.2.2 Dose Binning and Graphical Representation

According to the definition given in [Section 35.3.1](#), it is necessary to divide the range of expected dose values into equal intervals when constructing a histogram. For each interval, the volumes of the voxels receiving dose within that interval are accumulated in the appropriate element of an array, or bin. Cumulative DVHs are therefore obtained by adding the volume accumulated in each bin to the volumes in all bins corresponding to higher dose intervals. Differential DVHs treat the volume in each bin as a separate quantity, and a bin interval of between 2 Gy and 5 Gy is reasonable. For cumulative DVHs, the appropriate dose interval for the bins depends on the dose response curve for the structure of interest. An interval of 0.5 Gy has been shown to be reasonable, whereas 2 Gy is too wide an interval. The graphical representation of the resulting DVH is shown in [Figure 35.5](#).

This approach means that the bin size has been carefully selected at the very beginning of the computation process or that the dose values to all points sampled within a structure are stored before distributing them into the proper bins. It has been suggested by Niemierko and Goitein (1994) that it is not the optimal solution, because it requires an unnecessary *dose* sampling process (i.e. dose binning) after having achieved the *volume* sampling. They suggested replacement of *dose volume histograms* (DVHs) by so-called *dose volume distributions* (DVDs), in which the calculation points are simply sorted according to dose values and are plotted by assigning the corresponding cumulated volume to each dose value (see [Figure 35.6](#)).

**FIGURE 35.5**  
Dose volume histogram (DVH) plot, assuming that the dose has been calculated in seven points (i.e. seven voxels) evenly distributed throughout the structure volume, yielding dose values equal to 16, 31, 23, 24, 27, 28, 32 Gy. The abscissa axis represents the dose in Gy, using five Gy bins. The ordinate axis represents the volume in arbitrary units (i.e. number of voxels). The differential (a) and cumulative (b) forms are represented. The thinner solid line shows how it is possible to plot this histogram as a curve. (The number of points and the dose intervals have been reduced to illustrate the methodology.)

**FIGURE 35.6**

Dose volume distribution (DVD) plot for the same distribution as represented on Figure 35.5. Each point represents the exact dose at an individual dose calculation point which is assumed to represent the dose for the whole of the corresponding volume element. The graph can be plotted either as a continuous line through the points or with the familiar histogram steps (equally distributed along the *volume* axis rather than along the *dose* axis). In practice this distinction becomes irrelevant when a large number of points are plotted.

In practice, there is not much difference between these two approaches, but the DVD representation, which could be used in all situations, has particular advantages when there is a small number of sampling points.

### 35.3.2.3 Boolean Operations on Structures for Dose Volume Histogram Calculations

It is sometimes useful to have DVH information for structures that are completely or partially contained within another structure. Examples include the rectal wall, rather than the volume encompassed by a solid definition of rectum (i.e. all points lying inside of the external wall surface); a rectal tumour where normal rectum needs to be separated from tumour in the DVH calculation; or a combined DVH of both lungs. This cannot be performed by combining the individual DVHs assigned to each structure. To do this, a system of logical (boolean) operators is useful, such as *and*, *or*, *not*, *inside*, and *outside*. The DVH calculation then looks at each sampling point and determines within which logically specified region the point lies.

Another method, useful when one structure is contained within another, is to assign hierarchy numbers to each structure, the highest number representing the most important structure. Each element in the dose matrix is given a *tag* value, with the more important points given a higher value, so that any points occurring in both structures will have the highest priority for the structure of interest under calculation. For example, a structure within another can be subtracted out by assigning the inner structure a higher priority than the outer one.

### 35.3.3 CLINICAL USE AND LIMITATIONS OF DOSE VOLUME HISTOGRAMS

Care is required when comparing plans which have been computed with different dose computational parameters or using different algorithms because there is always some uncertainty related to DVH calculation and representation. Different dose calculation algorithms may not handle heterogeneities, or the penumbra, etc., in the same way; the dose sampling resolution or dose binning can also affect the results of the DVH, especially in regions of steep

dose gradient. A good way to test the accuracy of dose calculations is to use test phantoms of known dimensions and dose. Useful phantom designs include a set of concentric cubes and circles of known volume (see [Section 39.3.7](#)).

DVHs provide a graphical summary of the dose distribution within a structure; they do not give spatial information. They show that hot and cold spots exist, but do not indicate where they occur, nor whether there are several small high- or low-dose areas or a just a large one. To overcome this difficulty, Cheng and Das (1999) have introduced the concept of spatial DVH (zDVH). Dose-area frequency distributions can be used for organ surfaces (Li et al. 1997; Tucker et al. 2004) and some use can be made of dose-length histograms for long thin structures (Drzymala et al. 1991). Interpretation of the DVH plot is fairly subjective and implications of small differences between DVHs are not well understood. This indicates the usefulness of an objective numeric score, such as tumour control probability (TCP) or normal tissue complication probability (NTCP) (see [Chapter 36](#)) to provide a ranking when comparing plans (Munzenrider et al. 1991). DVHs do not indicate the complexity of the field arrangements and will not show any use of couch or collimator angles, etc. that cannot be achieved in practice. DVHs must therefore be used in conjunction with other methods for treatment plan evaluation, especially those which will give spatial information.

The ordinate of the DVHs can be presented in terms of absolute volume or as the fraction of the total volume of the organ. If fractional volumes are being used, it is important that the whole of the organ used as reference has been delineated. This requires that sufficient CT slices are available to cover the whole organ. Whether absolute or relative DVHs are more appropriate will depend on the organ in question. For lung, for example, the percentage of the total volume of lung is usually regarded as most relevant. Yorke et al. (2002) found a good correlation between the incidence of radiation pneumonitis and  $V_{20}$  for the ipsilateral lung, where  $V_{20}$  is defined as the percentage of normal lung that receives at least 20 Gy (see also Graham et al. 1999; Allen et al. 2003; Gopal et al. 2003; Bradley et al. 2005). DVHs of the rectal wall have been used extensively to assess the risk of rectal bleeding in prostate irradiation (see for instance Boersma et al. 1998; Jackson et al. 2001; Cozzarini et al. 2003). For such an analysis, dose surface histograms may also be of benefit (Fenwick et al. 2001).

In summary, the DVH is a very useful tool for 3D plan comparisons and as an input parameter for TCP and NTCP calculations. TCP and NTCP are quantitative methods of predicting the likelihood of local control (see [Chapter 36](#)). DVHs and the predicted behaviour of the cell population in question are used as input data. There is, however, large uncertainty in the clinical data, due partly to the lack of consistency in the definition of anatomical volumes, and partly to the uncertainties in dose computation and data collection (Deasy et al. 2002; Fiorino et al. 2002; Cho et al. 2002). So absolute probabilities are not fully reliable, but relative probabilities can be used to assess the relative merits of different treatment plans.

## 35.4 DOSE STATISTICS AND PLAN SCORING

### 35.4.1 DOSES AT REFERENCE POINTS AND DATA DERIVED FROM DOSE VOLUME HISTOGRAMS

The simplest form of reporting the dose in a structure, either a target volume or an organ-at-risk, consists of choosing a point meant to be representative of the dose distribution within the structure. This was the approach chosen by ICRU (ICRU 1993) as a means to obtain a uniform method for dose reporting in a given centre or amongst several centres (see [Section 37.6](#)). It is still the method currently used on manual treatment chart or within the recording and verification systems to ensure that the dose accumulated at the reference point of

**TABLE 35.1**

Examples of Dose Statistics for a Given Structure

Statistic	Definition
Total volume	The sum of all dose volume histogram (DVH) voxels found within a set of boundary contours. It can be compared to the volume obtained directly from the contours as a mean to gain confidence in DVH calculation
Mean dose	The sum of the doses assigned to each voxel divided by the total number of voxels
Modal dose	The most probable dose, i.e. the dose which corresponds to the bin where the larger number of voxels is found. The modal dose is sometimes considered to be most representative of the organ irradiation, but it is dependent on the choice of the dose bin
Median dose	The dose level where the same number of voxels are found at higher and lower doses
Min dose, $D_{\min}$	The minimum dose in the structure of interest. If this structure is the planning target volume (PTV), $D_{\min}$ should be appropriate to eradicate the tumour and ideally, the volume enclosed by the isodose surface $D_{\min}$ is the treated volume (TV)
Max dose, $D_{\max}$	The maximum dose in the structure, sometimes excluding those hot spots which are associated to too-small volumes (e.g. $<1 \text{ cm}^3$ ) (ICRU 1993)
Volume, $V_{D_{\text{ref}}}$ , corresponding to a reference dose, $D_{\text{ref}}$	The sum of all voxels receiving a dose greater than or equal to the user-supplied reference dose. For the PTV, the reference dose $D_{\text{ref}}$ may be the prescription dose, or a dose expressed in Gy or as a percentage of the prescription dose. $V_{D_{\text{ref}}}$ is expressed either as an absolute volume ( $\text{cm}^3$ ) or as a percentage of the total volume of the structure
Dose, $D_{V_{\text{ref}}}$ , corresponding to a volume equal to $V_{\text{ref}}$	The dose such that the volume receiving a dose higher than $D_{V_{\text{ref}}}$ is equal to $V_{\text{ref}}$ (where $V_{\text{ref}}$ is expressed either as an absolute volume or as a percentage of the total volume of the structure)

the PTV reaches the prescribed dose and that the dose to the organs at-risk remains below the predefined tolerance level (see [Section 41.2.5](#)). It is clear, however, that this method does not give any information about the dose homogeneity within the structures.

Dose statistics as outlined in Table 35.1 give a simplified view of the dose in a specified structure to compare 3D plans for evaluation purposes. They are obtained from DVHs, but because they are expressed directly as numerical information, they are easier to manipulate and can be used to define criteria for optimisation processes (see [Section 44.3.4](#)).

The parameters  $D_{V_{\text{ref}}}$  or  $V_{D_{\text{ref}}}$  allow the definition of one point on the cumulative DVH graph, where constraints can be set as a minimum for a PTV and as a maximum for an organ-at-risk.

### 35.4.2 CONFORMITY INDEX AND FIGURES OF MERIT

Considering the large number of parameters required to characterise a full 3D dose distribution with respect to the anatomical structures, it is attractive to try to define global quantities intended to summarize the overall dosimetric quality of a plan.

The conformity index (CI) is defined by ICRU (1999) as the quotient of the treated volume (TV, see [Section 29.2.4](#)) and the PTV. This definition implies that the TV totally encompasses the PTV. Then, if  $CI=1$ , the conformality is optimum, with a TV covering exactly the PTV. If the TV is smaller than the PTV (underdosage),  $CI<1$ . If the TV is too large for the PTV, causing potential damage to healthy tissue,  $CI>1$ . Van't Riet et al. (1997) and Knöös et al. (1998) have used a similar concept to serve as an optimisation parameter. Other forms of CI have been used for stereotactic techniques (Leung et al. 1999; Theodorou et al. 2000).

In cases where a fraction of the PTV lies outside of the TV, a CI equal to 1 could still be obtained even though the conformality of the dose distribution was very poor. To overcome this problem the percentage of the PTV included in the TV should be reported (ICRU 2004). However, a more general definition of the CI for a given dose level  $D$  is the following (Oozeer et al. 2000):

$$\text{CI}(D) = \text{IF}_{\text{PTV}}(D) \times [1 - \text{IF}_{\text{HT}}(D)] \quad (35.1)$$

where  $\text{IF}_{\text{PTV}}(D)$  is the irradiation factor of the PTV, defined as the fraction of the PTV receiving a dose higher than  $D$ ;  $\text{IF}_{\text{HT}}(D)$  is the irradiation factor of healthy tissue, defined as the ratio of the volume of tissue outside the PTV receiving a dose greater than  $D$  to the volume of isodose  $D$ . Taking  $D$  as the dose used to define the TV:

- If the TV is included within the PTV,  $\text{IF}_{\text{PTV}} < 1$  and  $\text{IF}_{\text{HT}} = 0$ , yielding  $\text{CI} < 1$ .
- If the TV encompasses the PTV,  $\text{IF}_{\text{PTV}} = 1$  and  $\text{IF}_{\text{HT}} < 1$ , yielding  $\text{CI} > 1$ .
- If the TV is partially covering the PTV,  $\text{IF}_{\text{PTV}} < 1$  and  $\text{IF}_{\text{HT}} < 1$ , yielding  $\text{CI} < 1$ .
- Only when TV is covering almost exactly the PTV, CI approaches 1.

In the expression of Equation 35.1, the importance of the PTV coverage and of the protection of healthy tissue are equally weighted. It is easy to adapt Equation 35.1 to reinforce the importance of either of these two constraints.

Conformity indices can be considered as simple forms of more general figures of merit or objective functions, which can then be used to score or optimise a treatment plan. For example, Jain and Khan (1992) and Jain et al. (1993) suggested a figure of merit calculated from inputs of TCP, NTCP, and oncologist preferences, and used to rank up to three competing treatment plans in order of merit by calculating a single numerical score for each treatment plan. A similar study was performed by Graham et al. (1996) for non-small-cell lung cancers.

Other more experimental methods of automating the decision process have been tried. Willoughby et al. (1996) described a system of evaluating and scoring radiotherapy treatment plans using an artificial neural network. Treatment plans were assigned a figure of merit by a radiation oncologist using a five-point rating scale. DVH data extracted from a large training set was correlated to the physician-generated figure of merit using an artificial neural network, and the net was tested on another set of plans. The accuracy of the neural net in scoring plans compared well with the reproducibility of the clinical scoring; the system is promising for the reliable generation of a clinically relevant figure of merit (see also Munley et al. 1999). Gopal and Starkschall (2002) have used a graphical representation, considering both the target coverage and the healthy tissue irradiation to rank the plans and help in the decision. The *receiver operating characteristics* (ROC) approach has also been used as a tool for plan scoring (Platoni et al. 1999; Dejean et al. 2001; Mavroidis et al. 2004).

The analysis of the three-dimensional dose volume distribution with respect to the target volumes and organs-at-risk forms the basis for the development of advanced radiotherapy techniques (see Chapter 43). Applied at the level of a patient population, it allows for an assessment of the margins to be used for optimal treatment (Van Herk et al. 2000). Provided that an adequate methodology is used, this allows for the analysis of clinical data and the improvement of the value of biological modeling (Deasy et al. 2002).

## 36.1 INTRODUCTION

Physicists working in radiotherapy spend a lot of their time measuring doses in phantoms and then calculating the dose distributions in patients due to a particular arrangement of beams. This is because, according to the present state-of-the-art practice, the radiation oncologist prescribes the treatment in terms of a (uniform) dose to the *target volume* accompanied by some sort of constraint on the dose to one or more *organs-at-risk*. However, the endpoints in radiotherapy that are truly of relevance are not dose distributions but the *probability of local control*, also known as the *Tumour Control Probability* (TCP) and the *Probability of Normal-Tissue Complications* (NTCP). This chapter deals with the modelling of TCP and NTCP with the emphasis on the *spatial* distribution of the absorbed dose within the target volume.

Some of the reasons why models for TCP and NTCP are desirable are listed below (the references cited are not intended to be exhaustive):

- Dose distributions in three dimension (3D) are inherently very complex and some way of assimilating this vast amount of information is needed (Mauro 1989; Goitein 1992).
- Biological models enable estimates to be made of the effect of uncertainties in dose and patient position on therapy outcome (Boyer and Schultheiss 1988; Mijnheer et al. 1989; Mackay et al. 1999; Zavgorodni 2004).
- The effect of non-uniformities in the tumour dose distribution can be approximately quantified (Brahme 1984; Sanchez-Nieto and Nahum 1999; Tomé and Fowler 2000).
- The values for  $\alpha$  (especially important for tumours) and  $\alpha/\beta$  from, for example, clonogenic assays can be both extracted from and fed into such models (Deacon et al. 1984; Peters et al. 1989; Mauro et al. 1989; West 1995; Bentzen 1997; Fenwick 1998; Sanchez-Nieto et al. 2001a; Buffa et al. 2001b; Levegrün et al. 2001, 2002; Wang et al. 2003a; Xiong et al. 2005; Carlone et al. 2006).
- Estimates can be made of the effects on local tumour control of hypoxia and other information derived from *functional* imaging (Poppel et al. 2002; Nahum et al. 2003; Ruggieri 2004; Nioutsikou et al. 2005; Ruggieri and Nahum 2006).
- The clinical effect of improvements in dose distributions through the use of new beam-delivery technology (e.g. MLCs, IMRT), 3D treatment planning systems, and new radiation modalities (brachytherapy, protons, light ions) can be approximately quantified (Webb 1993; Lee et al. 1994; Isacsson 1998; Gagliardi 1998, 2001; King et al. 2000; De Meerleer et al. 2000; Nahum and Glimelius 2001; Nutting et al. 2002).
- Optimisation/inverse planning is beginning to be done in terms of biological criteria such as highest TCP for a fixed low value of NTCP, equivalent uniform dose (EUD) etc. (Källman 1992; Nahum and Tait 1992; Mohan et al. 1992; Brahme 1999, 2001; De Gersem et al. 1999; Engelsman et al. 2001; Iori 2001; Sanchez-Nieto et al. 2001a; Schwarz et al. 2003; Peñagarícano et al. 2005; Kim and Tomé 2006; Hoffmann et al. 2006).

- Models for TCP and NTCP can serve as an aid to clarity of thought about radiotherapy (Dutreix et al. 1988).

## 36.2 TUMOUR CONTROL PROBABILITY

### 36.2.1 A RADIobiologically-BASED TCP MODEL

#### 36.2.1.1 General

So-called *dose-response curves* are believed to have a sigmoid shape. One approach is to fit a mathematical function to this curve (Walker and Suit 1981; Källman et al. 1992; Carbone et al. 2006). However, there is no natural way to accommodate changes in basic parameters such as tumour cell radiosensitivity, inhomogeneities in the dose distribution, variations in tumour volume, clonogenic cell density, etc. through empirical curve-fitting, such as the logistic model (e.g. Bentzen 2002). In the case of tumour control, in contrast to that for complications in normal tissues (see [Section 36.3](#)), it is possible to develop a model starting from the response of cells to radiation. Niemierko and Goitein (1993a) described such a model, which is similar to the one given here (Nahum and Tait 1992; Webb and Nahum 1993; Nahum and Sanchez-Nieto 2000).

#### 36.2.1.2 A Model for TCP Based on Poisson Statistics

In this section we will derive a model for tumour control using the linear-quadratic model of cell survival. Numerous radiobiological experiments have demonstrated beyond doubt that, except at doses below about 0.6 Gy in certain cell lines (see [Section 7.13.3](#)) the killing of cells by radiation can be described by the linear-quadratic model (See [Chapter 7](#) and also Fowler 1989; Steel 2002; Chapman 2003). This is generally written in the form

$$SF = \exp(-\alpha d - \beta d^2) \quad (36.1)$$

where  $SF$  is the surviving fraction after a (uniform) dose  $d^*$  of radiation to a population of cells. The parameters  $\alpha$  and  $\beta$  characterise the initial slope and degree of curvature, respectively, of the survival curve.

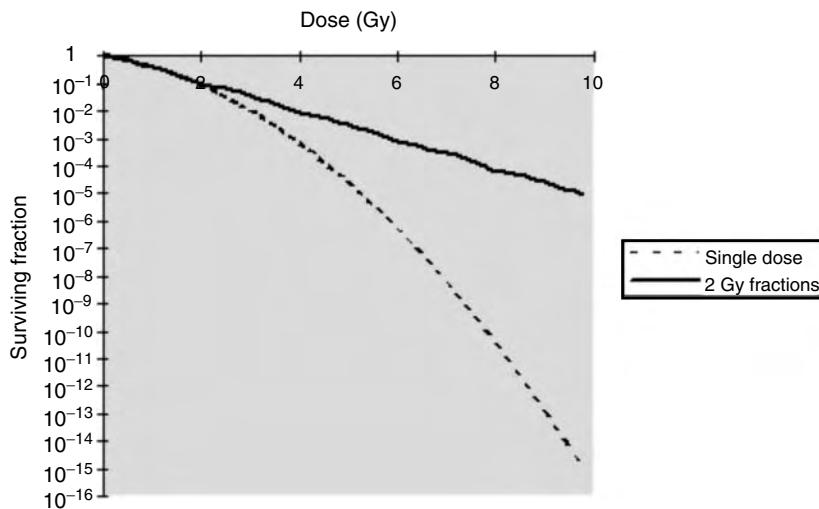

When the irradiation is *fractionated* as in external-beam radiotherapy ([Figure 36.1](#): full curve), for small fraction sizes such as 2 Gy, the effective slope of the resulting straight line is very nearly given by the value of  $\alpha$  alone (assuming  $\alpha/\beta$  is high). Replacing now  $SF$  by  $N_s/N_0$ , one can write:

$$N_s \approx N_0 \exp(-\alpha D) \quad (36.2)$$

where  $D$  is the total dose,  $N_0$  is the *initial* number and  $N_s$  is the average number of clonogenic cells that survive, assumed here to be irradiated uniformly and to have uniform radiosensitivity  $\alpha$  ( $\text{Gy}^{-1}$ ); the latter is sometimes denoted by  $\alpha_{\text{eff}}$ . The original formulation of this TCP model (Nahum and Tait 1992; Webb and Nahum 1993) was based on the approximate expression in [Equation 36.2](#). However, in order to model fractionation effects correctly the  $\beta$  term must be included (Sanchez-Nieto and Nahum 1999); Mauro et al. (1989) and Niemierko and Goitein (1993a) include it in their model, for example. Thus for  $n$  fractions, each of dose  $d$ , and thus

---

\* The convention adopted in this chapter is that dose is indicated by  $d$  except when it refers to total dose when  $D$  or sometimes  $D_{\text{tot}}$  is used.

**FIGURE 36.1**

Semi-log plot showing the modification of the linear-quadratic cell-survival curve (dashed) when the radiation is given in 2Gy fractions (full curve). (From Nahum, A. E. and Sanchez-Nieto, B., *Physica Medica*, 17(2), 13–23, 2001. With permission.)

total dose  $D$ , the average number of surviving cells  $N_s$  is given by:

$$N_s = N_0 \exp \left[ -\alpha D \left( 1 + \frac{\beta}{\alpha} d \right) \right] \quad (36.3)$$

It can be observed that if  $(\beta/\alpha)d \ll 1$  then Equation 36.3 reduces to Equation 36.2; this will be the case for small-fraction radiotherapy when the tumour clonogen  $\alpha/\beta$ -ratio is very high and for continuous Low-Dose-Rate (LDR) brachytherapy irradiation for which  $\beta \sim 0$  (see Section 9.4). Figure 36.2 shows how  $SF$  depends on total dose for  $d=2$  Gy for four different  $\alpha, \beta$  combinations.

The next step is to incorporate the endpoint, i.e. the eradication of the tumour, into the model. It will be assumed that a tumour is only controlled when every single clonogenic cell (i.e. cells with the potential for uncontrolled division) has been eliminated; this is known as the *target-cell hypothesis* of tumour control (Munro and Gilbert 1961). Thus, the quantity that we require is the *probability that no single clonogenic cell survives*. This can be obtained from the Poisson statistics result:

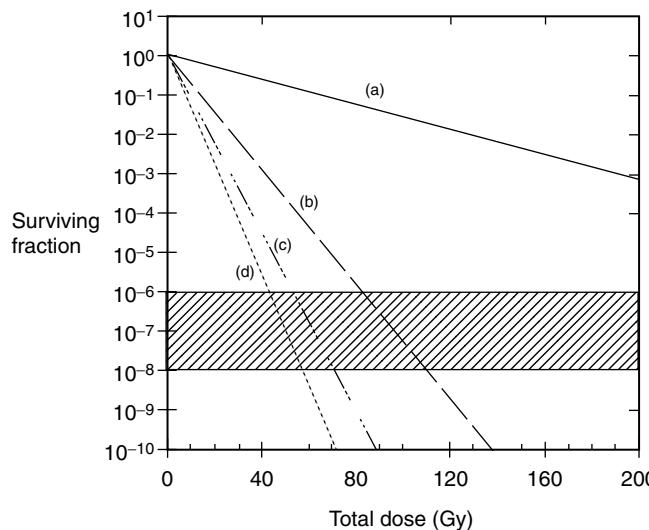

$$P(N, y) = \frac{e^{-N} N^y}{y!} \quad (36.4)$$

that gives the probability  $P$  of the occurrence of exactly  $y$  events when the mean number of events is  $N$  (e.g. Cooper 1969). Consequently, the desired probability corresponds to  $y=0$ , i.e.:

$$TCP = P(N, 0) = e^{-N} \quad (36.5)$$

A beautifully pedagogical demonstration by Monte-Carlo simulation of the correctness of Equation 36.5 has been given by Bentzen (2002)\*.

\* Porter (1980) discusses the mathematics of not just zero cells remaining, which we are assuming here, but also one-, two-, three cells etc; he concluded that they were “algebraic curiosities”.

**FIGURE 36.2**

The surviving fraction as a function of the total dose delivered in 2 Gy fractions, according to Equation 36.3, for different values of  $\alpha$  ( $\text{Gy}^{-1}$ ) and  $\beta$  ( $\text{Gy}^{-2}$ ): (a)  $\alpha=0.036$  and  $\beta=0$ ; (b)  $\alpha=0.149$  and  $\beta=0.00293$  corresponding to hypoxic prostate clonogens—see Section 36.1.5; (c)  $\alpha=0.2603$  and  $\beta=0$ ; (d)  $\alpha=0.2603$  and  $\beta=0.031$ . The choices of  $\alpha$  and  $\beta$ , taken from Nahum et al. (2003), are explained in Section 36.1.5. The hatched region,  $SF$  between  $10^{-6}$  and  $10^{-8}$ , indicates approximately the region where TCP can be expected to have a non-zero value. (Adapted from Nahum and Chapman 2004.)

Insight into the nature of the problem may be gained by considering that, if there is an average of one cell left after irradiation, then the probability of *no* cells remaining is  $1/e$  or 37%. We can see that even if the irradiation succeeds in reducing the number of cells from  $10^9$  to only (a mean value of) 4, say, the resulting TCP is only  $e^{-4}$  or 1.8% despite the fact that the surviving fraction is only  $4 \times 10^{-9}$ ; tumour *cure* is thus very difficult to achieve.

Combining Equation 36.1 and Equation 36.5, where  $N=N_s=N_0 S$ , we arrive at:

$$TCP = \exp[-N_0 \exp(-\alpha d - \beta d^2)] \quad (36.6)$$

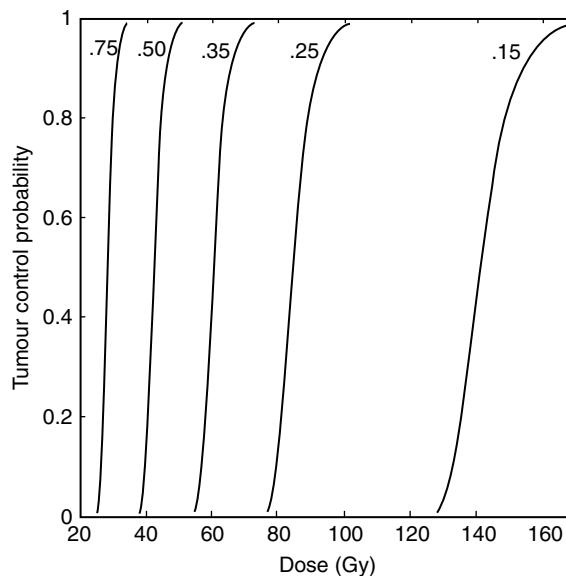

for the case of a dose delivered in one fraction\*. For the case of  $n$  fractions, each of identical dose  $d$  such that  $D_{\text{tot}}=d \times n$ , combining Equation 36.3 and Equation 36.5, the expression for TCP becomes:

$$TCP = \exp \left\{ -N_0 \exp \left[ -\alpha D_{\text{tot}} \left( 1 + \frac{\beta}{\alpha} d \right) \right] \right\} \quad (36.7)$$

A plot of the above expression for TCP as a function of dose  $D_{\text{tot}}$  produces the well-known sigmoidal curve. Using a realistic value for the number of initial clonogenic cells  $N_0$  of the order of  $10^9$  (Porter 1980; Steel 2002), values of  $\alpha$  from  $0.1 \text{ Gy}^{-1}$  to  $1 \text{ Gy}^{-1}$  (e.g. Deacon et al. 1984) and setting  $\beta$  to zero for simplicity, one obtains the family of curves shown in Figure 36.3.

Proliferation/repopulation can be approximately included in the expression for TCP by adding a term  $\gamma(T-T_k)$  inside the square brackets in Equation 36.7 where  $\gamma=\ln 2/T_d$ ,  $T_d$  is the average doubling time,  $T$  is the overall treatment time, and  $T_k$  is the time at which proliferation begins (e.g. Sanchez-Nieto and Nahum 2000). Tucker et al. (1990) and Zaider

\* If  $\beta$  is negligible then the  $\beta D^2$  term is simply removed as in Webb and Nahum (1993) and then Equation 36.6 is valid even for fractionated delivery where now  $D=D_{\text{tot}}$ .

**FIGURE 36.3**

TCP curves from Equation 36.7 for clinically realistic values of  $N_0=10^9$  and  $\alpha$  ranging from 0.15 to 0.75  $\text{Gy}^{-1}$  (as indicated on the curves) and with  $\beta=0$ . (Reproduced from Nahum, A. E. and Sanchez-Nieto, B., *Physica Medica*, 17(2), 13–23, 2001. With permission.)

and Minerbo (2000) have given a more rigorous treatment of the effect of including clonogen proliferation during irradiation.

### 36.2.1.3 Consistency with Clinical Data

Theoretical models must be compared to clinical data whenever possible. A number of Local Control vs Tumour Dose studies have been published (e.g. Morrison 1975; Batterman et al. 1981; Moore et al. 1983; Hanks et al. 1988, 1997; Stock et al. 1998; Martel et al. 1999; Jacob et al. 2005). Despite the limitations associated with such data, i.e. uncertainties in the dosimetry, inadequate patient numbers, imprecise clinical definition of local control, etc. there are almost no Tumour Control vs Dose curves with slopes anything like as steep as the ones in Figure 36.3. This has led some investigators to favour an empirical model to fit clinical dose-response curves, e.g. Mohan et al. (1992), Carlone et al. (2006).

Various hypotheses have been advanced over the years to explain the shallowness of the clinically observed Local Control vs Dose curves, e.g. Zagars et al. (1987) and Yaes et al. (1999). The most probable single explanation is *inter-patient heterogeneity* in the intrinsic radiosensitivity of the tumour cells, i.e. the  $\alpha$  and  $\beta$  values (Deacon et al. 1984; Zagars et al. 1987; Boyer and Schultheiss 1988; Dutreix et al. 1988). This is in contrast to the possible heterogeneity of radiosensitivity of the clonogenic cells within any one tumour, i.e. *intra-patient heterogeneity* (e.g. Suit et al. 1992). Hypoxia (i.e. poor oxygenation of cells), has long been considered to be a major cause of failure to achieve local control in radiotherapy. It is now believed to play an important role only in certain tumours (Dasu and Denekamp 1998; Steel and Peacock 1989; Movsas et al. 2000, 2002; Buffa et al. 2001a; Poppel et al. 2002; Steel 2002; Chapman 2003; Nahum et al. 2003; see also [Section 7.10](#) and [Section 36.2.5](#)). Explanations based on the effect of a very small hypoxic, and therefore radioresistant, fraction of cells (e.g. Källman et al. 1992) cannot, therefore, account for the shallow slopes in more than a small percentage of cases and only then for certain types of tumours (e.g. Yaes 1999; Steel 2002). In an analysis of clinical dose-response data (Brenner 1993) it was demonstrated that it was possible to explain the wide variations in the dose required to achieve local

control for a number of different lesions solely in terms of variations in  $\alpha$  from one lesion type to another *and* the variation in the number of clonogenic cells, assumed proportional to the volume of the lesion. The *bottom line* of this study was that it was not necessary to invoke any assumptions about, for example, the variation in the hypoxic cell fraction with tumour size. However, Brenner did not build into his analysis any inter-patient variation in radiosensitivity and as a consequence the number of clonogenic cells  $N_0$  required to fit the clinical data came out as unrealistically small (Webb 1994; Webb and Nahum 1998).

The TCP model being developed in this section (see also Nahum and Sanchez-Nieto 2001) explicitly incorporates inter-patient variation by assuming that  $\alpha$  is distributed normally amongst the patient population, with standard deviation  $\sigma_\alpha$ . Thus the final *TCP* is calculated as the average of the *TCPs* of these patients with different radiosensitivities according to

$$\overline{\text{TCP}}(D, N_0, \bar{\alpha}, \bar{\beta}, \sigma_\alpha) = \sum_i g_i \text{TCP}(D, N_0, \alpha_i, \beta_i) \quad (36.8)$$

where  $\text{TCP}(D, N_0, \alpha_i, \beta_i)$  is given by Equation 36.7 and a fraction  $g_i$  of the patients have  $\alpha = \alpha_i$  such that

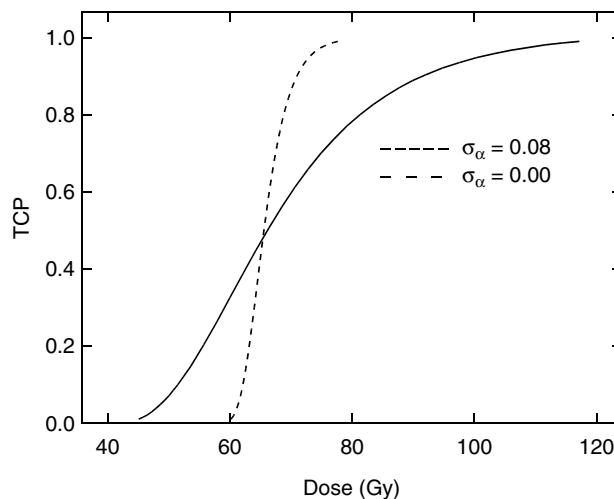

$$g_i \propto \exp\left[-(\alpha_i - \bar{\alpha})^2 / 2\sigma_\alpha^2\right] \quad (36.9)$$

where  $\sum g_i = 1$ . It is generally assumed that  $\beta$  also follows a normal distribution such that  $\alpha/\beta$  remains constant (Sanchez-Nieto and Nahum 1999; Nahum and Sanchez-Nieto 2001; Xiong et al. 2005).

As the value of  $\sigma_\alpha$  is increased, the slope of the TCP vs Dose curve decreases. One way of thinking about this is to regard this resulting TCP vs Dose curve as the sum of the curves for different  $\alpha$  values in Figure 36.3. One can say that there is a group of patients with radio-resistant tumours (i.e. low  $\alpha$  values who will never be cured ( $\text{TCP} = \text{zero}$ )), another group with radiosensitive tumours, i.e. high  $\alpha$  values that will all be (locally) controlled, and a group with intermediate  $\alpha$  values for which the term *stochastic fraction* applies, as the outcome for these patients is literally a matter of chance (Zagars et al. 1987).

This addition of a non-zero  $\sigma_\alpha$  to the TCP model was first applied to the case of bladder tumours (Nahum and Tait 1992). A mean  $\alpha$ -value of  $0.35 \text{ Gy}^{-1}$  was adopted, as determined by Deacon et al. (1984) for human bladder-tumour cells grown in vitro. The initial number of clonogenic cells,  $N_0$ , was estimated from the product  $\rho_{\text{cl}} \times V_{\text{tgt}}$  with the clonogenic cell density  $\rho_{\text{cl}}$  taken to be  $10^7 \text{ cm}^{-3}$  (which corresponds to approximately 1 tumour cell in ten being clonogenic) and a mean value of the target volume,  $V_{\text{tgt}}$ , of  $320 \text{ cm}^3$ ; this latter value was derived from an analysis of the actual target volumes, as outlined on CT, of patients entered into a clinical trial of conformal vs conventional pelvic radiotherapy (Tait et al. 1997). The steep sigmoid curve (dashed) in Figure 36.4 corresponds to  $\sigma_\alpha = 0$  and is equivalent to one of the curves in Figure 36.3. The full curve is a fit to clinical data from Batterman et al. (1981); the value  $\sigma_\alpha = 0.08 \text{ Gy}^{-1}$  was determined entirely empirically. The TCP at the actual clinical dose used,  $64 \text{ Gy}$  ( $32 \times 2 \text{ Gy}$ ) came out at just below 0.5 for both curves. This 50% control rate was consistent with clinical findings and lent some confidence to the model.

The more usual way of describing the slope is by the parameter  $\gamma = D(\Delta\text{TCP}/\Delta D)$  at either the 50% or 37% point on the TCP curve (Brahme 1984; Yaes 1999). Values between 1.7 and 2.0 are typical for human tumours (Fischer and Moulder 1975; Stewart and Jackson 1975), compared to around 7 for the conditions depicted in Figure 36.3. It was shown by Brahme (1984) that  $\gamma$  is related to the logarithm of the initial clonogen number  $N_0$  through  $\gamma = \ln N_0/e$ . If  $\sigma_\alpha$  is set to zero, the only way to obtain slopes similar to those consistent with clinical dose-response data is to set  $N_0$  equal to an unrealistically small number, of the order of tens or hundreds, of clonogens (e.g. Brenner 1993; Webb 1994; Webb and Nahum 1998; Nahum et al. 2003; Wang et al. 2003).

**FIGURE 36.4**

Tumour Control Probability (TCP) as a function of target dose, derived from Equation 36.7, Equation 36.8 and Equation 36.9, with  $\alpha = 0.35 \text{ Gy}^{-1}$ ,  $\rho_{\text{cl}} = 10^7 \text{ cm}^{-3}$  for a volume  $= 320 \text{ cm}^3$ , for  $\sigma_\alpha = 0.0$  (steep curve) and for the clinically more realistic  $\sigma_\alpha = 0.08 \text{ Gy}^{-1}$  (shallow curve);  $\beta$  was set equal to zero. (From Nahum, A. E. and Tait, D. M., *Advanced Radiation Therapy: Tumour Response Monitoring and Treatment Planning*, Springer, Heidelberg, 1992.)

### 36.2.1.4 Inhomogeneous Dose Distributions

Up to this point, it has been assumed that all cells receive exactly the same dose. Next, we incorporate a *dose distribution* into the TCP model. In order to do this, it is necessary to know the number of clonogenic cells  $N_{0,i}$  that receive a (total) dose  $D_i$ . This is most conveniently obtained from a *dose-volume histogram*, or DVH, generated by the planning computer (see Section 35.3). Strictly, what is required is the *differential* dose-volume distribution or histogram,  $dV/dD$  from which the more familiar *cumulative* DVH is calculated. Thus, one generalises Equation 36.3 to

$$N_s = \sum_i^n N_{0,i} \exp \left[ -\alpha D_i \left( 1 + \frac{\beta}{\alpha} d_i \right) \right] \quad (36.10)$$

where the summation is carried out over the  $n$  bins in the DVH.

The full expression for TCP can now be written as follows:

$$TCP = \frac{1}{\sigma_\alpha \sqrt{2\pi}} \int_0^\infty \left( \prod_i \exp \left[ -\rho_{\text{cl}} V_i \exp \left\{ -\alpha D_i \left( 1 + \frac{\beta}{\alpha} d_i \right) \right\} \right] \right) \exp[-(\alpha - \bar{\alpha})^2 / 2\sigma_\alpha^2] d\alpha \quad (36.11)$$

where the summation (of the indices of the exponential) over the  $i$  dose bins in the DVH (Equation 36.10) has been replaced by a *multiplication* of exponentials, i.e. of the control probabilities for the cells in each dose bin. The clonogenic cell density is denoted by  $\rho_{\text{cl}}$ ,  $V_i$  is the volume of tissue in the  $i$ th dose bin, and  $\bar{\alpha}$  is the mean value of the radiosensitivity in the inter-patient distribution, characterised by standard deviation  $\sigma_\alpha$ \*. It should be noted that this alternative way of computing the TCP is equivalent to writing the control probability for the *tumour* as the *product* of the control probabilities of all the elements, or *voxels*, comprising

\* It is tacitly assumed here that the radiosensitivity coefficient  $\beta$  varies over the patient population in the same way as  $\alpha$ ; Xiong et al. (2005) show that  $\sigma_\beta$  becomes important for low  $\alpha/\beta$  ratios.

the tumour, i.e.:

$$TCP = \prod_i VCP_i \quad (36.12)$$

Writing the expression for TCP in this way can serve as a conceptual aid to thinking about the effect on TCP of, for example, boosting one part of the tumour, e.g. if the (pre-boost) control probability of the voxel to be boosted is 0.95 then the maximum possible increase in (overall) TCP would be 5%. Equally well, it shows immediately that if any *voxel* in the tumour receives a low dose, such that its control probability (*VCP*)=0.10 say, then the (overall) TCP can never be higher than 0.10 no matter how high a dose be given to the clonogens in all the other voxels. Tomé and Fowler (2000) have modelled in detail the effect on the TCP of *boosting* subvolumes of a tumour.

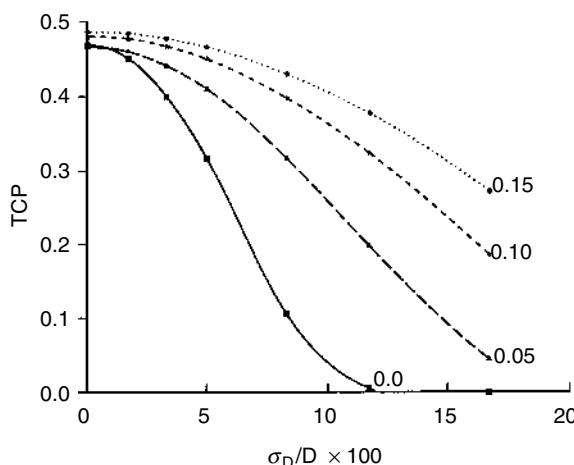

Sanchez-Nieto and Nahum (1999) explored the idea of converting dose values at grid points in a treatment plan (corresponding to voxels of certain dimensions containing a given number of clonogens) into VCP values. However, for any clinically realistic values of the total dose, all the VCPs take values of the order of 0.999..., i.e. extremely close to unity. This type of *bioeffect* distribution (e.g. Wigg 2001) would not therefore be a useful way of representing a treatment plan.

Strictly speaking the relevant DVH is not that for the *target* (i.e. planning target volume (PTV)) but, instead, that for the *tumour* volume (i.e. gross tumour volume (GTV) in ICRU 50 terminology), i.e. one should not include the margin added to account for patient movement. However, it is currently generally not possible to be more precise about such issues (see below). A potentially equally serious current limitation is the implicit assumption that the clonogenic cell density  $\rho_{cl}$  is constant right out to the edges of the tumour or target volume. It can be argued that the clonogenic cell density must drop off significantly outside the GTV and that therefore any lower values of the dose located in the PTV–CTV–GTV edge region coincide with very low values of the clonogen density, i.e. relatively small numbers of clonogens. Consequently including possible *cold spots* located in this edge region in the DVH (e.g. that for the PTV) used to compute the TCP will artificially lower the overall TCP. Certain aspects of this difficult issue are discussed in more detail below.

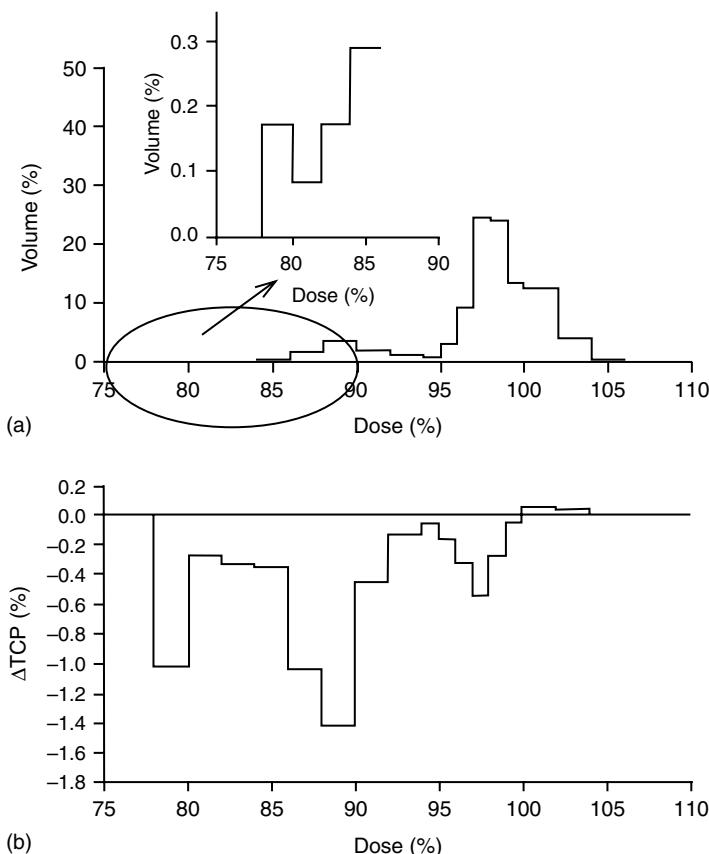

### 36.2.2 THE EFFECT OF DOSE NONUNIFORMITY ON TCP

Brahme (1984) applied his TCP model to the question of the effect on TCP of both inhomogeneities in the target dose distribution and uncertainties in the absolute absorbed dose determination. Nahum and Sanchez-Nieto (2001) carried out a similar exercise (see Figure 36.5) using the model described above for the tumour parameters shown in Figure 36.4. The dose distribution in the target volume, consisting of  $10^9$  clonogenic cells of uniform radiosensitivity, was assumed to follow a *normal* distribution, i.e.  $N_{0,i}$  was varied normally as a function of  $D_i$  (see Equation 36.10) with its width expressed in terms of  $\sigma_D/D$  (plotted along the  $x$ -axis in Figure 36.5). The four curves correspond to different values of  $\sigma_\alpha$ . The mean dose was kept constant, at 60 Gy.

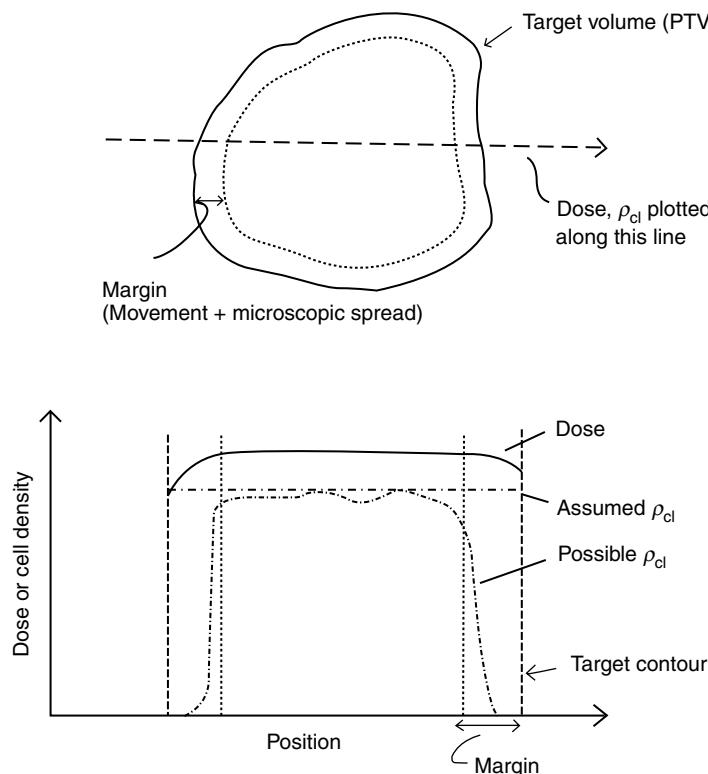

One immediate observation is that the TCP always decreases as  $\sigma_D/D$  increases, even though the mean dose does not change. Thus the maximum value of the TCP is for uniform dose, and *hot* and *cold* spots do not compensate each other, as has been pointed out elsewhere (e.g. Webb et al. 1994; Sanchez-Nieto and Nahum 1999). The figure shows that for a group of patients with tumours of exactly the same radiosensitivity, i.e.  $\sigma_\alpha=0.0$ , relatively small dose inhomogeneities seriously lower the TCP; this corresponds to the very steep dose-response curves in Figure 36.3. A clinically more realistic value of  $\sigma_\alpha$ , such as  $0.10\text{ Gy}^{-1}$  results in a much less dramatic reduction in TCP as the dose inhomogeneity is increased. Thus the message here is that appreciable inter-patient variability in radiosensitivity reduces significantly the consequences of deviations from target-dose uniformity. The corollary of this is the conclusion

**FIGURE 36.5**

The effect on TCP of nonuniformity in the target dose distribution, expressed as  $\sigma_D/D$ , for values of the inter-patient radiosensitivity parameter  $\sigma_\alpha$  from zero to  $0.15 \text{ Gy}^{-1}$ . The mean target dose is  $60 \text{ Gy}$ , the mean  $\alpha=0.35 \text{ Gy}^{-1}$ ,  $\beta=0$  and  $N_0=10^9$ . (From Nahum, A. E. and Sanchez-Nieto, B., *Physica. Medica.*, 17(2), 13–23, 2001. With permission.)

**FIGURE 36.6**

An example of the  $\Delta\text{TCP}$  method applied to the differential DVH (a) of a simulated prostate GTV. The parameters in the  $\Delta\text{TCP}$  calculation were  $\alpha=0.29 \text{ Gy}^{-1}$ ,  $\sigma_\alpha=0.07 \text{ Gy}^{-1}$ ,  $\alpha/\beta=10 \text{ Gy}$ ; the TCP was 43.9%. The  $\Delta\text{TCP}$  distribution (b) indicates that the TCP is reduced by 1.4% due to the volume in the 88–90% dose bin, and by 1.0% due to the 78–80% dose bin, etc. (From Sanchez-Nieto, B. and Nahum, A. E., *Int. J. Radiat. Oncol. Biol. Phys.*, 44, 369–380, 1999. With permission.)

**FIGURE 36.7**

Schematic drawing illustrating the problem of variation of clonogenic cell density at the edge of the PTV; a hypothetical dose and cell density profile through the centre of the PTV is shown. (From Nahum, A. E. and Sanchez-Nieto, B., *Physica Medica*, 17(2), 13–23, 2001. With permission.)

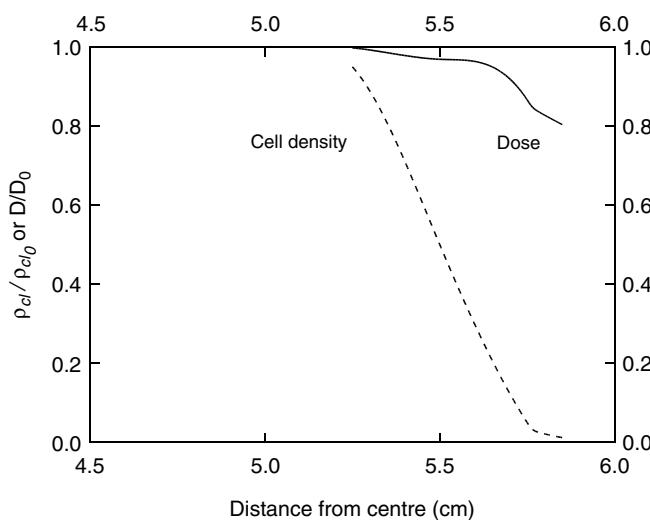

reached by Brahme (1984)—that for certain classes of tumours with steep dose-response curves, notably in the larynx (normalised dose gradient  $\gamma > 4$ ), only very small uncertainties in the absolute dose determination can be tolerated\*.

Sanchez-Nieto and Nahum (1999) have proposed a method whereby a TCP model could be used directly in a treatment planning system. This is done by assigning each dose bin in the (differential) DVH the quantity  $\Delta\text{TCP}$  (or deltaTCP) which is the amount by which the TCP is decreased or increased because of the volume of tumour/target in this dose bin *not* being equal to the prescribed dose. In this way the effect of *cold* dose bins can be seen directly (though the volume in the bin will not necessarily be contiguous) (Figure 36.6).

### 36.2.3 VARIATION IN CLONOGENIC CELL DENSITY

If the model described here is applied to the DVH of the PTV (see Section 29.2.3) then it is implicitly being assumed that the clonogenic cell density is constant over the whole of the PTV, i.e. one calculates the number of clonogenic cells  $N_{0,i}$  at dose  $D_i$ , in Equation 36.10 from the product of  $V_{0,i}$  and  $\rho_{cl}$ . However, this assumption of constant  $\rho_{cl}$  is quite unrealistic as the PTV includes a margin for microscopic spread plus a second margin for geometrical inaccuracies. This point is illustrated in Figure 36.7.

\* The calculations involved in producing Figure 36.5 have been repeated including a non-zero  $\beta$  value; this has the effect of slightly increasing the rate of decrease in TCP with increase in dose non-uniformity (W. Xiong, private communication).

**FIGURE 36.8**

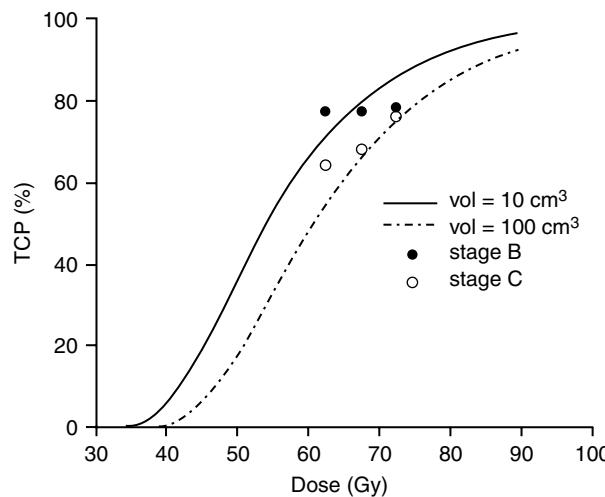

The variation in the dose corresponding to the iso-VCP condition for a tumour with a hypothetical relative variation in clonogenic cell density ( $\rho_{cl}/\rho_{cl0}$ ) its centre to the periphery given by the dashed curve. The central target dose,  $D_0$ , is 64Gy and the mean value of  $\alpha$  is 0.35 Gy. The solid line shows the relative dose variation,  $D/D_0$ , which is such that the voxel control probability (UCP) remains unchanged throughout the tumour. (From Webb, S. and Nahum, A. E., *Phys. Med. Biol.*, 38, 653–666, 1993. With permission.)

Although it is not known how the clonogen density varies throughout the PTV the model can be used to assess the effect that such variations might have on the local control probability. One way of looking at this is to calculate the change in dose that corresponds to a change in cell density  $\rho_{cl}$  when one requires that the *voxel control probability* (VCP) remains unchanged for a given volume element of cells. Figure 36.8 shows the iso-VCP dose corresponding to a decrease in clonogenic cell density given by the (hypothetical) dashed curve. One can see that for a considerable decrease in  $\rho_{cl}$  the *allowable* decrease in dose is very modest. Similar conclusions were drawn by Brahme and Ågren (1987).

### 36.2.4 APPLYING THE TCP MODEL TO PATIENT DATA

The TCP model described above has been applied to the DVHs for the GTV for prostate patients in a clinical trial on conformal prostate therapy (Figure 36.9). Parameters appropriate to prostate tumours were obtained by fitting the TCP model to the Hanks et al. (1988) clinical data set (Sanchez-Nieto and Nahum 1999). Two curves were calculated, corresponding to (uniformly irradiated) tumour volumes of  $10 \text{ cm}^3$  and  $100 \text{ cm}^3$ , which correspond approximately to stage B and C prostate cancer respectively; the parameters used to compute the curves shown in Figure 36.9 are given in the caption (Sanchez-Nieto and Nahum 1999). A much more detailed analysis of the relationship between prostate tumour radiotherapy outcome data and a TCP model has been made by Levegrün and colleagues (2000, 2001).

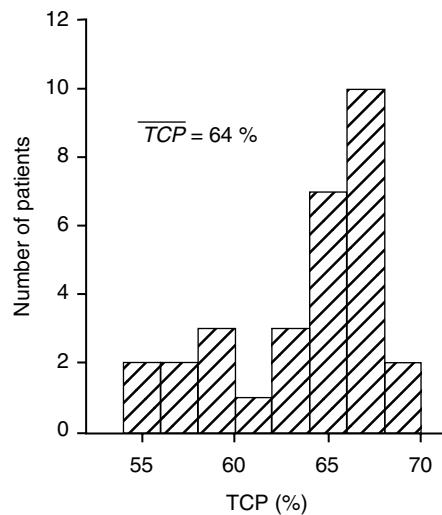

Figure 36.10 is a frequency distribution of the (population-averaged) TCP values for 30 patients treated in the non-dose-escalated arm of a clinical trial, at 64 Gy total dose (in  $32 \times 2$ -Gy fractions). The overall mean TCP came out at 0.64. The spread in values, from around 55% to 70% is due primarily to the different sizes of the GTVs (and hence different estimates of initial clonogen numbers); any non-uniformity in the dose distributions in these cases played only a minor role. It is important to realise that the TCP value for each patient represents a *mean* value for that particular treatment plan and patient anatomy, averaged over an  $\alpha$ -distribution characterised by  $\bar{\alpha} = 0.29 \text{ Gy}^{-1}$  and  $\sigma_\alpha = 0.07 \text{ Gy}^{-1}$ ; the individual  $\alpha$ -value for the patient in question

**FIGURE 36.9**

TCP curves resulting from the following parameters:  $\alpha = 0.29 \text{ Gy}^{-1}$ ,  $\sigma_\alpha = 0.07 \text{ Gy}^{-1}$ ,  $\alpha/\beta = 10 \text{ Gy}$ ,  $\rho_{cl} = 10^7 \text{ clonogens cm}^{-3}$ , dose per fraction = 2 Gy, volume =  $10 \text{ cm}^3$  or  $100 \text{ cm}^3$ . Solid and open circles represent 7-year recurrence-free clinical data for stage B and C respectively from Hanks et al. (1988). (From Sanchez-Nieto, B. and Nahum, A. E., *Int. J. Radiat. Oncol. Biol. Phys.*, 44, 369–380, 1999. With permission.)

is not known. Alternatively, the *individual patient* situation could be simulated by choosing a single  $\alpha$  value for each patient by random sampling of the normal distribution for  $\bar{\alpha} = 0.29 \text{ Gy}^{-1}$  and  $\sigma_\alpha = 0.07 \text{ Gy}^{-1}$ . In this case, the range of TCP values obtained would be greater than that indicated in Figure 36.10 but would, be a better representation of the true situation.

One frequently encounters the statement that the probability of controlling a tumour depends on the *minimum* dose in the target volume. The model can be used to examine this hypothesis. Nahum and Sanchez-Nieto (2001) analysed 43 typical treatment plans for

**FIGURE 36.10**

Frequency distribution of calculated TCP for the GTVs of 30 patients treated in the non-dose-escalated arm of the Royal Marsden prostate trial, using the following parameters:  $\alpha = 0.29 \text{ Gy}^{-1}$ ,  $\sigma_\alpha = 0.07 \text{ Gy}^{-1}$ ,  $\alpha/\beta = 10 \text{ Gy}$ ,  $\rho_{cl} = 10^7 \text{ clonogens cm}^{-3}$ , dose per fraction = 2 Gy, total dose 64 Gy. (From Nahum, A. E. and Sanchez-Nieto, B., *Physica Medica*, 17(2), 13–23, 2001.)

carcinoma of the bladder and calculated the TCP for the GTV of each plan using the same parameter values as for the *realistic* curve in Figure 36.4. For each plan the mean dose, the minimum dose and the effective dose  $D_{\text{eff}}$  were recorded. This latter dose is that value, which if uniform in the tumour, would give the same TCP as the actual dose distribution\*; it follows from Figure 36.5 that it must lie between  $D_{\text{min}}$  and  $D_{\text{mean}}$ . Nahum and Sanchez-Nieto (2001) found that, on the average,  $D_{\text{eff}}$  was much closer to  $D_{\text{mean}}$  than to  $D_{\text{min}}$ . It can therefore be concluded that, at least for treatment plans where the tumour dose is reasonably uniform (as was the case), the *mean* dose is much better than the *minimum* dose as a single indicator of clinical effectiveness.

Terahara et al. (1999) analysed the effect of tumour-dose inhomogeneity on local control for 132 patients with skull-base chordoma treated with combined photons and protons, with the prescribed doses ranging from 66.6 to 79.2 Cobalt-Gray-Equivalent (see Chapter 46). Poor correlation was obtained between local control and measures such as mean dose and prescribed dose, but there was a significant correlation with the minimum dose (low p-value) and with the quantity *EUD*. The *EUD*, proposed by Niemierko (1997), is close in concept to TCP; it is the uniform dose in the target that gives the same level of cell kill and involves summing up the contributions of the dose bins in the DVH in the same way as in Equation 36.10; Ebert (2000) has compared the relative usefulness of *EUD* and TCP. The Terahara et al. study thus effectively provides clinical support for the effect of inhomogeneous dose distributions on TCP predicted by the model described here (and in Nahum and Sanchez-Nieto 2001).

### 36.2.5 THE EFFECT OF HYPOXIA ON LOCAL CONTROL: A CASE STUDY

Very low values of  $\alpha/\beta \sim 1.5$  for prostate clonogens have been obtained from applying tumour local-control models to the clinical results obtained by external-beam therapy (XRT), on the one hand, and low-dose-rate (LDR) permanent brachytherapy seed implants (LDR brachy) on the other (Brenner and Hall 1999; King et al. 2000; Fowler et al. 2001; Lindsay et al. 2003; Wang et al. 2003b).

A study has also been carried out using the local control model described here but extended to incorporate hypoxic clonogens (Nahum et al. 2003a). A best set of prostate tumour-biology parameters was derived from averages of the literature values of the  $\alpha$ - and  $\beta$ -inactivation coefficients for human prostate cancer cell lines, derived from *in vitro* irradiation; these are given in Table 36.1. The new aspect of this study was the explicit incorporation of hypoxia into the local control model. Movsas et al. (2000, 2002) had obtained, using an Eppendorf probe *in vivo*, median  $pO_2$  values  $\leq 1$  mmHg in the prostates of brachytherapy patients in 21% of 115 cases. Oxygen Enhancement Ratios (OERs) of 1.75 and 3.25 for  $\alpha$ - and  $\sqrt{\beta}$ -inactivation respectively were incorporated into the TCP model, following Chapman (2003), together with clonogen densities of  $\sim 10^5$  cells/cm<sup>3</sup>. Severe hypoxia, increasing with PSA level, was assumed in a proportion of tumours, in accordance with the Movsas et al. experimental findings.

The clinical-response data from both the Hanks' external-beam, dose-escalation study, stratified by PSA value, and the Stock et al. LDR brachytherapy study were well predicted by the Nahum et al. (2003a) model without assuming a low  $\alpha/\beta$ ; values of  $\alpha/\beta = 8.5$  Gy and 50.3 Gy<sup>†</sup> were used for well-oxygenated and hypoxic clonogens respectively (Chapman 2003; Nahum and Chapman 2004). The fit to the Hanks external-beam data, stratified into three bands of PSA values, is shown in Figure 36.11. It should be noted that the local control vs dose curves

\*  $D_{\text{eff}}$  is identical to the Equivalent Uniform Dose (*EUD*) proposed by Niemierko (1997).

<sup>†</sup> The value of  $\alpha/\beta = 15.5$  Gy for hypoxic clonogens given in Nahum et al. (2003a) was found to be in error; it was subsequently corrected to 50.3 Gy in Nahum and Chapman (2004); this change did not affect the conclusions drawn from the study.

**TABLE 36.1**

The Tumour Biology Parameters Used in the Prostate Local-Control Study

$$\alpha = 0.2603 \text{ Gy}^{-1}$$

$$\sigma_\alpha = 0.06 \text{ Gy}^{-1}$$

$$\beta = 0.0312 \text{ Gy}^{-2} \text{ (for XRT)} \quad \beta = 0 \text{ (for LDR brachy)}$$

$$\text{OER}_\alpha = 1.75, \text{ i.e. } \alpha_{\text{hypoxic}} = \alpha_{\text{oxic}} / 1.75$$

$$\text{OER}_{\sqrt{\beta}} = 3.25, \text{ i.e. } \beta_{\text{hypoxic}} = \beta_{\text{oxic}} / (3.25)^2$$

Clonogen number:  $N_0 = 5 \times 10^6$  (LDR brachy);  $N_0$  variable between  $10^6$  and  $10^7$  (XRT)

Fraction size:  $d = 2 \text{ Gy}$  (for XRT)

for the intermediate and high PSA-level patients are no longer sigmoid in shape due to the incorporation of hypoxia.

Nahum et al. (2003a) concluded that neither  $\alpha/\beta$  ratios nor clonogen number need be extremely low to explain the response of prostate cancer to low dose rate (LDR) brachytherapy and external-beam therapy in contrast to other analyses (e.g. Brenner and Hall 1999; Fowler et al. 2001). It was strongly suggested that the overall cure-rate by radiation treatment is limited by severe hypoxia in the prostates of a non-negligible proportion of patients, this proportion increasing by PSA group.

### 36.2.6 CONCLUSIONS

The TCP model described here is mathematically simple and yet it is a reasonably complete description of the process of tumour eradication by radiotherapy, as it is able to deal with non-uniform dose distributions, variation in fraction size, proliferation (Tucker et al. 1990; Deasy 1996) and, in principle, variable clonogen density. The effects of hypoxia can be incorporated without any drastic modifications (Buffa et al. 2001a; Nahum et al. 2003a; see also [Section 36.2.5](#)), though modelling re-oxygenation is less straightforward (Poppel et al. 2002;

**FIGURE 36.11**

Tumour local control probability (TLCP) versus total external-beam radiotherapy dose delivered in 2 Gy fractions for prostate tumours whose clonogens have the same variable  $\alpha$  (i.e. non-zero  $\sigma_\alpha$ ) and fixed  $\beta$  radiosensitivities as those in the table. The two sigmoidal curves forming the envelope correspond to 100% aerobic (left-most) and 100% hypoxic (right-most) tumours. Within the envelope, the three curves describe patient populations whose hypoxic tumour-aerobic tumour ratios are 15/85 (dashed), 25/75 (full) and 60/40 (dashed-dotted) respectively. The data points are local-control rates (bNED) for prostate cancers of increasing stage with PSA levels of  $\leq 10 \text{ ng/ml}$  (□),  $10\text{--}20 \text{ ng/ml}$  (△) and  $> 20 \text{ ng/ml}$  (○) from Hanks et al. (1997). (Reproduced from Nahum, A. E. and Chapman, J. D., *Int. J. Radiat. Oncol. Biol. Phys.*, 58, 1637–1639, 2004. With permission.)

Ruggieri 2004; Ruggieri and Nahum 2006). Dose-rate effects can also be important in certain circumstances, principally when LDR or HDR brachytherapy is administered (see [Section 9.4](#) and [Chapter 55](#)); there are well-established formulas available to estimate the decrease in the  $\beta$  coefficient as the dose rate is reduced (e.g. Dale 1985; Steel 2002; Wang et al. 2003a, 2003b; [Chapter 55](#)). There are also suggestions that the extended treatment times for external-beam therapy (as in some IMRT treatments) may reduce cell-killing and hence TCP (see [Section 9.7](#)).

The main limitations in the clinical use of the TCP model are the lack of clinical data on radiosensitivity and clonogenic cell density; a useful compilation of such data is found in [Table 8.5](#) in Wigg (2001). Thus, the *absolute values* of predicted TCP must be treated with caution. There have been some recent attempts to use TCP models to fit clinical data on patient local control and/or survival and doses and hence to derive clinically reasonable parameter values, the most comprehensive of these being for prostate tumours (e.g. Sanchez-Nieto and Nahum 1999; Fowler et al. 2001; Levegrin et al. 2000, 2001; Lindsay et al. 2003; Nahum et al. 2003a) and there is a valuable study for the case of non-small cell lung tumours by Martel et al. (1999), further discussed by Fowler et al. 2004. There is enormous variation in the parameters obtained (especially in  $\alpha$  and  $\rho_{cl}$ ) depending on, for example, whether or not interpatient heterogeneity is incorporated (Brenner 1993; Webb 1994; Fenwick 1998; Webb and Nahum 1998; Brenner and Hall 1999; Buffa et al. 2000; Fowler et al. 2001; Nahum et al. 2003a; Wang et al. 2003a, 2003b; Carloni et al. 2006).

TCP modelling is a developing field. Refinements of the parameters and of the models themselves continue. Zavgorodni (2004) has looked at the radiobiological implications of inter-fraction dose fluctuations, due for example to patient set-up uncertainties, and derived an expression for the *equivalent constant dose* (ECD) producing the same cell survival fraction as a variable dose with a given standard deviation  $\sigma_d$ . The expression involves the mean dose, the number of fractions,  $\sigma_d$  and  $\alpha/\beta$ . Keall et al. (2003) have modified a TCP model to enable predictions to be made for the combination of gene therapy and radiotherapy. The work of Antipas et al. (2004) represents a much more ambitious type of modelling; the growth of a tumour is simulated including cell division, changing oxygenation status, cell death, tumour shrinkage in response to irradiation, apoptosis, etc.

All the current tumour-response models make the implicit assumption that each cell responds to the absorbed dose at the location of the cell, i.e. to the *local* dose. However, the existence of so-called *bystander effects* has been established beyond any doubt (e.g. Mothersill et al. 2004), i.e. irradiated cells affect the cells in their immediate neighbourhood. The key question for radiotherapy is over what distance do these bystander effects act? If this is only fractions of a millimetre then probably the consequences are minimal. However, if the *action distance* is several millimetres or even centimetres then drastic revisions of many of our ideas will be necessary; the experiments by Suchowerska et al. (2005) suggest that it may well be centimetres. Certainly the predictions of current *local dose* TCP models regarding the effect of *hot* and *cold* spots will require revision. The rationale for the renaissance of so-called *grid therapy* in the megavoltage era is at least partly based on the belief that bystander effects are important in external-beam radiotherapy (Mohiuddin et al. 1999; Trapp et al. 2004; Zwicker et al. 2004).

Significant changes are underway in patient dose-calculation methods ([Part F](#)). Monte-Carlo simulation, because of its highly accurate treatment of the effect of heterogeneities, is gradually being introduced into treatment planning systems (see [Chapter 28](#)). However, a unique feature of Monte-Carlo generated dose distributions is the statistical noise, which can be thought of as a large number of artificial *hot* and *cold* regions. If these fluctuations are too large, due to too few *histories* being executed, then they could affect the prediction of TCP, yielding an artificially low value even though the mean value of the dose in the tumour will be correct. Analyses of this intriguing problem have appeared (Buffa and Nahum 2000; Keall et al. 2000); it has been shown, for example, that for a photon-beam plan, TCP varies strongly with voxel-size for  $10^7$  histories, but this variation (i.e. underestimation) is negligible for  $10^8$  histories.

There is software freely available that evaluates TCP (and NTCP) models including the one which has been described in detail above. One such package is BIOPLAN (Sanchez-Nieto and Nahum 2000); Warkentin et al. (2004) describe a similar system. El Naqa et al. (2005) offer a comprehensive software package which will not only compute TCP (and NTCP) but also fit these models to the user's own clinical data.

---

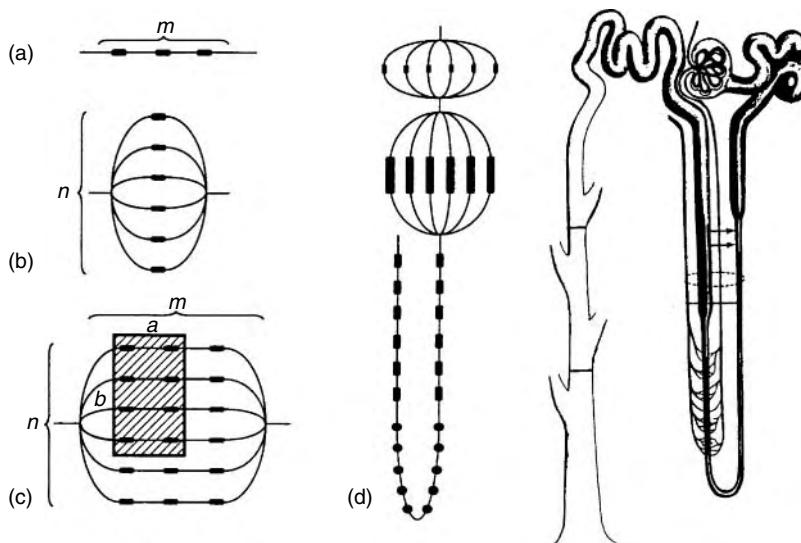

## 36.3 NORMAL TISSUE COMPLICATION PROBABILITY

### 36.3.1 GENERAL

The notion of using some type of biological index to characterize one or more features of a treatment plan was expounded upon early by Dritschilo who applied what he called a *complication probability factor* to rank rival treatment plans (Dritchillo et al. 1978). In spite of early attempts such as this, the increasing interest in NTCP modelling has, in large part, been a consequence of the development of 3D treatment planning systems and their use in conformal therapy. The potential of designing treatments with new and complex dose distributions to reduce normal tissue toxicity, and maybe escalate the dose to the tumour, lies behind attempts to characterize the merits of a treatment plan. This has become especially important because the limited clinical experience with innovative dose distributions makes it difficult to choose between two candidate treatment plans. NTCP is a particularly important index for ranking treatment plans. Like other quantitative indices (e.g. TCP), it reduces the large amount of data characterizing a three-dimensional dose distribution to a limited number of numerical indices, thus making the comparison of a number of rival plans more efficient. In addition, NTCP nominally represents an endpoint, which often determines the acceptability of a treatment plan, that is, whether the tolerance of normal tissues has been respected or exceeded.

The NTCP models currently in use stem from two main lines of development, both of which aim to predict the probability of a complication as a function of the dose (or biologically equivalent dose) and volume. These models can be distinguished by their descriptions of the *volume effect*, that is, how the probability of a complication changes with volume irradiated at a fixed dose. One of the lines of development has led to a phenomenological model which was first formulated by Lyman (1985), Lyman and Wolbarst (1987, 1989a), and later augmented by Kutcher and Burman (1989) and Kutcher et al. (1991); this model is generally known as the L-K-B model (see [Section 36.3.2](#)). The L-K-B model seeks to describe complication probabilities using (clinical) tolerance doses for different irradiated volumes as input data. The tolerance doses for different volumes are related through a power law, and thus the clinical data are used to determine the magnitude of the volume effect, which can vary widely. In spite of this flexibility, the L-K-B model does not exhibit a threshold effect with volume and so would not strictly apply to endpoints like radiation pneumonitis. It is possible, however, to augment the model by introducing a fifth parameter, the so-called critical volume, below which there is no complication.

A second line of approach begins by making certain assumptions about the functional and anatomic organization of tissues and organs such that different volume effects are specific to different functional organizations. For example, *serial* (critical element) models assume that certain organs are arranged like links on a chain, and when one link (a functional subunit) is damaged the entire chain is broken and a complication ensues (Schultheiss et al. 1983; Wolbarst 1984; Withers et al. 1988; Niemierko and Goitein 1991). Organs with this architecture reveal a small volume effect. *Parallel* models (critical volume models) assume that a complication does not occur until a significant fraction of the independent functional sub-units (the *functional reserve*) of an organ has been incapacitated (Wolbarst et al. 1982; Källman et al. 1992; Jackson et al. 1993; Niemierko and Goitein 1993b; Yorke et al. 1993). [Figure 36.12](#) is a schematic illustration of these ideas.

**FIGURE 36.12**

Schematic illustration of the concepts of (a) series, (b) parallel and (c) serial-parallel organisation of functional subunits in an organ; (d) is an example of the parallel-serial model applied to a functional subunit of the kidney, a nephron. (From Källman, P., et al., *Int. J. Radiat. Biol.*, 62, 249–262, 1992. With permission.)

The volume effect in these *parallel* tissues is necessarily large, since a complication does not occur if less than the functional reserve is irradiated. A model which makes explicit use of these ideas is the *relative seriality* model (Källman et al. 1992) described in [Section 36.3.3.3](#).

### 36.3.2 LYMAN–KUTCHER–BURMAN (L–K–B) EMPIRICAL MODEL

#### 36.3.2.1 Homogeneous Irradiation

Lyman (1985) argued that normal tissue complication probabilities depend upon volume as well as dose, and that they could be conveniently represented by an error function in dose and volume. For organs that are irradiated by a uniform dose to part of the volume and no dose to the rest, the probability of a complication can be represented by:

$$NTCP = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^t e^{-t^2/2} dt \quad (36.13)$$

$$t = \frac{D - TD_{50}(V/V_{ref})}{m TD_{50}(V/V_{ref})} \quad (36.14)$$

$$TD_{50}(1) = TD_{50}(V/V_{ref})(V/V_{ref})^n \quad (36.15)$$

The four parameters in this model are:

- $TD_{50}(1)$ , the dose to the whole organ which would lead to complication in 50% of the population (note that  $TD_{50}(V/V_{ref})$  is to be read as the  $TD_{50}$  at partial volume  $V/V_{ref}$ );
- $V_{ref}$ , a reference volume, which in many cases will be the (whole) organ volume;
- $m$ , a parameter representing the steepness of the dose–response curve;

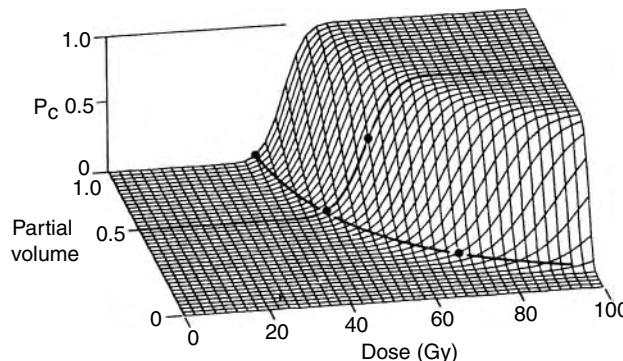

- $n$ , the exponent of volume in the power law that relates the tolerance doses for uniform whole and uniform partial organ irradiation.

This latter parameter represents the *volume effect*: when  $n$  is near unity, the volume effect is large and when it is near zero, the volume effect is small. As we shall find, a large volume effect ( $n$  close to unity) implies that the NTCP correlates with the mean dose, while a small volume effect ( $n$  close to zero) implies that it correlates with the maximum dose in the organ. Moreover, referring to the architectural models which are described below, the analogue of a parallel architecture organ would be one with a large value of  $n$ , and for a serial organ, one with a small value of  $n$ . Figure 36.13 shows the NTCP function that is generated by Equation 36.13 (together with Equation 36.14 and Equation 36.15).

This figure was constructed by Lyman to represent then current estimates of partial-volume tolerance doses for the heart (Lyman 1985). It also serves to illustrate several features of the Lyman model. The sigmoid curve picked out in the figure corresponds to uniform irradiation of 50% of the heart volume, for which  $TD_5$  is around 45 Gy and  $TD_{50}$  around 53 Gy. For a partial volume of unity the sigmoidal complication curve starts at around 30 Gy and reaches 100% at just over 50 Gy. As one moves towards *lower* values of the partial volume the sigmoid curve moves towards *higher* doses. In general, the more the curve moves (per unit decrease in partial volume) the greater is the volume effect, i.e. the larger the value of  $n$  (see also Figure 36.14).

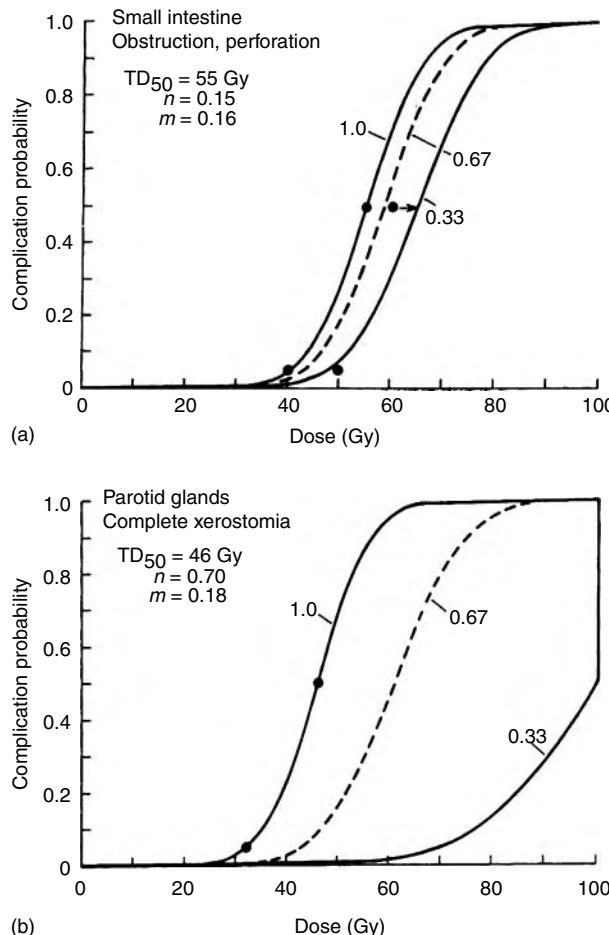

The NTCP for partial organ irradiation in the Lyman model is based upon clinical estimates of organ tolerance for partial uniform irradiation at different doses and volumes. Such data are difficult to come by. Nevertheless, Emami et al. (1991a) estimated tolerance doses from the literature and unpublished experience. They chose to transform the data into one-third, two-thirds, and whole-organ tolerances, rather than using the fractions reported in the literature, and this forced them to interpolate the published data. Values of the parameters  $TD_{50}$ ,  $m$ , and  $n$ , which provided the best fits of the Lyman model (Equation 36.13) to the Emami et al. partial organ tolerances are tabulated in Burman et al. (1991) for a large number of organs and endpoints. The values of  $n$  varied from near zero for some organs, e.g. the spinal cord, up to about 0.7 or greater for large organs like the liver and lung. Two examples of complication probabilities predicted by the Lyman model using the Burman et al. parameters are given in Figure 36.14.

It was clearly emphasised in Emami et al. (1991a) and Burman et al. (1991) that the partial organ tolerance doses themselves and hence the parameters derived from them were subject to considerable uncertainties. One important point to be made in this context is that these publications date from the very beginning of the era of 3D treatment planning and hence there are

**FIGURE 36.13**

A 3D surface representation of the Lyman model (Equation 36.13) for complication probability  $P_C$  for uniform partial irradiation of an organ, the heart in this example, as a function of partial volume and dose. (From Lyman, J. T., Radiat. Res., 104, S13–S19, 1985. With permission.)

**FIGURE 36.14**

Complication probability, or NTCP, vs dose for two organs evaluated from the Lyman NTCP model (Equation 36.13) for uniform irradiation of the whole (1.0), two-thirds (0.67) and one-third (0.33) of the organ in question, for (a) obstruction or perforation in the small intestine, which has a *small* volume effect ( $n=0.15$ ) and (b) complete xerostomia in the parotid glands, which has a *large* volume effect ( $n=0.70$ ). All the parameters are taken from the fits to clinical data in Burman et al. (1991). (From Kutcher, G. J., et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 21, 137–146, 1991. With permission.)

major limitations in the clinical data on which they were based. Since then, there have been a number of publications, which have suggested changes in the model parameters based upon new dose distributions, and toxicity data, which will be described in later sections (e.g. Ten Haken 2001).

### 36.3.2.2 Inhomogeneous Irradiation

Because of the uniform partial irradiation requirement the above approach will apply only to a limited number of treatments, namely those in which the organ is treated with parallel-opposed fields. For example, in head and neck cancer a large portion of the parotid glands are often irradiated to near uniform doses with opposed lateral fields, while the remainder receives a low (although nonzero) scatter dose. Nowadays, however, multi-field treatment techniques are the rule rather than the exception and these usually produce dose distributions that are inhomogeneous throughout the organ so that the above *uniform partial volume* modelling would not be applicable. Indeed, one of the difficulties with the data culled from the literature in the Emami compilation was that the condition of dose uniformity was not necessarily met.

It was necessary, therefore, to find a way of using the Lyman model in the more general case of inhomogeneous dose in the organ or tissue of interest. One way of doing this is to convert the organ's DVH into an *equivalent* uniform one using either interpolation (Lyman and Wolbarst 1989) or the so-called *effective volume* method (Kutcher and Burman 1989). If this DVH-conversion step is valid, then the dose and volume for the transformed uniform histogram can be used to read-off the complication probability from the Lyman representation of the uniform partial-organ data. In most instances both procedures lead to the same NTCP (Kutcher et al. 1991); here the latter method is described.

In the effective volume method, the DVH for the organ in question is transformed into one in which the volume  $V_{\text{eff}}$  (which is equal to or less than the whole organ volume) receives a dose equal to the *maximum* dose in the organ ( $D_{\text{max}}$ ). One operates on each dose-bin of the *differential* DVH in turn, multiplying the fractional volume  $\Delta V_i$  in that bin; of (mean) dose  $D_i$ , by  $(D_i/D_{\text{max}})^{1/n}$  to yield the effective volume for that bin,  $\Delta V_{\text{eff}}$ . Thus the effective volume is given by

$$V_{\text{eff}} = \Delta V_{\text{max}} + \Delta V_1(D_1/D_{\text{max}})^{1/n} + \Delta V_2(D_2/D_{\text{max}})^{1/n} + \dots$$

i.e.

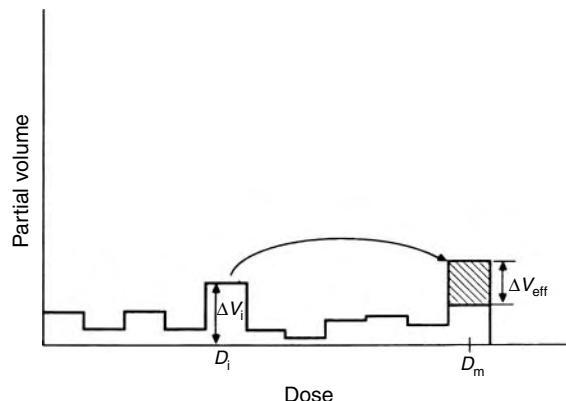

$$V_{\text{eff}} = \sum_{i=1}^k \Delta V_i (D_i/D_{\text{max}})^{1/n} \quad (36.16)$$

This is illustrated in Figure 36.15.

Moreover, there is a *family* of equivalent uniform DVHs with effective volume and dose related through the defining power-law relationship (Equation 36.15). Thus, there is an effective dose ( $D_{\text{eff}}$ ) or *EUD* that, if applied to the whole organ ( $V_T$ ), would yield the same NTCP:

$$D_{\text{eff}} = \sum_i \left[ D_i^{1/n} \frac{V_i}{V_T} \right]^n \quad (36.17)$$

The effective volume transformation is self-consistent with the power-law model for uniform irradiation in that it can be derived from just two hypotheses: the organ is homogeneous in its response to radiation; and each element of the organ obeys the same power-law relationship as the whole organ (Kutcher and Burman 1989). The former condition is clearly problematic. Most normal organs are not homogeneous in response. For example, the

**FIGURE 36.15**

Illustration of *dose-volume histogram reduction* using the *effective volume* method; the DVH shown is in differential form, as opposed to the more familiar cumulative version. (From Kutcher, G. J., et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 21, 137–146, 1991. With permission.)

nephrons of the kidney are not uniformly distributed, and the apex of the lung is less sensitive than the rest of that organ (e.g. Seppenwoolde et al. 2004).

It is instructive to consider the effect of different values of  $n$  on the calculation of  $V_{\text{eff}}$  and  $D_{\text{eff}}$ . For very small  $n$ , all terms  $(D_i/D_{\max})^{1/n}$  in Equation 36.16 will be negligible for all  $D_i < D_{\max}$  which will mean that all the volumes  $\Delta V_i$  at lower doses will make a negligible contribution to the effective volume, which will therefore be essentially equal to the volume at maximum dose; in other words the complication probability will be solely determined by the fractional volume of the organ receiving doses very close to the tumour or prescription dose. For  $n = 1$ , on the other hand, the effective dose (Equation 36.17) will be equal to the *mean* dose to the organ, and thus those parts of the organ receiving relatively low doses will play a significant role in contributing to the complication probability. Figure 36.16 is an example of how the NTCP of the parotid gland ( $TD_{50} = 46$  Gy,  $n = 0.70$ ) differs for two different treatment plans with quite different (cumulative) DVHs.

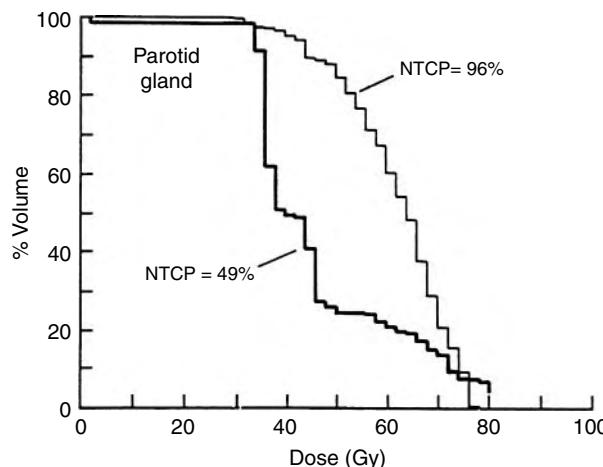

Niemierko has generalized the concept of EUD originally proposed for tumours (Niemierko 1997) to apply also to normal tissues and, in Niemierko (1999a), gave an expression for *EUD* identical to that for  $D_{\text{eff}}$  in Equation 36.17 above, except that the volume-effect exponent  $n$  was replaced by  $1/\alpha$ . It was stated that  $\alpha$  was a tissue-specific parameter, and that *EUD* was equal to the mean dose for  $\alpha = 1$ . Further,  $\alpha$  was negative for tumours and positive for all normal structures. Building on this EUD concept for normal tissues, Niemierko (1999b) proposed a *generalized unified model*:

$$p = \Phi\left(\frac{\ln \text{EUD} - \ln D_{50}}{\sigma}\right) \quad (36.18)$$

where  $\Phi(x)$  is the standard normal distribution function,  $\sigma$  is the standard deviation of log-tolerance in a population and  $D_{50}$  is the median tolerance dose. Alternatively, this can be expressed as

$$p = \Phi[\gamma_{50} 2\pi (\ln \text{EUD} - \ln D_{50})] \quad (36.19)$$

where  $\gamma_{50}$  is the slope of the normalized *NTCP* vs dose curve at  $p = \text{NTCP} = 50\%$  (see the definition of  $\gamma$  in [Section 36.2.1.3](#)). Niemierko stated that the fit of the model to several

**FIGURE 36.16**

NTCP values for xerostomia according to the L-K-B model for two different parotid gland DVHs (from different treatment plans) using the Burman et al., 1991 parameter values given in [Figure 36.14b](#). (From Kutcher, G. J. et al., *Int. J. Radiat. Biol. Phys.*, 21, 137–146, 1991. With permission.)

tumour and normal-tissue data sets was at least as good as fits of “other more complicated models proposed in the literature”.

### 36.3.3 ORGAN ARCHITECTURE MODELS

There have been a number of papers, quoted earlier, which have suggested that organ architecture is related to complication probability. Withers argued forcefully that the response of an organ to radiation might be related to the organisation of its more basic units (Withers et al. 1988). The simplest representation of an organ was that it was composed of independent *functional subunits* (FSUs) which could be defined either structurally (e.g. the nephrons of the kidney) or operationally (e.g. the FSUs of the skin). Moreover, it was suggested that the FSUs had either *serial* or *parallel* organizations. Since the FSUs are considered (by definition) to be independent of one another, at least in their response to radiation damage, the probability of a complication is amenable to statistical methods. In his paper, Withers applied these ideas to serial organs with uniform partial irradiation and derived the complication probability (see [Section 36.3.3.1](#)).

The NTCP for inhomogeneous dose distributions for both serial or parallel organs has been developed by Jackson et al. (1993) and Niemierko and Goitein (1991, 1993b) as well as by Källman et al. (1992)—see [Section 36.3.3.3](#). Here, briefly, the reasoning of Jackson’s solution is followed. Starting with a general inhomogenous dose distribution, Jackson derived a *risk histogram* (an extension of a DVH) which represented the family of fractional volumes of the organ in each of which the probability of eradicating its FSUs was equal to or greater than a certain probability. Using the risk histogram, he was able to calculate, by statistical methods, the probability  $P(M)$  of eradicating  $M$  and only  $M$  FSUs.  $P(M)$  is a complicated function of the organ architecture and the radiation conditions and the interested reader should refer to Jackson et al. for further details. An important point, however, is that once this function is known, it can be used to derive the complication probability for serial or parallel normal organs (as well as the control probability for tumours). For example, NTCP is calculated by summing  $P(M)$  from a lower limit  $L$  (the minimum number of eradicated FSUs required to realize a complication) to  $N$  (the total number of FSUs in the organ):

$$NTCP = \sum_{M=L}^N P(M) \quad (36.20)$$

If  $L=1$ , then we obtain a serial complication model where at least one FSU must be eradicated to realize a complication. If  $L$  is greater than unity, we have a parallel complication model in which at least  $L$  FSUs must be eradicated for a complication. Since the number of FSUs is usually quite large, typically  $10^4$ – $10^9$  (Thames and Hendry 1987), the derived dose–response curves are very steep. If we interpret this result as the dose response of an organ in an individual, then it is possible to obtain more realistic dose–response curves by averaging over a *population* of patients (cf. the TCP model described in [Section 36.2](#)). For example, we can average the NTCPs over a distribution of functional reserves of an organ or we can average over intra- or inter-organ distributions of radiosensitivities. Such an approach leads to models with at least 4 parameters, two for the local response function, and two for each population distribution, although fewer are possible for a serial model (Niemierko and Goitein 1991).

#### 36.3.3.1 Serial Organs

The description above is somewhat formal and general. We can obtain some insight by following Wither’s argument for a serial chain model (e.g. [Figure 36.12a](#)). In the case

of uniform irradiation of  $N$  of the FSUs and no radiation to the remainder, the probability of eradicating at least one FSU is given by one minus the probability of *not* eradicating any:

$$NTCP = 1 - (1-p)^N \quad (36.21)$$

where  $p$  is the probability of eradicating a single FSU. This relationship yields a sigmoid curve of  $NTCP$  versus dose. As the number of irradiated FSUs increases (that is, as the volume of irradiated organ increases) the sigmoid response shifts to the left and the complication probability increases. In addition, the partial volume dose-response curves become steeper as the volume increases. Niemierko and Goitein (1991) have also shown that the serial model can be extended in a rather straightforward fashion for non-homogeneous irradiation, and that the serial and L-K-B models agree at low complication probability, that is in the clinically significant domain. Finally, for the serial case, the whole-organ dose-response curve can be shown to uniquely determine the volume effect of the organ.

### 36.3.3.2 Parallel Organs

In parallel-element tissues, which have also been modelled using binomial statistics for homogenous irradiation (Yorke et al. 1993) and for inhomogeneous irradiation (Jackson et al. 1993, Niemierko and Goitein 1993b), a complication occurs if the fraction of eradicated FSUs exceeds a threshold, the so-called *functional reserve* of the organ. The kidney, liver, and lung are believed to behave as parallel organs. Because the number of FSUs is always large in these organs (Thames and Hendry 1987), the functional reserve of an organ can be defined by the fraction rather than the number of eradicated FSUs. Moreover, as mentioned above, it is likely that this functional reserve varies over a population of patients. For example, liver function will differ depending, for example, on the age and alcohol consumption of the patients. It is also possible that radiosensitivities may vary over a population of patients (cf. [Section 36.2.1.3](#)) or that there are *intra*-organ variations, although Jackson et al. (1993) have shown that intra-organ distributions have negligible effects. For simplicity, if we assume that there is a population distribution of functional reserves only (i.e. not of radiosensitivities), then the observed NTCP would be proportional to the fraction of patients in which the local damage exceeds the functional reserve, that is

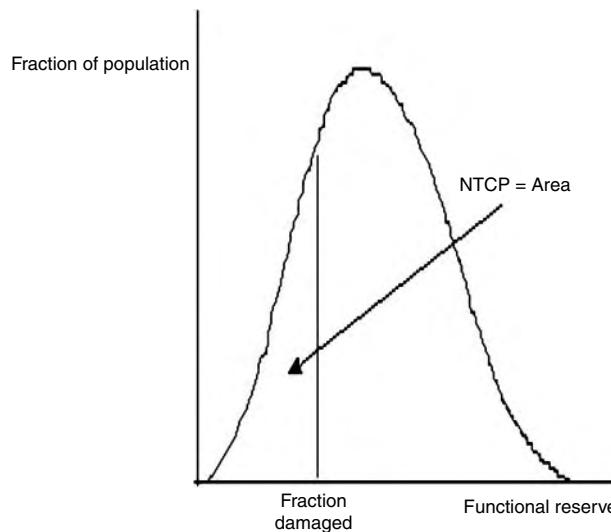

$$NTCP = H(f) \quad (36.22)$$

where  $H$  is the cumulative distribution of functional reserves for the population and  $f$  is the fractional damage of FSUs, given by

$$f = \sum_i p(d_i)(V_i/V_T) \quad (36.23)$$

where  $V_i$  is the volume of the organ receiving dose  $d_i$  with probability of damage  $p(d_i)$ .

Equation 36.22 and Equation 36.23 can be interpreted as follows. To obtain NTCP we first calculate the fractional damage from Equation 36.23 using the DVH for the organ and the local response function,  $p(d)$ . The NTCP is obtained by calculating the fraction of the population in which the fractional damage exceeds the functional reserve. This is nothing more than the area under the differential distribution of functional reserves from zero to the fractional damage, which is  $H(f)$  (see [Figure 36.17](#)). To take one example,  $f$  might represent the fraction of *acini* of the liver that have been irradiated, while  $H$  would represent the fraction of the patients whose functional reserve for radiation hepatitis was fully depleted. In this representation we have a 4-parameter model where two of the parameters represent the distribution  $H$  (mean and width) and two parameters represent the  $p(d_i)$ .

**FIGURE 36.17**

The calculation of NTCP in the parallel model in the limit where the distribution of functional reserves is used to obtain NTCP for a population.

### 36.3.3.3 The Relative Seriality Model

The so-called *relative seriality* model (Källman et al. 1992) represents an alternative attempt to construct a quasi-mechanistic model for NTCP which takes explicit account of the structure or *architecture* of an organ; the latter is assumed to consist of FSUs and/or *tissue rescuing units* (TRUs). These units are arranged in series, in parallel or in a combination of series and parallel as illustrated in Figure 36.12. The model includes a parameter  $s$  which reflects the degree to which the architecture of the FSUs is considered to be *serial* ( $s=1$ ) or *parallel* ( $s\rightarrow 0$ ).

Källman et al. began by writing down the dose-response relationship for tumours (i.e. TCP) and normal tissues (NTCP), and included the probit, logit and Poisson models, the latter being expressed as

$$P(D_{\text{tot}}) = 2^{-\exp[e\gamma(1-D_{\text{tot}}/\text{TD}_{50})]} \quad (36.24)$$

where  $P(D)$  is the probability of no cell surviving (and we retain here the upper-case Källman et al. notation for probability),  $D_{\text{tot}}$  is the total dose delivered (in small fractions),  $\text{TD}_{50}$  is the dose causing a 50% response rate (identical to  $\text{TD}_{50}$  in the L-K-B model), and  $\gamma$  is the normalised dose-response gradient (see Section 36.2.1.3). Källman et al. derived Equation 36.24 starting from the linear-quadratic model expression for the surviving fraction after fractionated dose delivery (Equation 36.3) and then use Poisson statistics to obtain the probability of eradicating all the cells (i.e. Equation 36.5)\*.

These authors then reasoned that the response, i.e. the NTCP, of an organ consisting purely of  $m$  serial subunits with local response  $P_i$  would be given by (cf. Equation 36.21)

$$\text{NTCP} = 1 - \prod_{i=1}^m (1 - P_i) \quad (36.25)$$

\* Källman et al. show that  $\gamma = (\ln N_0 + \beta \bar{D}^2/n)/e$  and  $\text{TD}_{50} \approx \ln N_0/(\alpha + 2\beta \bar{D}/n)$  for  $n$  fractions and mean organ dose  $\bar{D}$ . Källman et al. use the notation  $D$  rather than  $D_{\text{tot}}$  and  $D_{50}$  rather than  $\text{TD}_{50}$ , but their notation has been changed here for consistency with the rest of the chapter.

whereas for an organ with  $n$  parallel subunits with local response  $P_j$ ,

$$NTCP = \prod_{j=1}^n P_j \quad (36.26)$$

For an organ with an  $n \times m$  matrix of parallel and serial subunits (e.g. Figure 36.12c), the overall complication probability would then be given by

$$NTCP = \prod_{j=1}^n \left[ 1 - \prod_{i=1}^m (1 - P_{ij}) \right] \quad (36.27)$$

Källman et al. now assumed that all the subunits had identical sensitivities and further that the dose distribution in the organ was uniform. Writing all  $P_{ij} = P_\Delta$  one can then write Equation 36.27 as

$$NTCP = [1 - (1 - P_\Delta)^m]^n \quad (36.28)$$

from which follows, by inverting Equation 36.28, the key step of expressing the *local* response  $P_\Delta$  in terms of the organ response, i.e. NTCP:

$$P_\Delta = 1 - (1 - NTCP^{1/n})^{1/m} \quad (36.29)$$

At this point in the derivation, it became necessary for the authors to introduce further approximations and the model became more empirical in nature. The identity of the elementary compartments changed from FSUs to simply *volume elements* or *voxels*. In particular, they pointed out that the response of a structured tissue or organ would depend critically on the geometrical alignment of structures relative to the beam direction(s), e.g. the parallel structures and the serial structures may be in different locations. Källman et al. then introduced the parameter  $s$  describing the *relative seriality* of the organ or tissue. It was shown that  $s = 1/n$  and the response function of a subunit  $v$  of an organ,  $P_v$ , could be written

$$P_v = [1 - (1 - P(D_{\text{tot}})^s)^v]^{1/s} \quad (36.30)$$

where  $P(D_{\text{tot}})$  is given by Equation 36.24 and  $v$  is the fractional volume of the subunit.

After some further algebraic manipulation, it was shown that for  $M$  identical volume elements of fractional volume  $\Delta v$ ,

$$NTCP = [1 - (1 - (P_{\Delta v})^v)^M]^{1/s} \quad (36.31)$$

and finally, generalising Equation 36.30 to a *non-uniform* dose distribution, and expressing  $P_{\Delta v}(D_i)$  in terms of  $P(D_i)$  for the whole organ using Equation 36.29, the final expression for the *relative seriality* NTCP is obtained:

$$NTCP = \left[ 1 - \prod_{i=1}^M [1 - P(D_i)^s]^{\Delta v_i} \right]^{1/s} \quad (36.32)$$

where  $P(D_i)$  is evaluated from Equation 36.24 and the fractional volumed  $\Delta v_i$  at doses  $D_i$  are most conveniently obtained from the  $M$  bins of the differential DVH for the organ in question. Therefore, no DVH reduction is required in this model.

Källman et al. (1992) give values of  $TD_{50}$ ,  $\gamma$  and  $s$  for seven organs/endpoints based on the Emami et al. (1991a) compilation of clinical complication data. As examples, for the esophagus  $s = 3.4$  which corresponds to an organ with a highly serial structure, and for the lung,  $s = 0.0061$  which corresponds to a highly parallel structure.

The relative seriality model has been extensively employed in analysing treatment plans and in correlating clinical outcome with NTCP predictions (e.g. Gagliardi et al. 1996, 2000; Mackay et al. 1997; Gagliardi 1998). As an example, for the heart, for the endpoint

of cardiac mortality, Gagliardi et al. (2001) give  $TD_{50}=52.3$  Gy,  $\gamma=1.28$  and  $s=1.00$ ; these values were obtained from analysing patient data from two randomised breast radiotherapy trials.

### 36.3.3.4 Relationships between L-K-B, Serial and Parallel Models

Although the L-K-B and architecturally based models are derived in different ways they yield similar results for NTCP within certain limits. For example, as has already been mentioned, for small values of  $n$  the NTCP for the L-K-B model approaches that of the serial model. Thus we can think of organs with a small  $n$  as serial-like in their behaviour. Moreover, for small  $n$  the NTCP is determined primarily by the peak dose and is thus weakly correlated with the irradiated volume. As  $n$  increases so does the influence of volume on the probability of a complication. For  $n=1$ , the NTCP is a function of the mean dose delivered to the organ. For the two extremes,  $n=0$  and  $n=1$ , to a first approximation, the NTCP is thus correlated with dosimetric variables. When evaluating treatment plans in this limit, we do not have to resort to making any further assumptions about the biological models and the values of the parameters. It therefore possible to use these two extremes as a starting point or rough approximation when evaluating a treatment plan. We might, for example, use the mean dose when the lung, liver, or parotid glands are irradiated, and the peak dose for the spinal cord or small bowel.

It is important to note that organs with serial or parallel architecture have very different volume effects, as shown in Figure 36.18. For serial organs, the NTCP increases linearly with the irradiated volume, while for parallel organs, the NTCP is zero up to a critical volume and then increases supralinearly.

Finally, Kwa et al. (1998a) have demonstrated a relationship between the L-K-B and parallel models. For the parallel model if we assume that for moderate doses the probability of killing an FSU can be represented by a power law in dose:

$$p(d) = \text{constant} \times d^{1/r} \quad (36.33)$$

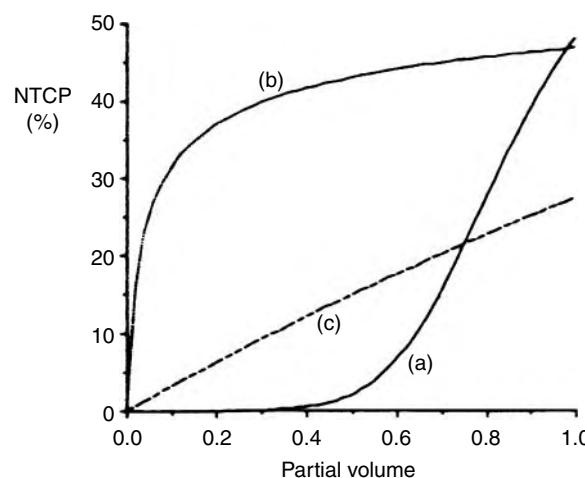

FIGURE 36.18

Comparison of the change in NTCP with volume at fixed dose (i.e. the volume effect), for parallel tissues (critical volume: curve (a)) and series (critical element) tissues with (curve (b):  $\sigma=15\%$ ) and without (curve (c):  $\sigma=0\%$ ) account being taken of interpatient variations in the model parameters. The NTCP for serial tissues show a linear response with volume irradiated, while for parallel tissues there is a threshold response. (From Niemierko, A. and Goitein, M., *Int. J. Radiat. Oncol. Biol.*, 25, 135–145, 1993b.)

then it is possible to show that  $D_{\text{eff}}$ , or the *EUD*, can be represented by:

$$D_{\text{eff}}^{\text{parallel}} = \sum_i [D_i^r V_i / V_T]^{1/r} \quad (36.34)$$

This expression is the same as that for the L-K-B model (Equation 36.17), if  $n=1/r$ . The assumption of a power law for  $p(d)$  is quite reasonable in the limit where the dose delivered is smaller than that required for killing half the FSUs. We would expect that the above correspondence between parallel and L-K-B models would break down at dose levels where there is a very high level of cell killing.

### 36.3.4 THE EFFECT OF FRACTION SIZE

NTCP models ought to be able to predict the effect of different fraction sizes, consistent with our current radiobiological understanding (see [Section 9.3](#)). In the case of the TCP model described in [Section 36.2](#) the influence of fraction size is automatically taken into account as the linear-quadratic expression for the surviving fraction of irradiated cells is used directly in the model, which requires as input the fraction size (strictly speaking all the fraction sizes in the differential DVH) and also  $\alpha/\beta$  for the clonogens. The clinical data on which the Emami compilation of tolerance doses is based corresponds to 1.8–2.0 Gy fractions delivered to the tumour (Emami et al. 1991a). In the case of the L-K-B and relative seriality NTCP models, however, there is no obvious way to include fraction-size effects inside the theoretical expressions as neither fraction number nor the  $\alpha/\beta$ -ratio explicitly appear anywhere.

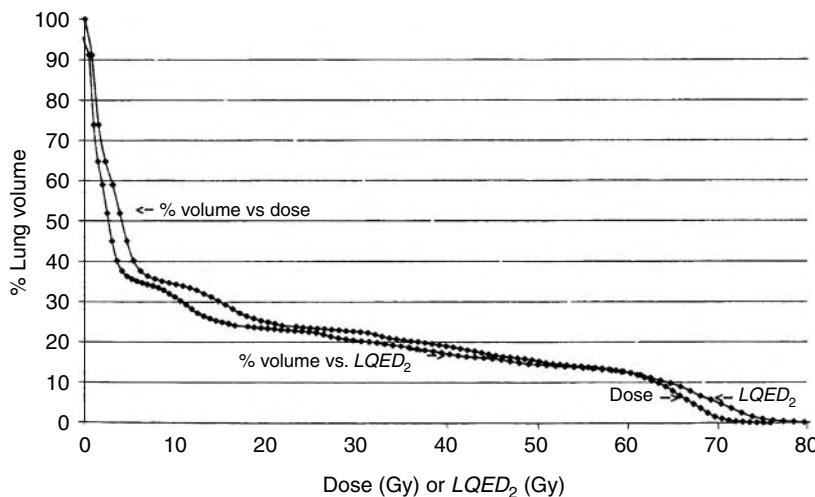

Fowler (2001) stressed that for the several different NTCP models in the literature it was *essential* that the linear-quadratic formula be used to correct the total doses delivered at a range of different doses-per-fraction to the biological equivalent of 2-Gy fractions *in every voxel*. Fowler continued, “Fortunately these corrections are easy to make, involving basically a re-scaling of the dose scale of a DVH”. We give here the expression as it appears in Wheldon et al. (1998):

$$LQED_2 = D_{\text{tot},j}(\alpha/\beta + d_j)/(\alpha/\beta + 2) \quad (36.35)$$

where  $LQED_2$  denotes the *linear-quadratic equivalent dose for 2-Gy fractions* (Fowler 1989),  $D_{\text{tot},j}$  is the total dose and  $d_j$  the fraction size at that total dose for the  $j$ th dose bin in the DVH. The effect of applying Equation 36.35 to a DVH is shown in [Figure 36.19](#). All volumes at doses below the total dose at which the fraction size is 2 Gy ( $\approx 60$  Gy in this case) are shifted to lower  $LQED_2$  doses and all volumes above this (prescription) dose are shifted to higher  $LQED_2$  doses.

The effect on NTCP values of carrying out the above conversion of total doses to  $LQED_2$  at the various fraction sizes in the normal-tissue DVH according to Equation 36.35 can be clearly seen in the example given in [Table 36.2](#). It is supposed that the organ in question is the rectum and the Rancati et al. (2003) updated parameters for the endpoint *proctitis* have been used. The reference prescription is 74 Gy in 2 Gy fractions. The fraction size has been varied from 1.6 Gy to 5.9 Gy, keeping the total dose isoeffective for  $\alpha/\beta=3$  Gy. The NTCP values, which take into account the fraction-size variation, are approximately constant (7.3% to 8.0%) whilst the NTCP *without any biological correction of the doses* vary between 15.7% and 0.1%.

It can be noted that the fraction-size corrected NTCP values are not quite constant but decrease slowly with increasing fraction size. This is a consequence of the fact that the single dose  $d$  in the Withers formula for deriving the isoeffective total dose is conventionally set equal to the prescription fraction size (see Equation 9.5 and, e.g. Bentzen and Baumann 2002) whereas the *effective* dose in any normal tissue will always be lower than that. The Withers formula will therefore tend to *underestimate* the true (normal-tissue) isoeffective dose for

**FIGURE 36.19**

The conversion of a (cumulative) dose volume histogram into a 2 Gy per fraction equivalent DVH (using  $\alpha/\beta=3.3$  Gy) for a typical lung in a 3D conformal plan. (From Yorke, E. D., *Semin. Radiat. Oncol.*, 11, 197–209, 2001. With permission.)

fraction sizes larger than 2 Gy and hence the NTCP values will be lower than might have been expected (Nahum et al. 2003a).

### 36.3.5 RELATIONSHIP OF MODELS TO CLINICAL COMPLICATIONS

#### 36.3.5.1 Radiation Proctitis

Quantitative evidence for a volume effect in the rectum has changed rather significantly due to interest in conformal therapy and dose escalation in prostate cancer. Earlier, Emami estimated that the whole volume tolerance dose for 5% complications in the rectum was 60 Gy (Emami et al. 1991a). In addition, it was suggested that the same value of  $TD_5$  be used no matter what volume was irradiated, because there was a minimal volume effect at best. In contrast, Benk et al. (1993) published a clinical study of 41 patients treated for prostate cancer with photons and protons, and found a statistically significant increase in the probability

**TABLE 36.2**

The Effect of the LQED<sub>2</sub> Correction to the DVH on NTCP for the Rectum/Proctitis

Fraction Size (Gy)	Fraction Number	Total Prescription Dose (Gy)	NTCP <sub>L-K-B</sub> (%)	
			No Biological Correction	With LQED <sub>2</sub> Correction
1.606	50	80.32	15.7	8.0
2.0 (ref.)	37	74.0	9.0	7.9
3.055	20	61.10	2.1	7.6
4.252	12	51.02	0.5	7.5
5.923	7	41.46	0.1	7.3

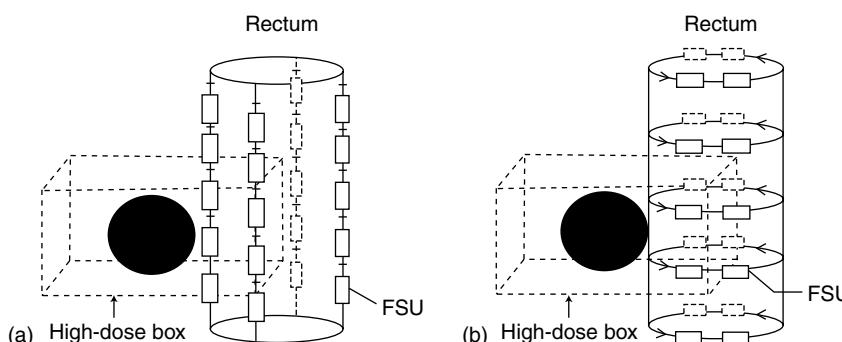

Data evaluated using the L-K-B model, as the fraction size is varied at isoeffective ( $\alpha/\beta=3$  Gy) prescription doses; the parameters used were  $TD_{50}=81.9$  Gy,  $m=0.19$ ;  $n=0.23$ . LQED<sub>2</sub> corrections to the (total) doses in the DVH assumed  $\alpha/\beta=3$  Gy. The DVH used was the OAR.dvh file supplied with the BIOPLAN biological model evaluation software (Sanchez-Nieto and Nahum 2000; Rancati et al. 2003).

of Grade-2 rectal bleeding when more than 40% of the anterior portion of the rectal wall received at least 75 Cobalt-Gray-Equivalent (see [Chapter 46](#)). The prostate and pelvis were irradiated with photons, while the prostate was boosted with a single proton field (Shipley et al. 1979). Since for the latter phase the rectum was immobilised with a stent, it was possible to know the position of the rectum and therefore more accurately determine dose-volume histograms for the rectal wall.

The presence of a volume effect has also been confirmed in other studies. For example, the results of the dose escalation study by the group at Memorial Sloan-Kettering in New York makes a compelling case for a rectal volume effect. They were able to raise the dose to the prostate to 81 Gy and more while keeping rectal bleeding below levels commonly found at much lower doses (Leibel et al. 1994; Zelefsky et al. 1995). This was possible since the dose escalation was constrained by limiting rectal irradiation such that no more than 30% of the rectal wall exceeded 75 Gy (Kutcher et al. 1996). Moreover, it was also found that rectal bleeding was reduced when some of the rectum was blocked in the boost phase of the treatment (Schultheiss et al. 1995). Dearnaley et al. (1999) reported on the first randomised clinical trial of conformal vs conventional radiotherapy of the prostate in which a statistically significant reduction in the incidence of Grade-2 rectal bleeding was found in the conformal arm.

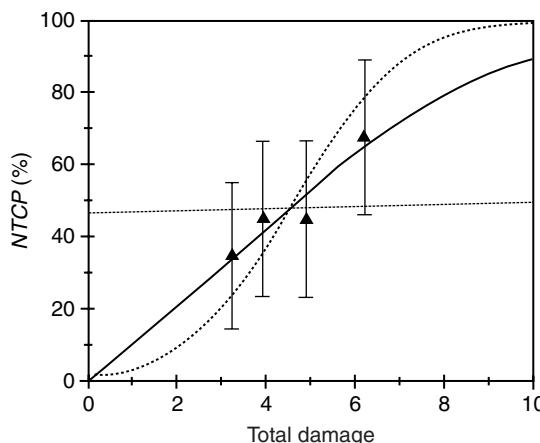

There remain a number of questions. How does rectal *motion* influence the correlation of dose and volume with rectal bleeding? What is the relative influence on rectal bleeding between increasing the length and increasing the fraction of the circumference of irradiated rectal wall? If we consider the rectum in two extremes, one in which the FSUs of the rectum are arranged as in Figure 36.20a, then full circumferential radiation would be required for a complication, while if the FSUs are arranged as in Figure 36.20b, then even partial circumferential irradiation would be sufficient. Dale et al. (1999) should be consulted for further discussion on this point.

Fenwick (1999) calculated rectal *dose-surface-histograms* for 79 prostate cancer patients, who received, using conformal or conventional radiotherapy techniques, a tumour (PTV) dose of 64 Gy (Tait et al. 1997; Dearnaley et al. 1999; Fenwick et al. 2001). Rectal bleeding complication data (dichotomised as Grade 0 versus Grade 1, 2, 3) was also available for these patients. The dependence of patients' complication status on rectal dose-distribution was statistically explored by fitting a parallel bleeding model to the dose-surface histogram and complication data (Fenwick et al. 2001). The *maximum-likelihood* fit of the model to the data suggests that local rectal-wall radiation damage increases sharply around a (physical) radiation dose of 58 Gy, although it should be noted that the dose-response is not defined very tightly by the data. The fit also indicates that patients' complication status depends significantly on the damage (calculated using the maximum-likelihood fit dose-response) totalled over the rectal wall: a reduction of 1% in the fraction of rectal wall receiving a dose

**FIGURE 36.20**

Two possible arrangements of FSUs for the rectum: (a) serially arranged along the length and (b) serially arranged around the circumference of the rectal wall; the prostate is represented by the black sphere. (From Dale, E., et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 43, 385–391, 1999. With permission.)

**FIGURE 36.21**

A plot of the maximum-likelihood fit curve (unbroken line) describing the dependence of the probability of Grade 1–3 bleeding on total damage (total number of radiation induced bleeding sites calculated as the fraction of the rectal surface area receiving a dose of more than 58 Gy), together with the steepest and shallowest sigmoid curves (dotted lines) which adequately fit the data. Also shown are points representing the observed complication rates (with 95% confidence intervals) and average calculated total damage for four cohorts of patients grouped by total damage. (From Fenwick, J. D., et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 49, 473–480, 2001. With permission.)

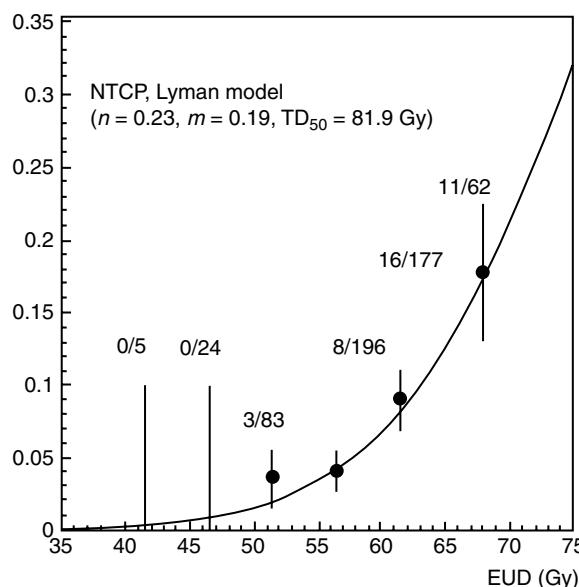

of 58 Gy or more leads to a fall in the Grade 1,2,3 bleeding rate of about 1.1% (95% confidence interval [0.04%, 2.2%]) (Figure 36.21).

Studies such as those of Hartford et al. (1996), Boersma et al. (1998), Jackson et al. (2001), Fiorino et al. (2002a), Akimoto et al. (2004), Rancati et al. (2004), and Tucker et al. (2004) support the finding that the incidence of rectal bleeding decreases as the fractional area of rectal wall irradiated to intermediate or high dose-levels is reduced.

Rancati et al. (2003) have fitted late rectal-bleeding data using four different NTCP models; the data were the rectal dose-volume histograms of 547 prostate cancer patients pooled from five institutions previously analysed by Fiorino et al. (2003). All patients in the study were treated with one fraction per day, 5 days a week, with the fraction size in the range 1.8 Gy to 2.0 Gy. It should be noted that the volume contoured for which the DVH was computed always corresponded to that of the *solid* rectum, i.e. not the more logical dose-wall histogram or the dose-surface histogram (Lu et al. 1995) computed by Fenwick et al. (2001). The authors admit that this was a practical rather than an ideal solution\*. The four NTCP models were the Lyman or probit model (Section 36.3.2) with the DVH *reduced* so that the whole organ volume was treated as receiving the EUD, using Equation 36.17, the relative seriality model (Section 36.3.3.3), the logistic model<sup>†</sup> and the Poisson model (Equation 36.24), both with the DVH reduced to the whole number *EUD*. The estimated best fit for the complete set of patients developing  $\geq$ Grade 2 bleeding (38 out of 547 or 6.9%) in the case of the Lyman model, with the dose expressed in terms of the (whole-volume) *EUD*, is shown in Figure 36.22. In fact, the Lyman, relative seriality and logistic models yielded virtually indistinguishable NTCP values for whole, 2/3 and 1/3 organ irradiation over the range of EUDs encountered in clinical practice.

\* See Fiorino et al. (2003) for a detailed study of this issue.

<sup>†</sup> The expression for NTCP for this model, also known as the logit formula, is  $NTCP(D) = 1/[1 + (D_{50}/D)^k]$  where  $k$  is the slope of the NTCP vs dose curve at  $D = TD_{50}$  and is related to the slope parameter  $m$  in the Lyman or probit formula through  $k = 1.6/m$ .

**FIGURE 36.22**

Incidence of late rectal bleeding as a function of EUD for the Lyman-EUD model: observed complication rates, shown as *number of complications/number of patients* in each EUD interval (solid circles) and predicted NTCP curve (full line, obtained using best estimates of parameters  $n$ ,  $m$  and  $TD_{50}$  as shown—see Table 36.2. (From Rancati, T. et al., *Radiother. Oncol.*, 67, 275–283, 2003.)

The complete set of best-fit parameter values for the four different models, with all Grade  $\geq 2$  scored as *bleeders*, derived from the complete patient population (non-conformal and radical 3D-conformal as well as post-prostatectomy treatments, and prescription doses ranging between 64 Gy and 79.2 Gy), is given in Table 36.3. Note that the fitting exercise was performed both with and without applying corrections to the DVHs for fraction size, using the L-Q model with  $\alpha/\beta=3$  Gy (see Section 36.3.4).

When only severe (Grade 3) bleeding was considered, the dose-response curve had a steeper slope ( $m=0.06$  instead of 0.19) and the volume-effect parameter  $n=0.06$  instead of 0.23; this suggests that for this endpoint the rectum behaves in a more serial manner. However, the number of patients experiencing Grade 3 bleeding was only 10 out of the 547 and therefore this finding, however interesting, must be treated with caution.

The authors conclude by pointing out some *truths* concerning NTCP models. They emphasise that all the models used in their analysis are phenomenological in nature and thus the resulting dose-response curves cannot be considered to encompass the complexities of rectal radiobiology. Further, the good agreement as demonstrated in Figure 36.22 cannot be taken to imply that the Lyman-EUD model (in this case) used with the best-fit parameters will make reliable *predictions* when applied to arbitrary rectal DVHs. In fact, the predictions made by the models using the parameters obtained in the present study are to be tested in a separate ongoing *prospective* study on a large, independent patient population. Furthermore, this new study will include not only dose-volume histograms but also rectal surface dose maps (see Figure 36.27 in Section 36.3.6).

### 36.3.5.2 Radiation Hepatitis (Radiation Induced Liver Disease)

One of the most informative examples of how NTCP models and data can be successfully used is by Jackson and colleagues (1995) for radiation-induced liver disease (RILD also called radiation hepatitis). They used clinical outcomes in 93 patients treated for tumours of the liver, dose-volume histograms, the parallel model and the method of maximum likelihood to

**TABLE 36.3**

Estimated Parameter Values for the Four NTCP Models, with 1D-68% Confidence Intervals

Model	$TD_{50}$ (Gy)	$m$ or $k$ or $\gamma$	$n$ or $s$
<b>Lyman-EUD</b>			
No correction for fraction size	$81.9 \pm 1.8$	$0.19 \pm 0.01$	$0.23 \pm 0.05$
LQED <sub>2</sub> correction ( $\alpha/\beta = 3$ Gy)	$81.8 \pm 2.3$	$0.22 \pm 0.01$	$0.29 \pm 0.06$
<b>Logit-EUD</b>			
No correction for fraction size	$82.2 \pm 1.8$	$7.85 \pm 0.5$	$0.24 \pm 0.05$
LQED <sub>2</sub> correction ( $\alpha/\beta = 3$ Gy)	$83.5 \pm 2.3$	$6.1 \pm 0.4$	$0.30 \pm 0.06$
<b>Poisson-EUD</b>			
No correction for fraction size	$87.7 \pm 1.9$	$0.51 \pm 0.07$	$0.23 \pm 0.04$
LQED <sub>2</sub> correction ( $\alpha/\beta = 3$ Gy)	$88.2 \pm 2.4$	$1.30 \pm 0.06$	$0.29 \pm 0.06$
<b>Relative seriality</b>			
No correction for fraction size	$83.1 \pm 1.8$	$1.69 \pm 0.13$	$0.49 \pm 0.12$
LQED <sub>2</sub> correction ( $\alpha/\beta = 3$ Gy)	$83.6 \pm 2.3$	$1.42 \pm 0.11$	$0.50 \pm 0.12$

$m$  applies to the Lyman model,  $k$  to the Logistic model and  $\gamma$  to the Poisson and RS models;  $n$  applies to the EUD DVH-reduction method,  $s$  to the RS model.

determine the model parameters (Lawrence et al. 1990; Lawrence et al. 1992; Jackson et al. 1995). They assumed that the organ had a functional reserve described by two parameters (whose values were obtained from the maximum likelihood fit) and that NTCP was given by the integral of the functional reserve up to the mean fraction of eradicated FSUs, that is, up to the fraction damaged. For each patient the fraction damaged was calculated by summing the product of the fractional volume of each voxel of the organ times the probability of damage. The latter was calculated using each patient's DVH and an assumed local-response function with two parameters (whose values were also obtained from the maximum likelihood fit).

The method of maximum likelihood was used by first assigning a best guess for the model parameters. The predicted probability of a complication for each patient was then compared against the observed grade of complication in that patient. The overall likelihood  $L$  of the observations was taken as:

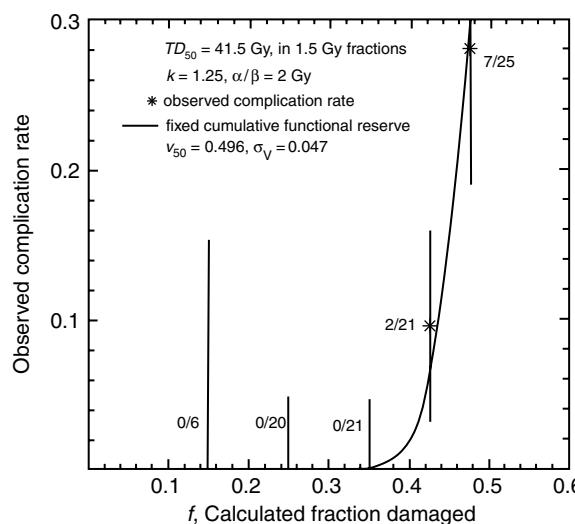

$$L(\gamma_1, \gamma_2, \dots) = \prod_m^{\text{complication}} O_m(t_m, \gamma_1, \gamma_2, \dots) \prod_n^{\text{no complication}} (1 - O_n(t_n, \gamma_1, \gamma_2, \dots)). \quad (36.36)$$

where

$$O_m(t_m, \gamma_1, \gamma_2, \dots) = o(t_m) \text{NTCP}_m(\gamma_1, \gamma_2, \dots), \quad (36.37)$$

where  $L$  is the likelihood,  $o(t_m)$  is the probability that a complication will manifest itself after the follow-up time  $t_m$  for the  $m$ th patient, calculated from complication and follow-up time data with the Kaplan–Meier method (Kaplan and Meier 1958), and  $\gamma_1, \gamma_2, \dots$  indicates the model parameters. The likelihood is a product over all patients of the chance that there is a complication multiplied by the chance there is no complication, which is maximised with respect to the model parameters.

The results of applying such an analysis to the radiation hepatitis data are shown in Figure 36.23; the observed complication rate has been plotted as a function of calculated fraction of the liver, which is damaged. The observed complications are zero up to a threshold, followed by a steep response, exactly as predicted by the parallel model. The

**FIGURE 36.23**

The observed complication rate for radiation hepatitis as a function of calculated fraction of damaged liver. (From Jackson et al., *Int. J. Radiat. Oncol. Biol.*, 31, 883–891, 1995. With permission.)

best fit for the functional reserve distribution (and confidence intervals) predicts that a threshold volume of about one-third must be exceeded before complications are observed. Moreover, complications were seen only in the cohort of patients that received whole-liver irradiation as part of the treatment course. The lack of complications among patients given only partial-volume irradiation suggests that an attempt to increase local control through dose escalation is feasible for these patients. Furthermore, the observation of complications in this subset of patients would be likely to reduce the correlated uncertainties found for the model parameters.

Dawson et al. (2002) carried out an analysis of radiation-induced liver disease using the L-K-B model. This was an updating of their earlier analysis (Lawrence et al. 1992), now extended from the original 79 patients to 203 patients, of which 19 developed Grade 3 or higher RILD. The patients had either unresectable intrahepatic cancer or metastatic spread to the liver from colorectal carcinoma. All patients were treated on dose-escalation protocols, 61 with whole-liver irradiation, 20 of which had a boost to a partial liver volume, and 142 were treated with partial liver irradiation. Two fractions a day of 1.5–1.65 Gy/fraction (11 fractions/week) were delivered with a minimum inter-fraction interval of between 4 h and 6 h. Either fluorodeoxyuridine (FUDR) or bromodeoxyuridine (BUDR) was used as a radiation sensitizer for the first four weeks. Three-dimensional techniques were used throughout and the targets were expanded to account for both setup uncertainty and breathing motion. The GTV was subtracted from the organ to obtain *normal liver* DVHs for the NTCP analysis. The physical (total) dose values were converted to biologically isoeffective doses at 1.5 Gy/fraction according to Equation 36.35 using  $\alpha/\beta = 2 \text{ Gy}$ , i.e. to  $LQED_{1.5}$ , before the DVHs were reduced to effective volumes  $V_{\text{eff}}$  at maximum dose (see Section 36.3.2.2). Table 36.4 gives the new, previous (Lawrence et al. 1992) and original (Burman et al. 1991) L-K-B model parameters for radiation-induced liver disease.

The differences between the three parameter sets in Table 36.4 are expressed in terms of ten-percent iso-NTCP curves in  $V_{\text{eff}} - \text{dose}$  space in Figure 36.24. The dashed curve corresponds to the original Burman 1991 parameter set, the intermediate curve to the Lawrence et al. (1992) set and the upper curve to the Dawson et al. (2002) set based on 203 patients with correspondingly narrow confidence limits. Quite clearly the Burman 1991 estimates were too conservative as the two upper curves indicate that considerably larger partial volumes than

<sup>a</sup> The most recent parameter set can be considered as the most reliable—see text.

those indicated by dashed curve can be irradiated at all doses in the 40 Gy to 100 Gy range without exceeding 10% probability for radiation hepatitis.

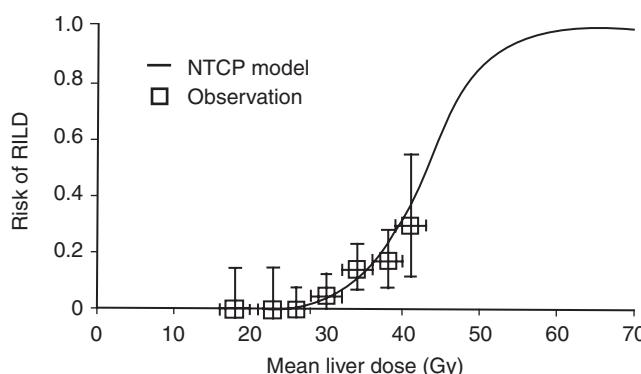

The value  $n=1.1$  in the 209-patient fit suggested to Dawson et al. that there should be a strong correlation between RILD and *mean dose* in the normal liver. The observed complications were stratified into 4 Gy wide mean-dose bins and compared to the predictions of the L–K–B model using the authors' best-fit parameter set in Figure 36.25. No patient developed RILD at a mean liver dose below 30 Gy, which corresponds to a *threshold* value characteristic of a parallel organ. It should be noted that the L–K–B model cannot predict thresholds for RILD, unlike Jackson et al. (1995), and hence may overestimate the complication probability at small volumes of liver treated to high dose.

Dawson et al. also performed separate analyses on the patients with primary malignancies and those with liver metastases treated with FUDR. Respectively, they obtained  $n=0.90$  (0.66–2.0),  $m=0.09$  (0.05–0.23) and  $TD_{50}(1)_{HB}=39.6$  Gy (37.1–43.7) for the 84 patients with primary malignancies and  $n=1.27$  (0.70–>3),  $m=0.18$  (0.10–0.4) and  $TD_{50}(1)_{LM}=50.8$  Gy (45.4–99.0) for the 85 patients with liver metastases.

The Ann Arbor group (i.e. Ten Haken and colleagues) use the L–K–B NTCP model in an active way to plan the treatment of patients with unresectable intrahepatic malignancies; using

**FIGURE 36.24**

Ten percent iso-NTCP curves displayed in Effective Volume vs. Dose space (normalised to 1.5 Gy b.i.d.) for the three sets of parameters given in Table 36.3; the most recent 203-patient fit is the uppermost curve and suggests that the original Burman et al. estimate was far too pessimistic. (From Dawson L. et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 53, 810–821, 2002. With permission.)

**FIGURE 36.25**

Observed NTCP for liver complications compared to predictions of the Lyman–Kutcher–Burman NTCP model with the patients grouped into mean-liver dose bins 4 Gy in width; the error bars correspond to 80% confidence intervals. The parameters used in calculating the NTCP curve were  $n=1.1$ ,  $m=0.18$  and  $TD_{50}(1)=43.3$  Gy. (From Dawson L. A. et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 53, 810–821, 2002. With permission.)

their revised set of L–K–B parameters (see Table 36.4) they determine the safe (defined as a 10% risk of RILD) prescription dose up to 90 Gy (McGinn et al. 1998).

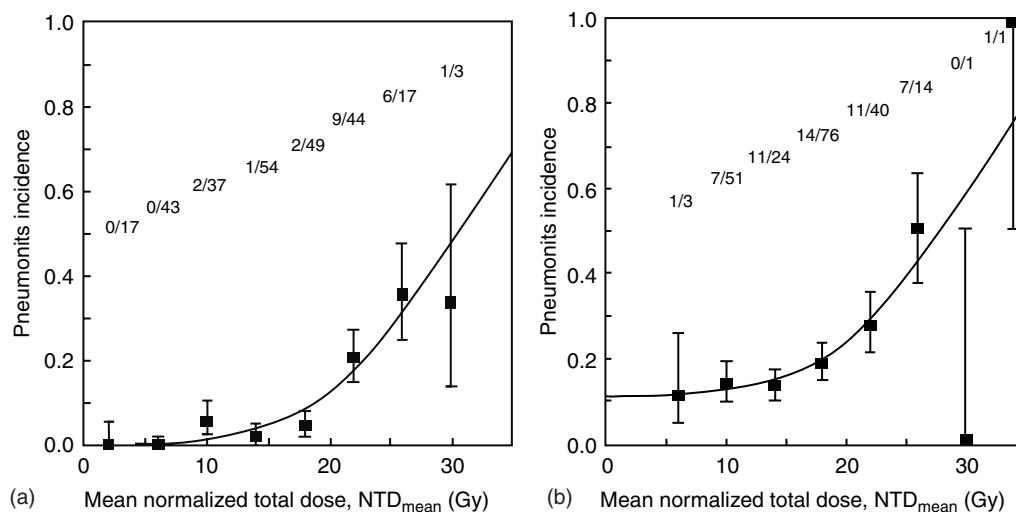

### 36.3.5.3 Radiation Pneumonitis

The need to limit complications in the lung plays an important role in the treatment of several tumours in the thoracic region of the body, including lung tumours themselves, tumours in the breast and malignant lymphoma. Severe radiation pneumonitis in the first six months following radiotherapy can be fatal. It is therefore essential to know as much as possible about the relationship between the 3-D dose distribution and the incidence of radiation pneumonitis.

Convincing evidence for a large volume effect for pneumonitis in *mouse* lung was published by Liao, Travis, and Tucker (Liao et al. 1995). They demonstrated that mice with 70% of the lung irradiated to 20 Gy in one fraction were all dead after 28 weeks. In contrast, those with 40% of the lung irradiated to 20 Gy all survived. Additionally, lethality occurred at lower doses for mice given whole lung irradiation than for mice with 70% of the lung irradiated. These data strongly suggest that a parallel model may be appropriate for pneumonitis, since a tolerance dose for death after 28 weeks was not found for mice given 40% lung irradiation.

They have also argued that the base of mouse lung is more radiosensitive than the apex. If such a large difference were seen in (human) clinical data, then for equal numbers of tumours in the base and apex, when the overall complication rate is 20%, we would estimate that the complication rate for tumours in the base of the lung would be of the order of 30% higher than for tumours in the apex. Evidence to support this observation comes from Martel et al. (1994), who reported that all nine lung cancer patients with pneumonitis ( $\geq$ Grade 1) had tumours in the middle or lower lobes, and Graham et al. (1995), who found that the incidence of  $\geq$ Grade 3 pneumonitis was 6% in 49 patients with upper lobe tumours and 29% in 21 patients with middle or lower lobe tumours.

The clinical evidence for lung tolerance prior to conformal radiation therapy has been reviewed by Travis (1991) and by Marks (1994). They point out, for example, that whole lung volume tolerance doses that were established for patients treated with hemi-body irradiation (Van Dyk et al. 1981), after corrections for fractionation, are generally consistent with tolerance doses deduced from patients treated with various fractionation schedules to volumes in excess of 75% (Wara et al. 1973). Few quantitative data for partial volume tolerances were available before the advent of conformal treatment techniques. However, there were indications that the probability of pneumonitis was related to the volume of lung irradiated

**FIGURE 36.26**

The incidence of radiation pneumonitis as a function of mean dose corrected for fractionation ( $NTD_{mean}$ ) for a population of 504 patients from 5 institutions: (a) all lymphoma and breast patients and lung patients from one of the institutions ( $N=264$ ); (b) all other lung patients ( $N=276$ ). (From Kwa, S. L. S. et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 42, 1–9, 1998b. With permission.)

(Brady et al. 1965a; Brady et al. 1965b; Perez et al. 1980; Rothwell et al. 1985; Seydel et al. 1985). Emami et al. (1991a) in their review of the literature concluded that the volume effect in the lung was very large, and the Burman et al. (1991) fit yielded a value for  $n$  of 0.87\*.

Kwa et al. (1998b) looked at the incidence of pneumonitis in 540 patients from 12 institutions. Since the patients with lung cancer showed higher complication rates at lower doses, the patients were divided into those with lung cancer and others, mainly breast and lymphoma. Kwa et al. found that the rate of Grade 2 and higher complications for each group could be fitted to the Lyman model with  $n=1$  (Section 36.3.2), suggesting that there was a large volume effect in lung, and that the complications were correlated with mean dose (see Figure 36.26).

Seppenwoolde and Lebesque (2001) reviewed the then current literature on how well the various models fitted or predicted the clinically observed incidence of radiation pneumonitis and concluded that there was no consensus on the best model. This led Seppenwoolde et al. (2003) to undertake a major new analysis of the data from 382 breast cancer, malignant lymphoma and inoperable non-small-cell lung cancer patients from two centres, the Netherlands Cancer Institute and the University of Michigan at Ann Arbor. The DVHs were reduced to a single parameter using various dose-effect relationships, e.g. mean lung dose and the volume of lung receiving more than some particular *threshold* dose such as  $V_{20}$  (see Section 35.3.3). The two lungs (defined using CT by binary thresholding, thus excluding the GTV) were considered as one organ. 1 Gy dose bins were used in calculating the DVHs and the same treatment planning system, U-Mplan (University of Michigan) was used at both centres. Thus, maximum consistency in dose-volume information was ensured. Table 36.5 gives a comparison of the values of the parameters in various models in the literature values compared to those found by Seppenwoolde et al.

\* It is essential to be aware that for the L-K-B model, and all the other lung complication models (see e.g. Table 36.5) except that of *relative seriality*, the lungs (minus tumour) are treated as a *single paired organ*.

$D_{50}$ , local dose for 50% local damage; SPECT, single photon emission tomography; MLD, mean lung dose;  $V_{D_{th}}$ , lung volume receiving more than threshold dose  $D_{th}$ ;  $rdV_{50}$ , relative damaged volume resulting in a 50% complication rate.

<sup>a</sup> Optimized in maximum likelihood analysis.

<sup>b</sup> No inhomogeneity corrections applied to the dose distributions.

<sup>c</sup> For radiation pneumonitis Grade  $\geq 1$ , the lungs were considered as *separate organs*.

Source: From Seppenwoolde, Y. et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 55, 724–35, 2003. With permission.

Seppenwoolde et al. (2003) concluded that the underlying dose-effect relationship for radiation pneumonitis was linear (i.e. mean lung dose fitted the data best) rather than a step function (i.e. a model based on the volume of lung receiving more than a certain dose D,  $V_D$ , as described in [Section 35.3.3](#)). However, there was a high correlation between these two parameters ( $r^2=0.82$ ). Therefore, in clinical practice both the mean lung dose and  $V_{13Gy}$  (or  $V_{20Gy}$ ) could be used for predicting pneumonitis.

All analyses involving dose-volume data will be affected by the accuracy of the dose calculations themselves. In the case of treatment plans involving lung tissue, this can be particularly problematical because the average density of the lungs is around one-third of that of water; such situations represent a critical test for dose-calculation algorithms (see [Part F](#)). De Jaeger et al. 2003 re-evaluated published dose-effect relations for radiation pneumonitis using the more accurate 3-D convolution photon-beam algorithm (see [Section 26.3.4](#)) which takes the increased range of the secondary electrons in the low-density lung tissue into account. They found that the *equivalent-pathlength* (EPL) algorithm (see [Section 26.2.3.2](#)) consistently *overestimates* the dose at the lung-tumour boundary by about 10%. Re-evaluation using a *convolution-superposition* algorithm (see [Section 26.3.4](#)) showed that lung complications occur at a 12–14% *lower* dose. Thus,  $TD_{50}$  changed from 34.1 Gy to 29.2 Gy. This type of re-evaluation can be expected to become more common as more accurate dose-computation methods such as 3-D convolution and Monte-Carlo simulation (see [Chapter 28](#)) replace current less accurate ones.

### 36.3.6 CONCLUDING REMARKS

Two major methods of describing complication probabilities have been covered, namely, an empirical method and an *architectural* description. Underlying these NTCP models is the *volume effect*, which is central to how normal organs behave in response to inhomogeneous distributions of radiation and which therefore, has important implications for the design of treatment strategies. In organs with a small volume effect, it may be advantageous to use many fields in order to distribute the dose over a larger volume and thereby reduce the peak dose in the organ. Conversely, in parallel organs, it would be better to use a small number of fields to keep fractional damage below the organ's functional reserve. Intensity modulation (see Chapter 43) may prove useful in adjusting the volumetric distribution to normal organs while maintaining the intended dose to the large volume. In the future, we may find that organ architecture will play an important role in *designing*, in addition to evaluating treatment plans (Kutcher et al. 1994).

In spite of their importance, NTCP values should be used with caution when evaluating treatment plans, since the models suffer from a number of problems (Glatstein 2001). To begin with, they are generally quite crude and hardly even try to represent the multiple and inter-related toxicities observed in clinical practice (Deasy et al. 2002). In this respect, modelling of NTCP is much more complex than TCP because of the large and complex taxonomy of treatment toxicities (Niemierko and Goitein 1993b; Withers and Taylor 1993; Glatstein 2001; Schultheiss 2001; Travis 2001; Yorke 2001; Deasy et al. 2002). And even when clinical responses are reduced to the bare essentials, perhaps to one or a few critical endpoints, the paucity of clinical data and their large uncertainties makes it difficult to rely on the calculated complication probabilities (Deasy et al. 2001; Glatstein 2001). These uncertainties can lead not only to large variations in the *absolute* values of the calculated NTCPs (Lebesque et al. 1995) but can also affect the *relative ranking* of candidate treatment plans. However, this situation is changing as the foregoing sections have made clear; the increased use of 3D planning by many institutions is beginning to provide large databases of three-dimensional dose distributions potentially correlated with clinical endpoints. Although the endpoints characterising clinical complications, as is well known, are difficult to define and the data are painstaking to collect, nevertheless, there is a continuing accumulation of such data. There are also indications that the pooling of clinical data and the ability to share dose distributions between institutions electronically will provide databases that are more robust where models can be refined (Kwa et al. 1998b; Deasy et al. 2003; Rancati et al. 2003; El Naqa et al. 2006). Some consensus may then be reached on the models and their parameters, at least for some important organs and endpoints, e.g. Seppenwoolde et al. (2003) in the case of radiation pneumonitis in lung and Rancati et al. (2004) in the case of proctitis in the rectum. As a complement to the preceding sections, excellent summaries of the status of the NTCP models themselves and their application to a number of organs/endpoints can be found in Ten Haken (2001) and in Cattaneo et al. (2001). In the meantime, tools (such as BIOPLAN - Sanchez-Nieto and Nahum 2000 and that described in Warkentin et al. 2004) are available which simplify the evaluation of the existing models (of both NTCP and TCP).

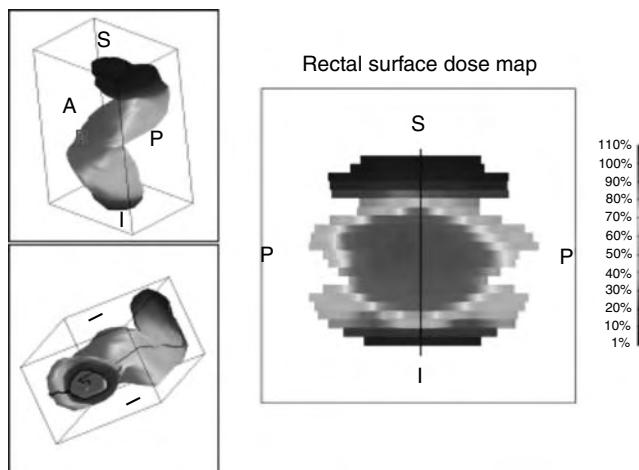

One potentially serious limitation of all the NTCP models described above is that information on the dose distribution is restricted to the dose-volume histogram for the organ or tissue concerned. Consequently no spatial information is retained (see Section 35.3.3); a contiguous region and separated *islands* of high dose with the same total volume cannot therefore be distinguished from each other. Nor can the *position* of the high-dose region in the organ, even if contiguous, be taken into account; this is known to be a limitation in the case of lung (e.g. Seppenwoolde et al. 2004). Due to the similarities between most clinically employed treatment techniques, this lack of spatial information is probably much less severe than it can seem, but ways of removing this limitation are nevertheless desirable. One way of doing this for the case of tubular organs such as the rectum is to effectively *unfold* the curved surface onto a flat surface; this can be compared to the way in which maps of the Earth's surface are

reformatted in Mercator's projection. This idea, introduced by Sanchez-Nieto et al. (2001b) and further developed by Hoogeman et al. (2004), is shown in Figure 36.27. It would enable a clear distinction to be made, for example, between high-dose regions that wrap entirely around the circumference of the rectum and those that do not.

The development of further NTCP models is probably unnecessary. However, the generation of more dose-volume-complication data for the organs and endpoints of most interest is essential in order to derive more reliable values of the parameters for the currently established models such as the L-K-B (Section 36.3.2) and relative seriality (Section 36.3.3.3) formalisms. Furthermore, it is now necessary to start using the models and their associated parameters to make *predictions* of complications and to compare these predictions with the observed complication rates (Gagliardi et al. 2000). Only in this way will NTCP models come to be used with confidence in the clinic. Furthermore, for those organs/endpoints for which a reasonable amount of reliable dose-volume-complication data already exists (e.g. radiation pneumonitis in the lung; proctitis in the rectum; RILD in the liver), one can start *optimizing* treatment plans based on the calculated NTCP values. Two of the forms that this active use of NTCP modelling could take are

1. Start with a *relative-dose* treatment plan arrived at using, for example, dose-based criteria (e.g. PTV within 95–105% of  $D_{\text{presc}}$ ,  $V_{90\%}$  of OAR <80% of  $D_{\text{presc}}$ ) and then adjust  $D_{\text{presc}}$  until  $NTCP_{\text{OAR}}$  is equal to a value specified in the local clinical protocol, e.g.  $NTCP_{\text{proctitis}} = 3\%$  (Nahum and Tait 1992; Ten Haken et al. 1993; McGinn et al. 1998; Sanchez-Nieto et al. 2001a).
2. Use NTCP and TCP as part of the *objective function* in the (computer) optimisation/inverse-planning process, thus allowing the mathematical and radiobiological properties of the models to drive the search for the optimum plan (e.g. Peñagarícano et al. 2005; Hoffmann et al. 2006).

Finally, it should not be forgotten that other variables such as fraction size, clonogen proliferation rate and the patient's performance status should ideally be incorporated into both the biological models and the optimisation process (Glatstein 2001; Bentzen 2004; Fowler et al. 2004; Nahum and Bentzen 2004). Low-dose hypersensitivity (LDHRS—see Section 7.13.3) may also play an important role in our understanding of how certain complications depend on dose and volume. One consequence of factoring LDHRS into NTCP

**FIGURE 36.27**

(See colour insert following page 590.) A rectal dose-surface map calculated from a 3D treatment plan for prostate cancer (Sanchez-Nieto et al. 2001b); spatial information of the high-dose region is preserved unlike in dose-volume (or dose-surface) histograms. (Reproduced from GUINNESS, a treatment plan analysis software tool developed by Stefano Gianolini at the Institute of Cancer Research, Sutton.)

models, via a modification of the L-Q expression below around 0.6 Gy, will be an increased contribution to overall NTCP from those volumes of normal tissue receiving doses well below the tumour dose, i.e. at the 20% and lower isodoses. A significant increase in such volumes through the use of rotational techniques such as tomotherapy or many-field IMRT may be undesirable for certain organs and endpoints in which the killing of cells exhibiting LDHRS play a significant role in causing the complication. Finally we should mention the question of cancer *induction* by radiotherapy (see [Section 61.5.2](#)). Concerns have been raised (Glatstein 2002; Hall and Wuu 2003) that certain modern conformal techniques such as (many-field) IMRT, IMAT and tomotherapy (see [Chapter 43](#)) may increase cancer induction due to the increase in volumes irradiated at low doses compared to non-IMRT few-field techniques and especially compared to the use of proton beams (see [Chapter 46](#)). Hitherto cancer induction has not been classed as a complication due to the presumed low or extremely low frequency of occurrence. Models of (second) cancer induction probability (SCIP) which take into account details of the dose distribution in different organs and also the patient's age and general prognosis (Lindsay et al. 2001) would be desirable additions to the collection of tools for predicting the clinical effect of radiotherapy. Sachs and Brenner (2005) have produced a very useful analysis from which such SCIP models can now be developed.

## INTRODUCTION

Quality assurance is an essential part of the radiotherapy process. In recent years, it has become accepted that this is not just about ensuring that the treatment machines are correctly calibrated, but that it includes every part of the process. The ISO9000 standard has been used as the basis for such a system in a number of countries (Bleehen 1991; Leer et al. 1999). This book is not intended to be a quality assurance manual, so the treatment in this Part is restricted to the elements of the quality system that require the application of physics. It is the responsibility of the physicist to establish the physical and dosimetric framework underpinning the delivery of radiotherapy treatments. In [Chapter 37](#), an introduction is given to some general principles underlying the quality assurance of this framework. In the remaining chapters, the physical aspects of quality control of each part of the process are considered. [Chapter 38](#) deals with quality control of external beam treatment machines, including in [Section 38.8](#) some practical guidance on dose calibration for photon treatments, the details of which have already been described in [Part D](#). [Chapter 39](#) deals with quality assurance in treatment planning including both the purchase and commissioning of the planning system and the ongoing quality control of the system and of individual patient plans. Quality control of treatment involves both portal imaging and in vivo dosimetry, and these are dealt with in [Chapter 40](#). A modern radiotherapy department is heavily dependent on networked systems, and consideration needs to be given to the quality assurance of these. This is covered in [Chapter 41](#). The Digital Imaging and Communications in Medicine (DICOM) standard is becoming universally used to transfer data in radiotherapy, and [Chapter 42](#) is devoted to this particular aspect of network communication.

---

\* With contribution from Jean-Claude Rosenwald.

Radiotherapy is a form of treatment that is directed towards the eradication of tumour cells and it has the inherent potential to damage normal tissue also. Calibration errors can lead to injury in a large number of patients. A systematic approach to the quality assurance of the whole radiotherapy process is therefore essential (WHO 1988; AAPM 1994a; Thwaites et al. 1995).

---

## 37.1 DEFINITIONS

Before discussing the requirements of a quality system, it is first necessary to set out some definitions. According to WHO (1988),

“**Quality Assurance** is concerned with all those procedures that ensure consistency of the medical prescription and the safe fulfilment of that prescription as regards dose to the target volume, together with minimal dose to normal tissue, minimal exposure of personnel, and adequate patient monitoring aimed at determining the end result of treatment.”

This is based on the general definition adopted by the International Organisation for Standardisation (ISO 1995) and also by the British Standards Institute (BSI) that:

“**Quality Assurance (QA)** is defined as all those planned and systematic actions necessary to provide adequate confidence that a structure, system or component will perform satisfactorily in service”, or will satisfy given requirements for quality.

**Quality Control (QC)** is the regulatory process through which the actual quality performance is measured, compared with existing standards and finally the actions necessary to keep or regain conformance with the standard (ISO 1995).

So QC describes the operational techniques and activities that are used to fulfil the requirements for quality. It forms part of the wider quality assurance programme or system.

**Quality Standards** are the set of accepted criteria against which the quality of the activity in question can be assessed.

**Quality Audit** is an independent review of the quality assurance and quality control programmes, which is ideally external to the process or part of the process under review, i.e. performed using independent procedures and by independent persons who are not responsible for the performance of the product or process under review.

The aim of the introduction and development of these concepts in relation to radiotherapy is to produce and maintain consistent and continuing quality in treatment. The overall aim is to ensure that the clinical requirements on the quality of radiotherapy are met, to achieve optimum treatment in terms of maximising tumour control probability, whilst at the same time maintaining normal tissue injury to within clinically acceptable levels. As one part of this, the implementation of a quality assurance programme will minimise errors and accidents. However, the attainment of quality in treatment is a much more fundamental goal than that, being concerned with the general reduction of uncertainties throughout the whole radiotherapy process.

---

## 37.2 REQUIREMENTS OF A QUALITY SYSTEM

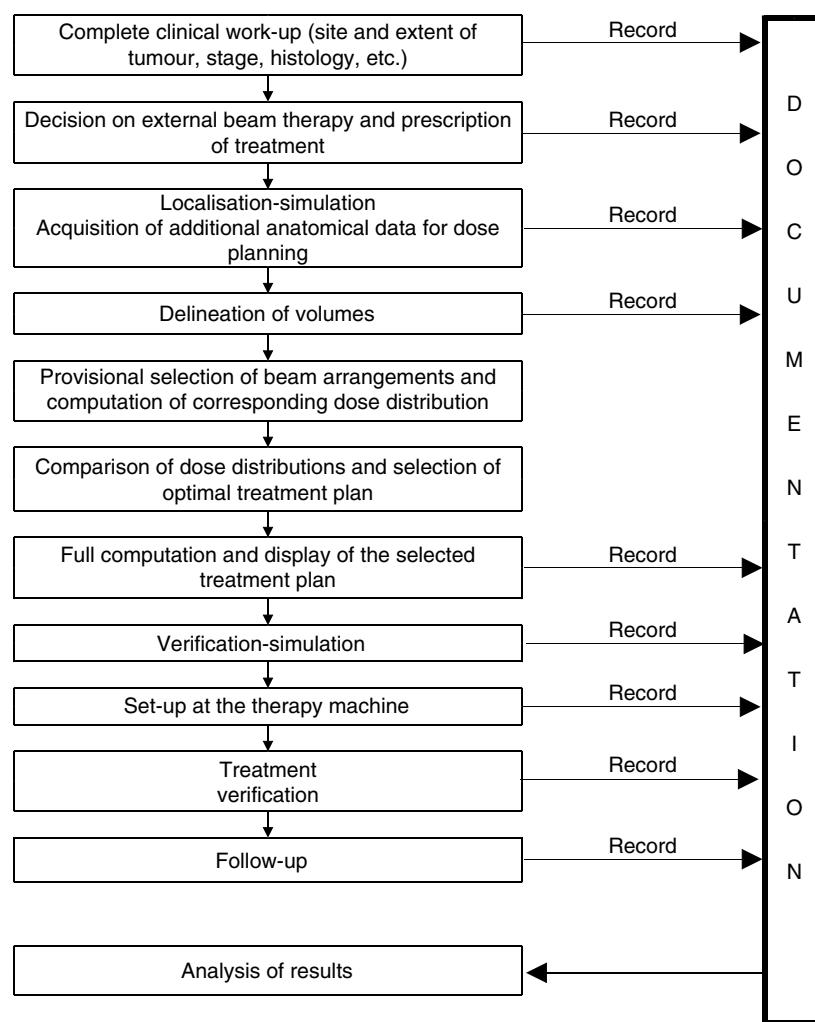

A systematic approach to quality assurance requires the following principal elements:

- Clear definition of responsibilities
- Documented procedures
- Accurate record keeping

- Control of system failures
- Internal and external audit of procedures
- Attention to training needs

ESTRO (Leer et al. 1999) have published a guide to the implementation of a quality system based around the requirements of the ISO9000:1994 quality system (ISO 1994). This quality standard has since been replaced by the ISO9000:2000 standard (ISO 2000) which reduces the requirement for extensive documentation and introduces the additional requirement to demonstrate continual improvement. The new standard requires that the whole process should be considered, but allows more freedom to define the level of documentation required.

It is good practice to begin by drawing a flow chart of the patient's journey and to use this to form the basis of an assessment of the QC procedures that are required to ensure that each stage of the process is completed accurately. This is summarised in Figure 37.1.

**FIGURE 37.1**

The radiotherapy process as defined in ICRU Report 50. (From International Commission on Radiological Units, Prescribing, recording and reporting photon beam therapy, ICRU Report 50, ICRU, Bethesda, MD, 1993.)

## 37.3 QUALITY-CONTROL PROCEDURES

A quality assurance system will require QC procedures to ensure that all equipment and processes are conforming to established specifications. A number of sources of such procedures are available. At the end of this Part, there is a full bibliography. Particularly useful are the AAPM reports from Task Groups 23, 40, and 45 (AAPM 1994a; 1994b; AAPM 1995, respectively), as well as IEC Publication 976 (IEC 1989) and IPEM Report 81 (IPEM 1999). It must be emphasised that these reports should not be treated as recipe books for carrying out QC. Rather, they provide a yardstick against which the quality system of the individual department can be judged. The quality procedures must be adapted to the particular circumstances, equipment and treatment techniques in use.

---

## 37.4 BASIS FOR TOLERANCE LIMITS

For each parameter on which QC is carried out, it is necessary to provide a tolerance limit. It is a fundamental tenet of a quality system that the basis for these tolerance limits should be the fitness for purpose of the process. In this case, the aim is to deliver radiotherapy with the required clinical accuracy, and to determine the tolerances necessary to evaluate these requirements. In some situations, the limiting factor may not be the clinical accuracy required, but the accuracy achievable at the present time. It is in these areas that the struggle for improvement should be concentrated.

### 37.4.1 STATEMENTS OF ACCURACY

The term *accuracy* in radiotherapy is often used loosely. As a starting point, absolute accuracy must be distinguished from *precision* or *reproducibility*. Overall uncertainty is a combination of random and systematic uncertainties. Random uncertainties can be estimated from repeated independent observations and can be expressed as a standard deviation (SD). Systematic uncertainties on the other hand can only be estimated by an analysis of the process under consideration, assigning reasonable variations to parameters where the uncertainties are not, by definition, exactly quantifiable. They can be expressed as effective SD, being taken as the estimate of the limits within which the correct value is expected to occur in around 70% of cases. Uncertainties of both types (SD or effective SD) can be combined in quadrature to provide an estimate of overall uncertainty\* (BIPM 1980; Mijnheer et al. 1987; NIST 1994; BSI 1995; NIST 2000; ISO 2002). As is well recognised, systematic errors contribute to absolute deviations from the correct value in any situation whilst random errors are associated with precision. However, the distinction can become blurred in certain circumstances.

In radiotherapy, within one centre and one radiation modality, it is reproducibility of dose delivery that is critical. However in transferring experience from one centre to another or in intercomparing results between centres or between modalities, for example in clinical trials, some systematic uncertainties also become important. When the radiation oncologist prescribes a dose to a given patient, the prescription may be subject to different interpretations and, as a consequence, to large deviations in the dose actually delivered to the target volume for the same prescription. This cause of discrepancy will be further discussed in [Section 37.6](#). In intercomparisons between a number of centres, some systematic uncertainties are effectively randomly distributed. On the other hand some systematic uncertainties are common to all participants and can be omitted from routine consideration, e.g. those associated with a given

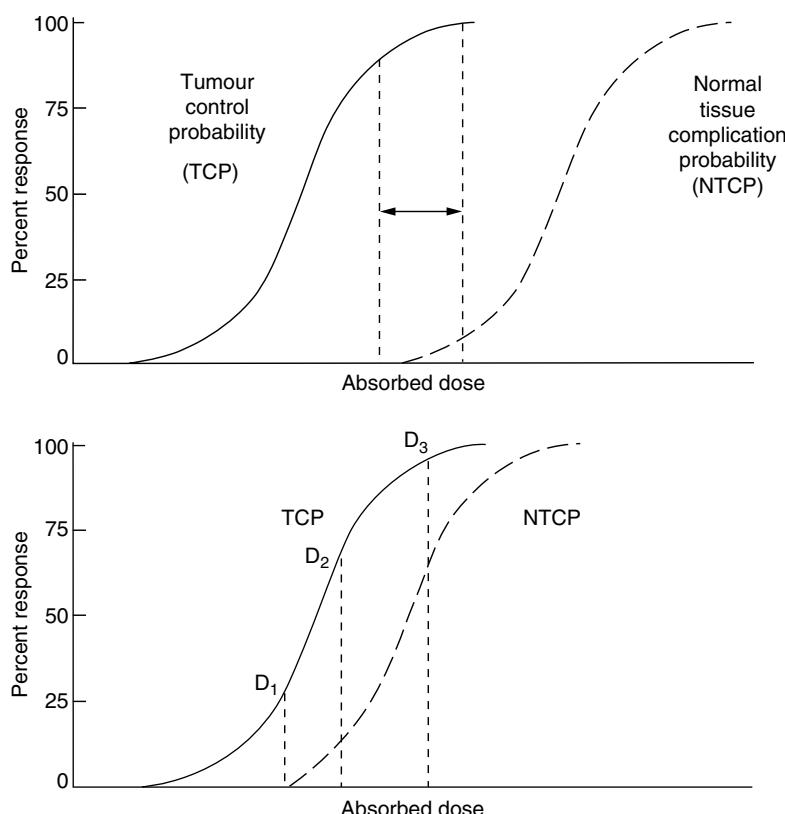

---

\* The NIST online reference (NIST 2000) provides a particularly useful resource on definition of uncertainties.

dosimetry protocol if all participants follow the same protocol, or those associated with basic physical data if the protocols involved are all based on the same consistent set. Such factors only require consideration when estimating absolute accuracy but play no part in estimations of dosimetric consistency (precision). Thus a clear understanding is required of which uncertainties require inclusion in any given situation. However in practice it is often difficult to separate the two types (Dutreix 1984). As a further point in aiding clarity of discussion of uncertainties, it should be noted that any stated values should also have their meaning defined. All values stated in this Chapter, whether for individual parameters or for cumulative values, where all involved uncertainties are combined in quadrature, are given as one SD or effective SD.

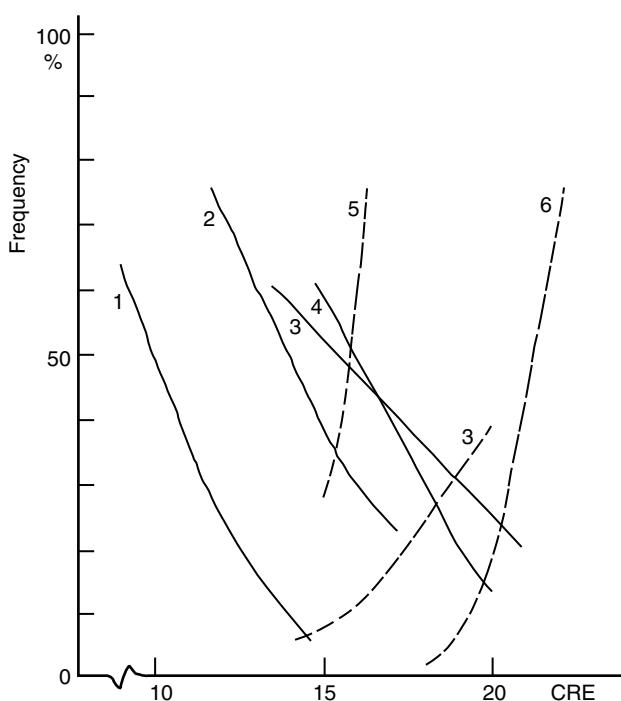

### 37.4.2 DOSE EFFECT RELATIONSHIPS AND ACCURACY

Two sets of dose relationships are of importance in any radiotherapy situation, the relationship between dose and tumour control (see [Section 7.4.2](#)) and that between dose and normal tissue complications (see [Section 8.6](#)). Each has the characteristic form shown in Figure 37.2, exhibiting threshold doses, relatively steep rises, and saturation at high doses. The most common practical radiotherapy situation is to find that the curves overlap along the dose axis such that the aim of radiotherapy is to attempt to maximise control of the tumour while maintaining normal tissue complications at an acceptable level.

**FIGURE 37.2**

Dose effect curves for tumour control and normal tissue complications. The curves are sigmoid and are assumed here to have the same shape and steepness, for simplicity. The upper figure shows a favourable situation for radiotherapy where a dose selected within the range shown by a double arrow is satisfactory. The lower figure shows a less favourable one where none of the 3 dose levels indicated by  $D_1$ ,  $D_2$  or  $D_3$  can achieve both a high TCP and low NTCP.

**FIGURE 37.3**

Dose response curves collected from the clinical literature for local recurrence frequency (solid line) and frequency of complications (broken line) versus the cumulative radiation effect (CRE). 1. Malignant lymphomas, Fuks and Kaplan (1973); 2. Nasopharynx, Moench and Phillips (1972); 3. Bladder, Morrison (1975); 4. Tonsil, Shukovsky and Fletcher (1974); 5. Skin reaction Turesson and Notter (1984); 6. Brachial plexus, Svensson and others (1975). (From Johansson, L. et al., *Int. J. Radiat. Biol. Relat. Stud. Phys. Chem. Med.*, 41, 411–420, 1982.)

The general requirements on accuracy are obtained by considering the steepness of the dose-effect relationships. It is obvious for relationships of this general type that if uncertainties on a delivered dose are large, then the probability of tumour control will be reduced or the incidence of normal tissue complications increased depending on the direction of the deviation from the stated dose. Thus clinical accuracy requirements must be such as to ensure that deviations are acceptable in these terms, with high accuracy on the steep part of the curves (Figure 37.2).

Clinical dose-effect data have been reviewed by a number of authors (e.g. Johansson 1982; Moore et al. 1983; Mijnheer et al. 1987; Brahme et al. 1988). Some examples are given in Figure 37.3 with the doses for different fractionation schedules corrected to an equivalent dose. These curves are subject to a number of uncertainties but give an indication of the steepness of the dose response curves. More detail is given in Part B.

### 37.4.3 REQUIRED ACCURACY IN ABSORBED DOSE DELIVERY

As a general requirement, it is necessary to base accuracy recommendations on the steeper dose-effect relationships encountered in routine clinical situations. These are generally for normal tissues. The International Commission on Radiation Units and Measurements (ICRU), in Report 24 (1976), reviewed the limited information available up to that time and considered that  $\pm 5\%$  accuracy was required in the delivery of absorbed dose to the target volume, but that in critical situations  $\pm 2\%$  may be required. However, it was recognised that the latter figure was not generally realisable in then-current practice. It was not made clear what uncertainty value the figures represented. Mijnheer and others (1987) obtained a figure

for required accuracy by considering normal tissue effects. They considered the steepness of dose-effect curves in terms of the percentage increase in absorbed dose to produce a change in the probability of normal tissue complications from 25% to 50%. A representative value of 7% was taken for this relative gradient and it was concluded that any transfer of clinical information from one centre to another will involve unacceptable risks of complications if overall uncertainty in absorbed dose is larger than this value. This was then assigned to the 2 SD level, resulting in a value of 3.5%, one relative SD, as the general accuracy requirement on absorbed dose delivery. Brahme and others (1988) considered the effects of variations in dose on tumour control for typical values, showing that the largest loss in tumour control introduced by dosimetric inaccuracy is found at the highest level of tumour control probability. A general figure of 3% (relative SD) on the delivered absorbed dose to the patient was recommended as the tolerance level on accuracy in dose delivery, to keep variations in the probability of tumour control within acceptable limits.

Thus overall a figure of 3% SD can be taken as the currently recommended accuracy requirement, considered as one relative SD, on the value of the dose delivered to the patient at the dose specification point. This implies there is a 96% probability that changes will be clinically observable for dose changes at twice this level, in situations described by the steeper dose-effect relationships. This is also consistent with more anecdotal evidence on clinical observations following inadvertent dose changes due to dosimetric errors (Dutreix 1984).

#### 37.4.4 REQUIRED ACCURACY IN ABSORBED DOSE DISTRIBUTIONS

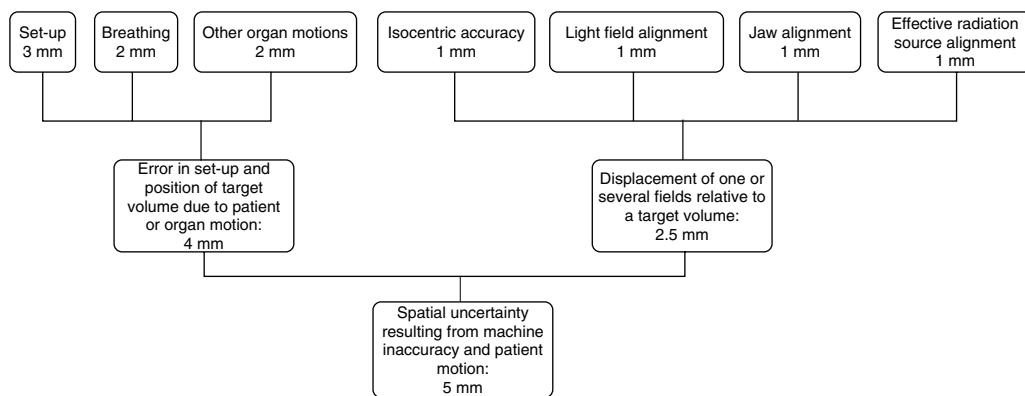

Besides variations in the overall level of absorbed dose delivered, variations in the dose distribution across the target volume may be expected to affect the outcome of treatment and to contribute to the steepness of practical dose-effect relationships. Brahme (1984) has considered the effects of different distributions on uniform tumour volumes and argued that a SD of the dose distribution in the range of 3% to 5% was required. Combining this with the recommended uncertainty in delivered dose to the specification point gives a requirement that the accuracy of dose to all other points in the target volume should be around 4% to 6%. As a general recommendation, a figure of 5% can be taken, again being one relative SD.

#### 37.4.5 REQUIRED GEOMETRIC ACCURACY IN RADIOTHERAPY

Geometric uncertainties arise for a variety of reasons, including treatment machine specifications and tolerances, simulation and treatment set-up, patient or organ movement during treatment and changes of patient shape between fractions. Clinical information is limited concerning the effects of such variations on treatment outcome. Geometric miss of tumour/target will obviously decrease tumour control probability, whilst overlap of fields with adjacent normal structures, particularly critical organs, will be detrimental in terms of complications. In general appropriate margins are allowed around the target volume to allow for these uncertainties so it is difficult to find definitive data on the effect of inaccuracies. For this reason estimates of the required accuracy must be based on modelling studies (e.g. Brahme et al. 1988).

Many studies were carried out when computerised tomography (CT) was introduced routinely to radiotherapy to look at the impact of using CT on tumour localisation as compared to conventional methods (e.g. Badcock 1983; Dobbs et al. 1983) and on the impact of CT or simulator CT on treatment planning (e.g. Redpath 1988). These unambiguously show the significant advantage of using CT methods for determining margins and for input to the treatment planning process and can provide information on the changes in dose variation across target volumes due to changes in determination of those volumes.

The estimation of required geometric accuracy is best carried out by considering the various sources of uncertainty, combining them to give an overall value, and using the best practically

**FIGURE 37.4**

Cumulative geometric uncertainties in external beam therapy. (Redrawn from AAPM, Report 13, *Physical aspects of quality assurance in radiotherapy*, American Institute of Physics, New York, 1984. With permission.)

achievable figures as the level to be recommended. On this basis the AAPM (1984) arrived at a figure corresponding to 5 mm, one effective SD, as illustrated in Figure 37.4. Mijnheer and others (1987) considered a wider set of data and recommended an accuracy of positioning of field edges and shielding blocks of 4 mm, one SD. This is in general agreement with the philosophy underlying the IEC recommendations for geometric tolerances of radiotherapy equipment (Rassow et al. 1988).

### 37.4.6 OVERALL ACCURACY REQUIREMENTS

In summarising all the currently available evidence, general recommendations on accuracy in radiotherapy can be made:

- Three percent on the absorbed dose delivered at the specification point
- Five percent on the dose at all other points in the target volume
- Four millimetres on the position of field edges and shielding blocks in relation to the treatment isocentre

All these are given as one SD and all are general requirements for routine clinical practice. In certain cases (for example, palliative treatments) higher values may be acceptable. However it is generally impractical to work to different standards of accuracy for different treatment techniques and so these values must be widely applied. In some special cases, smaller uncertainties may be demanded if very steep complication curves are involved or tight geometric tolerances are required, as in stereotactic treatments (Chapter 45) or proton therapy (Chapter 46).

It must be appreciated that these figures are on final delivered dose to the patient at the end of all the contributing stages involved in the radiotherapy process and this implies that the accuracy of individual contributions to the overall delivered dose must be higher. The dosimetry chain begins with primary dosimetry standards and the required basic physical data. It leads through dosimeter calibration, treatment-beam calibration in reference conditions, relative dosimetry in all other conditions, and the treatment planning process, including acquisition of patient data and specification of treatment volume and dose. It ends with the delivery of the prescribed, planned, and accepted treatment to the patient under day-to-day conditions over the course of the treatment. The accuracy requirement on each part of the whole process must be significantly less than the overall recommendations to achieve the final values recommended.

---

## 37.5 ACCURACY CURRENTLY ACHIEVABLE

### 37.5.1 GENERAL

Uncertainties are introduced at all levels in the dosimetry chain. The overall cumulative uncertainty can be estimated in one of two ways, which complement each other: (1) by an a priori approach, considering potential sources of uncertainty at every stage, using all available information to assign reasonable practical values, or at worst making educated guesses in the absence of hard data; (2) by appropriate dosimetric intercomparisons or audits to assess cumulative uncertainties experimentally at various levels. The nearer to treatment conditions that the intercomparison is carried out, the more factors are included. Differences in uncertainties at different levels can provide information on those introduced in the intervening steps. Neither method is ideal. For example inter-centre intercomparisons cannot detect any systematic errors common to both the auditing system and the audited centre. In addition inevitably there are omissions of some clinical factors in inter-centre dosimetric intercomparisons, as these can only be used to investigate limited combinations of clinical treatment conditions (Thwaites et al. 1992; Thwaites et al. 2003b). However inter-centre comparisons can be complemented by internal audit using in vivo dose measurement and on-line portal imaging.

### 37.5.2 ESTIMATION OF ACHIEVABLE UNCERTAINTIES

Various attempts have been made to analyse the radiotherapy process to estimate cumulative uncertainties on delivered dose (e.g. Brahme 1984; Dutreix 1984; Mijnheer et al. 1987; Brahme et al. 1988). This has been done considering each major step, including

- The determination of the absorbed dose to a reference point in water
- The establishment of other doses relative to this
- Treatment planning
- Treatment delivery to the patient

These steps are then broken down into substeps and best estimated uncertainties at each level are assigned to each contributing factor. The overall cumulative uncertainties obtained in this way have ranged from 2.5% to 8.5%, as one effective SD. The different values in part reflect the judgements used by different authors, the number of separate sub-steps and parameters they included and whether they tended towards an optimal or a conservative approach. A figure of 5% (1 SD) could be taken to be representative of these types of estimates and they would be likely to produce smaller uncertainties for simpler treatments and larger for more complex treatments.

More recently, uncertainty estimates based on harder evidence from intercomparisons, audits and in vivo dosimetry have been made (e.g. Thwaites 1993; Thwaites 2003; Thwaites 2004). [Table 37.1](#) provides an example for external beam megavoltage x-ray treatments, following U.K. procedures and codes of practice for basic dosimetry and utilising results from:

- The U.K. dosimetry intercomparisons and audits, all based on site visits and ion chamber dosimetry (Thwaites et al. 1992; Nisbet and Thwaites 1997)
- The Scottish + audit group of the U.K. radiotherapy dosimetry audit network (Thwaites et al. 2003b), which includes intercomparisons in a number of phantoms simulating treatment sites, also based on site visits and ion chamber dosimetry, and some inter-centre in vivo intercomparisons
- Analysis of QC records and specific experimental evaluation of the uncertainties at many levels in the radiotherapy process in one department (Allahverdi and Thwaites 1998)
- Systematic in vivo (diode) dosimetry in one department over more than 10 years (Thwaites et al. 2003a)

**TABLE 37.1**

Uncertainties in External-Beam Megavoltage X-Ray Dosimetry Based on Experimental Determinations

Source/Level	Single Centre (different beams/times) (%)	Multi-Centre (%)
<b>1. Dose at reference point in water phantom</b>		
Uncertainties quoted on calibration factors by the U.K. standards lab (NPL) are 0.7% (1 effective SD)	0.7	0.7
Variation in reference dose determination	0.5	0.7–1.0
<b>2. Dose to phantoms representing various treatment sites</b> (at a range of points within target volumes; given relative to reference dose)	0.8–1.8	1.1–2.3
<b>3. Patient dose at specification point</b> (based on estimates from in vivo dosimetry; for a wide range of treatment sites and techniques; given relative to reference dose) where lung is significantly involved	1.5–3.0 (5.0)	1.6–3.3 (5.2)
<b>4. Estimated overall cumulative uncertainty on delivered patient dose</b> at the specification point including standards lab uncertainty (i.e. relative to absolute Gy) where lung is significantly involved	1.7–3.1 (5.1)	1.8–3.5 (5.3)

The beam/dosimetry calibration method follows the U.K. system and code of practice (based on a direct absorbed dose to water calibration covering that beam quality at the standards laboratory). It is assumed that uncertainties may be combined (and separated) in quadrature. All uncertainties are given as 1 effective SD.

The uncertainties in Table 37.1 are all given as effective SD values; 95% confidence levels can be taken to be approximately twice these values. It may be noted that the final cumulative patient dose uncertainties for a single centre are not very different from those for multi-centre intercomparisons. The values at level 2 indicate what is achievable in relative dosimetry comparisons between phantom measurements and planned doses, i.e. normalised to the local reference dose value. The values at level 3 similarly indicate what is achievable in comparing patient measurements and planned doses, i.e. again normalised to the local reference dose value. The values at level 4 indicate the overall uncertainties relative to absolute dose, i.e. including the basic dosimetry (standards laboratory) uncertainties.

The general overall cumulative uncertainties at the specification point, for many treatment sites and techniques other than when lung is significantly involved, are within—or very close to—the recommended required values of 3% (1 SD) (see [Section 37.4.6](#)). They are likely to be representative of fairly optimal situations in normal clinical practice. However, overall uncertainties will be larger if any steps or sub-steps have larger uncertainties. For example other more recent multi-centre dosimetry intercomparisons or audits carried out by ESTRO-EQUAL (Ferreira et al. 2003) and the U.S. RPC (Aguirre et al. 2003) using mailed thermoluminescent dosimeters (TLD) have shown larger variations than those quoted above where direct comparison is possible. For example, in determination of reference dose in megavoltage photon beams SD of 1.6% to 1.9% are observed. In part this reflects the wider international spread of such audits, involving different codes of practice and different standards laboratories in the dosimetry chain. In part, also it reflects the larger inherent uncertainties in the use of mailed TLDs compared to site visits using ion chambers.

The only significant exception to the general values is treatments where there is marked involvement of lung. Here in vivo measurements indicate that uncertainties may increase due both to movement and to the ability of planning systems to cope with such situations. This will depend on many factors, including the exact site, the beam directions, the planning algorithms involved (see [Section 39.3.3](#)), the approach used for lung correction, and so on.

The overall cumulative uncertainties are estimated for patient-delivered dose at the specification point. For other points within the target volume, additional uncertainties are present, which can be estimated by folding in uncertainties from multi-point measurements in phantom or from 2D (or 3D) verification of fields and treatments (here for example, experience is rapidly growing from the development and implementation of verification methods for intensity modulated radiotherapy (IMRT)). Optimal uncertainties in these points are likely to be similar to those at level 2 in the table, giving estimated cumulative uncertainties (1 SD) on the dose at other points in the target volume in the range of approximately 2% to 4.5%. These figures may also be interpreted in the context of the various levels recommended for assessing the accuracy of treatment planning systems, as discussed in [Section 39.3.4.2](#) (and, for example, by Venselaar et al. 2001).

It may be noted that realistic phantom intercomparisons have shown uncertainties which are in general agreement with [Table 37.1](#), for example, the START trial audit (Venables et al. 2003) reported SD of 1.2% and 1.3% in the results of phantom measurements at the specification point for 2D and 3D breast plans respectively, with the totality of individual measurements lying within the range –10% to +12% compared to locally planned values. The RTO1 trial audit (Moore et al. 2003) showed a 1.3% SD at the isocentre for multi-centre measurements at the specification point in a prostate phantom, comparing to locally planned values, with a 2% SD for measurements within the clinical target volume and a 4% SD for all measurements, including some outside the target volumes. There are also results beginning to appear from clinical trial QA groups carrying out systematic in vivo measurements on patients entered into the trials. For example, Venables and others (2004) have reported the distribution of measured/expected doses for more than 400 breast patients in the START trial, where the mean value observed was 0.99 and the SD 4%. Here the measurements used a mailed TLD system, with its own uncertainties reported as close to 3% (1 SD). When this is taken into account there is good agreement with the data used for Table 37.1.

Geometric uncertainties translate into dosimetric uncertainties, in part depending on considerations of choices of margins for target volumes and for organs at risk and also on correction strategies. A rapidly growing database of information is available from studies considering positioning uncertainties and organ motion (see [Section 39.2](#) and Hurkmans et al. 2001). A major review (BIR 2003) provides detailed discussion of geometric uncertainties in general and also for particular treatment sites\*. Overall geometric uncertainties have been reported from a few mm to between 1 cm and 2 cm (1 SD), depending on site, techniques, immobilisation, etc. and must be evaluated in each centre for the procedures in use.

---

## 37.6 ICRU DOSE SPECIFICATION AND REPORTING

As pointed out in [Section 37.4.1](#), clarity of the prescription of the radiation oncologist is fundamental. The ICRU (1993, 1999, 2004) have published recommendations on the reporting of radiotherapy doses. The geometric part of these recommendations is discussed in [Section 29.2](#), to which the reader is referred for the definition of the planning target volume (PTV). The various possibilities for dose specification are discussed briefly in [Section 35.4](#). Here, the specification of the dose is considered in the context of the need to ensure consistency of dose specification and reporting.

The ICRU defines the ICRU reference point and recommends that the dose at this point be always reported. The recommendations relate to the recording and reporting of radiotherapy doses and do not make it a requirement that the dose is prescribed to the ICRU reference point. However, it improves consistency if all prescriptions are to this reference

---

\* This is discussed further in [Section 29.3](#) and [Section 29.4](#).

point. Even if the prescription is to a different point it is sensible for dose distributions to be normalised to the ICRU reference point. It should then be apparent that a prescription is different because a prescription to the minimum dose within the PTV, say, will appear as a prescription to 95% of the reference point dose, in which case the *reported* dose would be about 5% larger than the *prescribed* dose.

The ICRU reference point is chosen according to the following criteria:

- The dose at the point should be clinically relevant and representative of the dose throughout the PTV.
- The point should not be in a region of steep dose gradient.
- It should be possible to calculate the dose at the point accurately.
- The definition of the point should be clear and unambiguous.

For simple plans with a single intersection point that is close to the centre of the PTV, the intersection point, usually the isocentre, is defined as the ICRU reference point. However, where this point is not representative of the dose to the PTV it is appropriate to define an alternative point. In selecting this point, the first of the above factors is fundamental. The aim is to select a point that is approximately at the middle of the tumour mass of the PTV. Examples of situations where a point other than the isocentre are appropriate are as follows:

1. *Glancing field breast treatments.* Here, the isocentre may be very close to the chest wall or to the skin surface. In either case this point is not representative of the dose to the majority of the PTV and in addition there are uncertainties in the absolute dose value because of loss of lateral scatter. A point half way between the skin surface and the ribs at a point midway between the beam entry points is appropriate.
2. *Asymmetric fields.* It is common practice to facilitate matching of fields to place the isocentre on the match plane. Here the reference point should be placed in the centre of the half field.
3. *Weighted parallel-opposed fields.* The centre of the PTV on the central axis of the beam is the obvious choice here.
4. *Electron beams.* For electron beams the reference point is always in the central part of the PTV and for single fields this should be on the beam axis at the level of the peak dose. Where adjacent fields are used a reference point should be defined for each field (ICRU 2004). For more complex techniques a corresponding point should be chosen.
5. *Simultaneous boost fields.* It is becoming common practice to treat the gross tumour volume (GTV) and nodal fields with a single dose distribution either by IMRT or by combining a number of matched fields. In this case there will be several PTVs and it is appropriate to define a reference point that is representative of the PTV dose for each.
6. *IMRT fields.* IMRT fields are inherently somewhat non-uniform even in the centre of the field and it may therefore be inappropriate to define a point dose. The median or modal dose in the PTV (see [Section 35.4.1, Table 35.1](#)) is a useful alternative, although this does not meet the requirement to be easily calculated.

In addition to the reference-point dose, the ICRU recommends that the maximum and minimum doses to the PTV also be reported. In considering the maximum dose, it is recognised that a very small area of high dose is unlikely to be clinically significant. It is therefore recommended that the maximum dose should be the average dose in a volume of 15 mm diameter. For the minimum dose there is no such volume criterion and it is the minimum point dose that should be reported.

Differences in prescription and dose reporting are a significant factor in the variability of doses in radiotherapy. A survey of the fractionation practice in the U.K. in 1990 (Hendry and Roberts 1991) showed that 20% of U.K. radiation oncologists prescribed doses (allowing for fractionation) more than 10% different from the mean. Subtle factors can also lead to different prescriptions. For example in Europe it is common practice to prescribe lung doses with

corrections made for the lung inhomogeneities, whereas in the U.S.A. it has been common practice to prescribe the dose as calculated without lung corrections\*, although this may be changing with the advent of IMRT. Thus what may appear to be the same dose could be over 10% different for individual patients (Frank et al. 2003). For prostate cases the difference will be approximately 5% (Ginestet et al. 2000) because of attenuation by the femoral heads. This issue can lead to considerable confusion both in the analysis of historical studies and in present day prescription. Surprisingly ICRU Reports 50 and 62 (1993, 1999) do not make recommendations as to what should be done<sup>†</sup>. It is therefore essential that any reported dose includes a statement about whether inhomogeneity corrections have been made or not. In interpreting published data this issue must be given careful consideration.

---

## 37.7 ERRORS AND ACCIDENTS

Although it is clearly important to minimise the uncertainty in the patient dose associated with the combination of these individual uncertainties, there are occasionally errors made in patient treatment that are of a significantly greater order of magnitude. A quality assurance system must therefore spend at least as much effort in minimising the possibility of such errors. The IAEA publication on the lessons learnt from radiotherapy errors (IAEA 2000b) considered the causes of a number of such incidents around the world. It identified the problem of ensuring accuracy when a large number of tasks have to be performed many times every day differing only slightly from one patient to the next. When many people work together contributing a small part of the entire process and staff in several disciplines must interact in highly technical measurements and calculations the potential for mistakes is large. It must be acknowledged that all staff make mistakes and there is therefore a requirement for defence in depth and for checks to be made that require new thought. Particularly telling is the story of a physicist who checked the same calculation at weekly intervals and only on the third occasion spotted the error. Checks must therefore be devised that are as independent as possible of the previous work. It is also essential that working conditions are as conducive to careful work as possible, with attention paid to reducing interruptions and distractions, and that staff have the proper amount of time allocated to the work they have to do.

Critical steps were identified in the process. These were:

- Commissioning of the treatment machine and treatment planning computer
- Periodic calibration
- Identification of the patient
- Target volume localisation
- Preparation of the treatment plan
- Prescription of the dose and fractionation
- Simulation
- The first treatment session
- Daily positioning and parameter selection
- Accumulation of doses on the treatment sheet
- Maintenance of equipment

---

\* The rationale for not correcting for inhomogeneities is that current doses are based on historical experience where no lung corrections were made. However, the difference between the real (inhomogeneity corrected) dose and the uncorrected dose will differ from one patient to another which will introduce increased variability. It is also argued that inhomogeneity correction algorithms do not all yield the same result and are in any case not 100% accurate.

<sup>†</sup> In both reports the example lung case is presented without lung corrections. In contrast, the sample prostate case in Report 50 is inhomogeneity corrected, whereas in Report 62 it is not.

Critical steps were also identified in brachytherapy (see [Chapter 51](#)), including

- Removing sources after brachytherapy
- Identification of sources
- Activity specification and measurement

To minimise the possibility of error, a number of prevention measures are identified. These include the quality system approaches of ISO9000, but identify also some less obvious factors. Particular attention must be taken to consider the unusual situations that may occur and to prepare staff for them. All procedures and training programmes should pay attention to the identification of those situations that could lead to an accident in an unusual or unplanned situation. One person, usually a medical physicist, should have overall responsibility for all aspects of the dosimetry system to ensure that the lines of communication concerning dosimetry of patients are working properly. This requirement requires that the physicist should be closely involved in all aspects of the treatment process so that misunderstandings do not occur.

The vital importance of communication is also identified. Problems include failure to transmit information, transmission of incorrect information and communication to the wrong person. Communication should be written wherever possible, and printed forms should be used to avoid the problems of unreadable handwriting. Safety-critical communications include:

- Prescription
- Input data for preparation of treatment plan
- Proposed treatment plan and calculation, prescribed dose
- Patient immobilisation and shielding aids
- Confirmed plan
- Equipment fault report
- Request for maintenance
- Instruction to discontinue treatment
- Maintenance complete

Responsibilities for these communications must be clearly assigned and formal procedures established, including the design of forms and checklists. Particular attention must be paid to the procedures for the transfer of treatment machines between staff groups. For example, after a repair the machine must be checked by a physicist and then handed over to the treatment staff. Care is also required after measurements or calibration changes have been made on the machine. These may have required a change in the operating conditions of the machine or the over-riding of an interlock.

Because of the impact of errors, as opposed to inaccuracies, as much attention must be paid to the establishment of proper procedures for reducing both their frequency and impact as to the accurate calibration and maintenance of the equipment. This attention to procedures is enshrined in European and national law (EC 1997a; HS 2000) which requires procedures to be written by the employing authority and followed by the staff.

---

## 37.8 EQUIPMENT QUALITY ASSURANCE

### 37.8.1 EQUIPMENT USED IN EXTERNAL BEAM RADIOTHERAPY

The equipment currently used in radiotherapy encompasses a large variety of devices, from very simple mechanical items to highly sophisticated computerised systems. A typical list of

**TABLE 37.2**

## Typical Equipment Used in External Radiotherapy

Dosimetric equipment (ionisation chambers, water tanks, films, TLD, etc.)
Treatment machines (cobalt-60, accelerators)
Immobilisation and positioning devices (head holders, casts, masks, lasers, etc.)
Localising/imaging devices (simulator, CT scanner, etc.)
Computerised treatment planning systems
Beam limiting devices (blocks, multileaf collimator)
Beam modifying devices (wedges, compensators)
High energy imaging devices (films, electronic portal imaging)
Computerised record and verify systems (with or without network integration)

such equipment is given in Table 37.2. QC systems must be set up for each of these items of equipment, methods for some of which will be described in subsequent chapters.

### 37.8.2 STEPS IN EQUIPMENT QUALITY ASSURANCE

Between the acquisition of a new piece of equipment and its clinical use, several steps must be taken: the acquisition should always be based on a well-defined list of items, characteristics and features on which the user and the supplier must agree. This constitutes the *specification* phase that is required before any official order. After delivery and/or installation of the equipment, a series of *acceptance tests* must be conducted. Their aim is to make sure that the equipment meets the specifications previously agreed upon. During the acceptance procedure, the user is not expected to cover all aspects of clinical use. For sophisticated systems such as a treatment machine or a computerised treatment planning system, a significant time is still required to perform measurements, adjustments and tests before it can be clinically used. This is referred to as the *commissioning* phase, where the ability of the system to meet the clinical requirements in terms of possibilities and accuracy must be assessed.

After commissioning, the equipment must still be kept under control to make sure that the original characteristics are not changed inadvertently. This is done by setting up *periodic QC checks*, performed at regular intervals or after each major event such as repair or software updating.

## 38.1 INTRODUCTION

The tests described in this chapter are considered for each area of quality control (QC). It is not the purpose of this book to provide a detailed manual of QC. However, a brief description of tests that can be done to check a particular area is given together with some discussion about the testing and the issues that arise when parameters are found to be out of tolerance.

Details of these methods can also be found in other publications (IPEM 1999; AAPM 1994a) and some discussion about each area is also given.

### 38.1.1 QUALITY CONTROL OF LINEAR ACCELERATORS AND COBALT MACHINES

In the early days of megavoltage radiotherapy when cobalt-60 units were widespread, only limited QC checks were required. These included a monthly check of the dose rate and the mechanical alignment. The advent of linear accelerators required more frequent detailed QC.

Although at first the main concern was to maintain accurate output, it was soon recognised that, if overall accuracy of treatment was to be within the tolerances expected by radiation oncologists, other parameters needed regular checking. In summary, these tolerances (see [Section 37.4](#)) are

- Accuracy of delivered dose to the specification point  $\pm 3\%$  (1 standard deviation (SD))
- Accuracy of delivered dose at all other points in the target volume  $\pm 5\%$  (1 SD)
- Accuracy of positioning beam edges and shielding blocks in relation to the planning target volume (PTV)  $\pm 4$  mm (1 SD)

A number of QC protocols have been written and these often differ as to the frequencies recommended (see, for example, Table 38.1). For each individual department, it is necessary for the local physicist to put together a coherent and comprehensive series of checks. In some countries there will be a legal requirement to carry out a minimum series of checks. In others the physicist professional body may have published recommendations that do not have the full force of law. It is important to read these recommendations carefully. In The Netherlands (NCS 1996), it was decided to define a minimum level that would be regarded as mandatory, whereas in the U.K. the frequencies quoted were largely based on the median frequencies resulting from a national survey. In deciding on the appropriate frequency for an individual department a number of factors will need to be considered:

- The treatment techniques and fractionation schedules being used in the department
- The equipment being used (e.g. age, stability based on experience, control system)
- The time and resources and equipment available for QC

The aim of the QC process is to ensure that patients are given accurate treatment. For example, if a machine is being used regularly for stereotactic single fraction high dose treatments the QC checks relating to the mechanical alignment and stability with arc rotation will need to be carried out more frequently, perhaps even before each treatment. On the other hand for treatments being given over a six-week period a dose inaccuracy of 3% for two or three fractions can be easily compensated and less frequent checks may be appropriate. In practice it may be difficult to adjust frequencies to this level of detail. An analysis of the issues associated with the frequency of checks has been carried out by McKenzie and others (2006). Some checks are very quick to perform and others may take several hours. Evidently it makes sense to consider carefully requirements for the latter. In some situations, such as for IMRT treatments (see [Section 39.3.9.3](#)) or electron treatments, it may be appropriate to carry out individual patient QC measurements.

As well as providing assurance of continuing accuracy of dose delivery, QC also provides the radiotherapy department with an invaluable record of the safety of treatment given by the centre so that in case of litigation, machine error can be eliminated.

The quality assurance (QA) documentation produced by professional bodies will be used by bodies involved with auditing, accreditation, or in legal cases as a guide to *best practice*. Whilst these are valuable documents, most are based on surveys of existing practice and are in danger of becoming standard practice set-in-stone, rather than allowing a process of continual review.

### 38.1.2 RESPONSIBILITIES

The EC directive (EC 1997a) requires that QC is the responsibility of a Medical Physics Expert (MPE). This requirement has been translated into the national legal framework in most European countries. The EC directive is based in turn on documents such as the IAEA Basic Safety Standards (IAEA 1996). This physicist (with the assistance of the maintenance engineer or technician) must co-ordinate the QC checks and interpret deviations in terms of the effect that they will have on patient treatment. There is also an important role for the radiographer/technologist in daily QC and continued vigilance is required when operating the unit to make note of any error message or abnormal functioning.

### 38.1.3 TOLERANCES

Tolerances are given in most of the reports discussed above. A summary of European requirements (EC 1997b) is given in [Table 38.2](#). Measurement of many of these parameters does not require special techniques and will not be discussed further. In what follows we will consider the assessment of those parameters where the interpretation of the results requires a greater degree of understanding

---

## 38.2 ISOCENTRIC TREATMENT MACHINES

Modern megavoltage machines use an isocentric mounting. The aim is that the rotation axes of the collimator, gantry and treatment table should pass through a single point called the isocentre. Because of mechanical limitations, this aim is not exactly achievable and so the *isocentre* is then defined as the centre of the sphere that contains the axes of rotation of these components for all gantry, collimator and couch angles. The diameter of this sphere (the *isosphere*) defines the size of the isocentre. The position of the isocentre is usually indicated optically by two or more orthogonal lasers, which should be set up to indicate the centre of the sphere.

Ultimately, the aim is that the centre of the target volume within the patient shall be placed at the isocentre. If the gantry, collimator and couch all rotate about this point, the radiation beam

**TABLE 38.2**

Criteria for Acceptability of Linear Accelerators and Cobalt Units as Required by the EC (1997b)

Test	Remedial Action Level
Gantry and collimator rotation indication	$\pm 1^\circ$
Yoke rotation (cobalt only)	$\pm 0.2^\circ$
Isocentre diameter	$\pm 2 \text{ mm}$
Source distance and beam axis indicators	$\pm 2 \text{ mm}$
Numerical field size indicators	$\pm 2 \text{ mm}$
Light field compared to radiation field	$\pm 2 \text{ mm}$
Treatment couch scale	2 mm
Couch deflection under load	5 mm
Immobilisation devices (e.g. casts etc.)	$\pm 2 \text{ mm}$
Patient alignment devices	$\pm 2 \text{ mm}$
Light field indication (field size)	$\pm 2 \text{ mm}$
Light field indication (density measurements)	$\pm 1 \text{ mm per edge}$
Dose calibration at reference point	$\pm 3\%$ for photons and $\pm 4\%$ for electrons
Output constancy (including accelerators, cobalt and orthovoltage)	$\pm 2\%$
Timer of cobalt unit	$\pm 0.01 \text{ min}$
Electron/photon beam type	Correct type
Beam flatness and symmetry	$\pm 3\%$ (Photons and electrons and cobalt)
Orthovoltage beam symmetry	$\pm 6\%$
Transmission factor of wedge or compensator	$\pm 2\%$
Dose monitoring system	
Precision	$\pm 0.5\%$
Linearity	$\pm 1\%$
Dose rate effect	$\pm 2\%$
Stability	$\pm 2\%$
Variation with gantry angle	$\pm 3\%$

can be made to come from a wide variety of directions by rotation of these components of the treatment machine and the beam will still be centred on the target. Therefore, in addition to the coincidence of these mechanical axes of rotation, it is necessary that the radiation source is on the axis of rotation of the collimator and that the direction at which the electron beam strikes the target is coincident with this axis. Furthermore, the collimators must be centred on this axis.

Because the radiation beam is invisible, optical systems have been designed which indicate its position and are used to align the patient. With modern accelerators with multileaf collimators (MLCs) it is no longer common practice to set the *borders* of the radiation field to skin marks and the aim of patient treatment set-up is to ensure that the *isocentre* of the machine is placed at the desired point within the tumour. Some years ago an isosphere diameter of 4 mm was the best that could be achieved, but the standard specification of modern accelerators is 2 mm. Accelerators optimised for stereotactic treatment can now achieve an isocentre diameter of 1 mm. The coincidence of the radiation and light field is less critical than it used to be for the purpose of patient set-up and in testing machine alignment more emphasis should be placed on ensuring the alignment of the radiation beam and of the collimators. Methods of assessing the radiation beam are discussed in [Section 38.2.2](#).

Tests associated with the isocentre may have one of three aims:

- Setting up and optimising the isocentre at installation or in the event of a problem
- Investigating the isocentric accuracy of a machine on a routine basis
- Checking that the optical indication of the isocentre position is correct

At installation, or where the isocentric accuracy is found to be below the required specification, the actions that can be taken depend on the mechanical design of the accelerator. All machines will have some possibility to optimise the isocentre, but this should only be necessary at installation and will usually be carried out by the manufacturer's installation engineer. One or more of the following actions may be possible:

- The machine head may be slightly rotated or tilted with respect to the gantry by loosening or tightening the attachment bolts.
- On some machines, it is possible to adjust the axis of rotation of the gantry (e.g. by adjustment of the jockey wheels on a ring gantry).
- The gantry balance weights may be altered.
- The attachment of the accelerator to the floor may be adjusted with the help of shims.
- The couch position may be adjusted to bring its rotation axis into coincidence with the rotation axis of the collimator (with the gantry vertical).

Once the isocentre size has been minimised, the position of the isocentre, being the best point in space to give the least excursion with (couch) gantry and collimator rotation, is defined and the optical and mechanical indicators of the isocentre position are set up (see [Section 38.2.1.2](#)).

If it is considered impossible to bring the isocentre excursions within tolerance (because of wear on machine bearings), it may be necessary to restrict the use of the linear accelerator to certain types of treatment not requiring high accuracy or small fields.

Although the ultimate aim is to establish the position and size of the radiation isocentre, adjustments are most easily carried out without the use of the radiation beam and a systematic approach to mechanical and optical alignment should result in the correct alignment of the radiation beam. In the following section (Section 38.2.1) approaches to isocentre-related tests will be described that do not require the radiation beam.

## 38.2.1 MECHANICAL ALIGNMENT OF ISOCENTRIC MACHINES

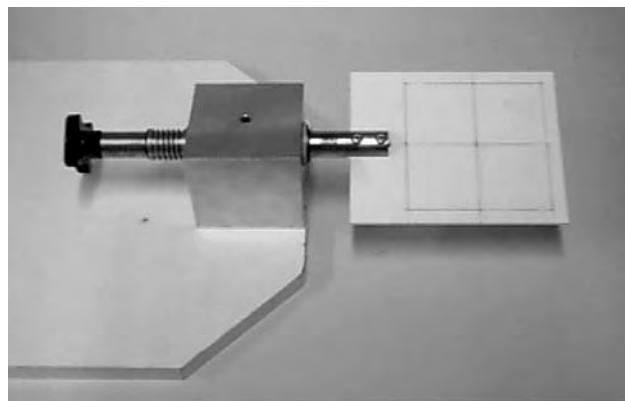

### 38.2.1.1 *Optical Alignment Checks*

Routine checks of the alignment of the optical indicators are the simplest way to assess the mechanical accuracy of a treatment machine. However, if problems are identified by such methods, more elaborate methods are required (as described in [Section 38.2.1.2](#)). The projection of the graticule at the centre of the field should provide an accurate indication of the centre of the beam and hence of the centre of rotation of the collimator. This can be checked as follows:

- Place a white board, with a clear thin black cross marked on it on the treatment table at the level of the isocentre (i.e. 100 cm from the target).
- Set the gantry to be exactly vertical using a spirit level on the front face of the collimator (or by some other method). Align the cross with the projected light field centre, then rotate the collimator and note the excursion of the optical cross from the fixed cross every 90°. This should not exceed the stated tolerance (e.g. 1 mm)\*.
- Any movement of this optical beam centre with gantry angle can be checked by rotating the gantry to 90° and 270° having set a rotatable plate (see [Figure 38.1](#)) at the isocentre when the machine was vertical—this plate can also be used to check that the wall laser beams correctly indicate the isocentre.

---

\* This test is often combined with a check on the optical field size and its rotation tolerances.

Rotatable plate for assessing optical isocentre accuracy. (Photograph courtesy of Clatterbridge Centre for Oncology.)

### 38.2.1.2 Definitive Mechanical Isocentre Assessment

If problems are identified by a quick optical check, a mechanical check of the isocentre is called for. The fundamental basis of an isocentric linear accelerator is the coincidence of the axis of rotation of the collimator and of the gantry. The aim of this test is to determine the mechanical relationship of these two axes.

A definitive assessment of the mechanical isocentre can be carried out using a mechanical front pointer attached to the head of the treatment machine (see Figure 38.2) together with a

**FIGURE 38.2**

(See colour insert following page 590.) Precision front pointer suitable for mechanical isocentre measurement. The pointer is attached to the front of the collimator and the screw adjustments allow it to be centred on the collimator axis of rotation (see text). The telescopic device that is placed on the treatment couch allows the position of the fixed pointer to be moved precisely.

rigid pointer, such as a hypodermic needle, attached to the end of the treatment table. This static pointer is used to assess the movement of the moving pointer in space. The moving pointer must first be adjusted to be coincident with the axis of rotation of the collimator. This is done by adjusting the pointer until no movement of its tip can be detected as the collimator is rotated. This can usually be achieved without difficulty.

Once this has been done the rotation of the gantry can be assessed. As the gantry rotates, flexing of the gantry structure will occur which causes the tip of the pointer to move both parallel to the gantry axis and perpendicular to it. Initially the distance of the tip of the pointer from the head is adjusted so that its tip is at the same point with the gantry at  $90^\circ$  and  $270^\circ$ . The fixed pointer is then set to this point and its height adjusted to be half way between the position of the moving pointer tip with the gantry at  $0^\circ$  and  $180^\circ$ . The gantry is then rotated and the movement between the two pointers is observed. The position of the fixed pointer may be further adjusted so that it gives an optimum indication of the isocentre. Finally the lasers are adjusted to point to this position.

If the position of the fixed pointer determined as described in the previous paragraph is coincident with the position of the moving pointer with the gantry at  $90^\circ$  or  $270^\circ$  there is no problem. However, it is commonly found that the height of the moving pointer with the gantry at  $90^\circ$  or  $270^\circ$  is below this point\* as illustrated in Figure 38.3. Since most treatments are given with the gantry at one of these four cardinal angles it may be appropriate to set the indication of the isocentre to the mid-point of the position of the moving pointer with the gantry at  $90^\circ$  or  $270^\circ$  as this will indicate the height of the beam centre for these beam directions. As a consequence of this choice, the source-isocentre distance will be slightly larger with the gantry at  $0^\circ$  (and smaller at  $180^\circ$ ) than observed at  $90^\circ$  or  $270^\circ$ . Provided that the source axis distance change is smaller than 2 mm to 3 mm, this may be the best option (Figure 38.3).

This method can also be used to assess the accuracy of the indicated isocentre. In this case the fixed pointer is set to the indicated position and then for each gantry angle (every  $30^\circ$  or  $45^\circ$ ) the distance between the pointers in both the transverse plane and the longitudinal plane must be measured and recorded. These can either be plotted in polar co-ordinates and compared with an acceptance baseline or a tolerance can be defined (e.g. 2 mm) which, if exceeded, triggers appropriate action.

### 38.2.1.3 Isocentric Couch Rotation Axis

If non-coplanar treatments or treatments in an inclined plane are carried out in the department it is important to include the couch rotation within the assessment of the isocentre. The couch rotation axis can be checked using the mechanical front pointer<sup>†</sup> and graph paper on the couch. The couch is rotated and the excursions of the front pointer noted. Care must be taken not to shift the couch laterally or longitudinally while rotating it. It is frequently the case that couch rotation is less accurately isocentric than collimator rotation.

### 38.2.1.4 Establishment of Vertical Axis

It is also important that the couch moves precisely vertically, and with the gantry vertical the optical indication of the beam should also be vertical. The vertical movement of the couch

---

\* The reason for this is that the flexion of the supporting arm, in a plane perpendicular to the gantry axis, is usually more pronounced when the beam is horizontal than when it is vertical. However, in the direction parallel to the gantry axis, the flexion is opposite when the beam is rotated from  $0^\circ$  to  $180^\circ$  and it is commonly observed that the tip of the rotating pointer shifts slightly outwards from the gantry. The average position is found at  $90^\circ$  or  $270^\circ$  and constitutes here again the best compromise.

<sup>†</sup> Alternatively if the graticule has been shown to be at the centre of rotation of the collimator it may be more convenient to use this instead.

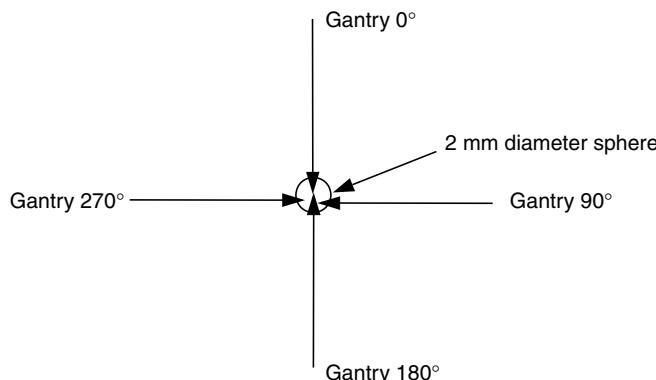

**FIGURE 38.3**

Figure indicating the possible position of the tip of the moving pointer at four gantry rotations. It may be appropriate to set the horizontal indication of the isocentre to be at the mean of the position with the gantry at 90° or 270° rather than at the centre of the 2 mm diameter sphere containing the isocentre.

can first be established using a plumb line held so that the pivot point from which it hangs does not move as the line is extended. The beam indication can then be checked as the couch is driven up and down.

### *38.2.1.5 Considerations Relating to the Mechanical Isocentre*

If one of the optical isocentre measurements is out of tolerance it is important to recognise why and how drift has occurred. Adjustment of one optical indicator to align with another that is incorrect will lead to a progressively more unsatisfactory set-up. It is usually necessary to reassess the mechanical isocentre before proceeding with making any adjustments.

When deciding where to centre the isocentre, it is important that the radiographers/technologists understand how this relates to the wall laser settings. These lasers must be aligned with the centre of a horizontal beam throughout their length and not just at the isocentre. This cannot be achieved just by altering the angle of the laser beam and it is essential that the lasers are accurately centred at the correct position on the wall. A laser level that gives a horizontal line across the room from the couch top is useful for this (a water level using a clear plastic pipe can also be used).

An important point connected to the checks at gantry angles 90° and 270° is that the electronic indicators of these angles may have drifted. These should be checked against the mechanical angle indicator and, if there is still some uncertainty, against the true vertical and horizontal. A laser tool can also be used for this.

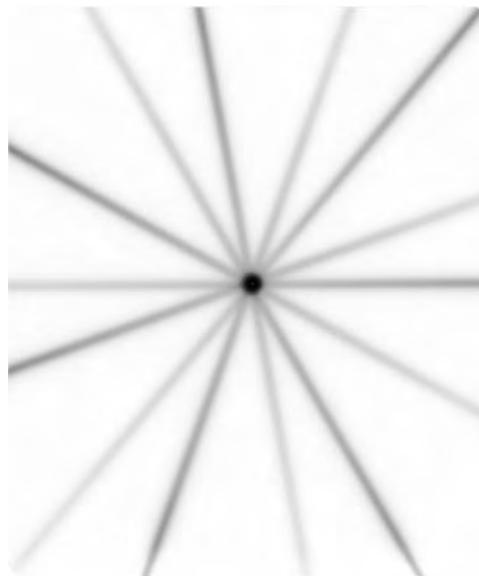

It is also important to check that the couch top is horizontal, whatever weight is added within representative values (see IEC specifications (1989)). Some deflection in the sagittal plane is inevitable, but it should be possible to set the couch top exactly level in the transverse plane.

## **38.2.2 RADIATION BEAM ALIGNMENT**

### *38.2.2.1 Radiation Isocentre*

Ultimately, it is the radiation beam alignment that determines the accuracy of treatment. This can be assessed directly using a star film or the Winston–Lutz test.

A star film is created by mounting an envelope wrapped film vertically in a poly-methyl-methacrylate (PMMA, known as Perspex or Lucite) holder in the plane of rotation of the

**FIGURE 38.4**

Star film exposed at 50° gantry increments. The film is placed in a PMMA holder in the plane, through the machine isocentre, that is perpendicular to the axis of rotation of the gantry.

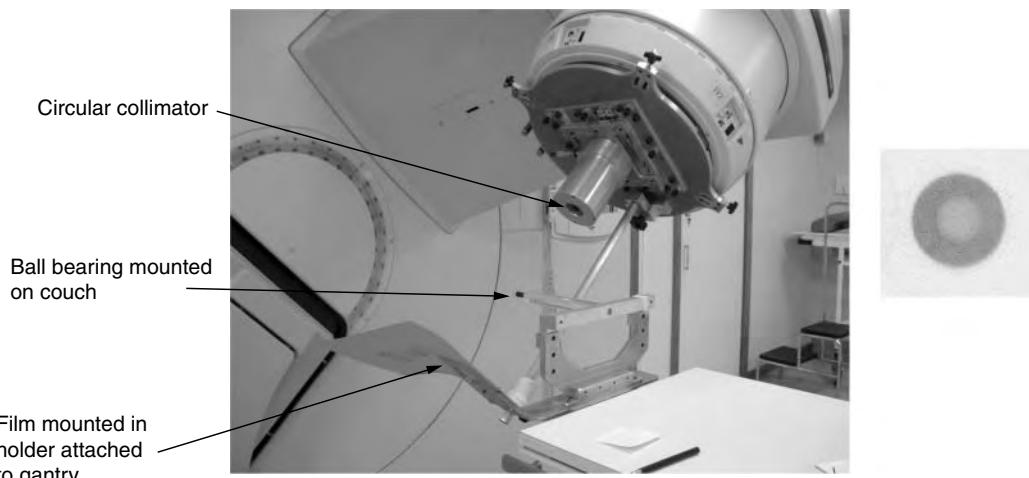

gantry with its centre at the indicated position of the isocentre. As narrow a field as possible\* is set and the film irradiated with the gantry at 0°, 120° and 240° (these directions are not prescriptive). The PMMA holder may have holes drilled at the centre and at 120° increments around the centre to coincide with the directions of irradiation. The holes are used to pierce the film to assist analysis. The image on the film will be a star shape and it is relatively easy to draw lines on the film indicating the centre of each beam. These should all meet at the marked isocentre. If the film is scanned into a computer, automatic analysis becomes possible. An example for which the increments were 50° is shown in Figure 38.4. It will be noted that this method gives no indication of errors in the direction orthogonal to the plane of rotation.

An alternative method developed originally for stereotactic radiotherapy is the Winston–Lutz test (Lutz et al. 1988). This was originally carried out using a circular collimator as shown in Figure 38.5. With a circular applicator attached to the head of the machine and a ball bearing suspended at the isocentre, the gantry may be rotated and films exposed at appropriate angles. The apparent movement of the image of the ball bearing relative to the circular field is easily observed. For stereotactic treatments, rotation of the couch and collimator can also be included among the different exposures. A circular field can be defined using an MLC and the similar set of exposures made. A small square field could also be defined. An electronic portal imaging device (EPID) can also be used.

### 38.2.2.2 Radiation and Light Field Coincidence

There are various methods of measuring coincidence between the radiation field and the light field, and at the same time checking the calibration of the field size indicators, by using film. The film must be placed on some back-scattering material, such as water equivalent plastic (which also provides a flat surface), and build-up of the appropriate thickness placed on top.

\* The narrow field may require to be set using the MLC, because of restrictions in the minimum field size of standard collimators.

**FIGURE 38.5**

Set-up to carry out a Winston–Lutz test using a stereotactic collimator and head ring. The image on the right shows the image of the ball bearing coincident with the centre of the circular collimator.

Some test objects combine the two tests in one by having lead/tungsten markers at the field edges to which the optical field is aligned. Prisciandaro describe how an EPID can be used for radiation and light field coincidence measurement with such a test object (Prisciandaro et al. 2003).

It is usually more convenient and easier to interpret if the field is set to a particular value on the field indicator and the edges of the optical field are then marked onto the film either with a pressure mark or a pinprick\*.

Following exposure to give an optical density of between 1.0 and 1.5, the radiation beam edge at the optical density representing 50% of the dose at the centre of the field can be found using a hand held densitometer or a film scanner. The distance between the optical edge and the radiation edge should not exceed tolerance (typically 2 mm). Ideally the film should be calibrated on each occasion but if the film has been checked to have a linear response over the range used and this is checked occasionally, it is not necessary to do a calibration every time. A slow film should be used which typically requires an exposure of about 0.5 Gy. This ensures that the resultant x-ray field represents the stable running condition instead of the initial switch-on condition—during the first few monitor units (MU)—when, particularly in bent beam accelerators, the servo systems are operating to centre the electron beam on the target. For monthly testing it is usual to measure at least the reference field size ( $10\text{ cm} \times 10\text{ cm}$ ), but it is nice to use different field sizes in rotation as well. Software is available to facilitate the analysis of scanned films.

### *38.2.2.3 Considerations Relating to Radiation Alignment of the Beam*

The field size and the penumbra width can be measured when a scanning densitometer or film scanner is used. The most likely cause of any misalignment is due to problems with the

\* With test objects containing lead markers the field has to be set visually to the appropriate size. For modern accelerators with assisted setup of the field shape this is therefore rarely the best option. However, as digital imaging takes over such methods may become essential.

optical beam; only rarely is it due to x-ray beam misalignment as a misalignment of the x-ray beam would probably be identified in assessing beam flatness (see [Section 38.3.5](#)). If an x-ray collimator has drifted out of calibration or shifted mechanically, both the x-ray beam and the optical beam will be affected. If the angle of the face of the x-ray collimator has tilted slightly with age or mechanical shock, the x-ray penumbra may be affected.

A second method for measuring all the field size parameters (i.e. x-ray field size versus optical field size and penumbra width) is to use an in-air scanner with the ion chamber set into a block with its centre of measurement at 100 cm from the source (Aird et al. 1995). The chamber is placed in a special white-faced plate in which the chamber's effective measuring point is about 2 mm below the surface of the plate and marked by a fine, black cross. The chamber can be moved so that the cross is aligned to particular points in the light field and its position noted. Build-up of the appropriate thickness is added to the block after each alignment has been made. For comparison of the x-ray and optical fields, the plate is first placed on the central axis of the beam and readings that represent 100% at the centre of beam taken. The cross on the plate is then aligned with the optical beam edge and readings taken that should represent 50%. The difference from 50% can be translated into a distance error in mm by comparison with the x-ray beam profile for the particular field size investigated.

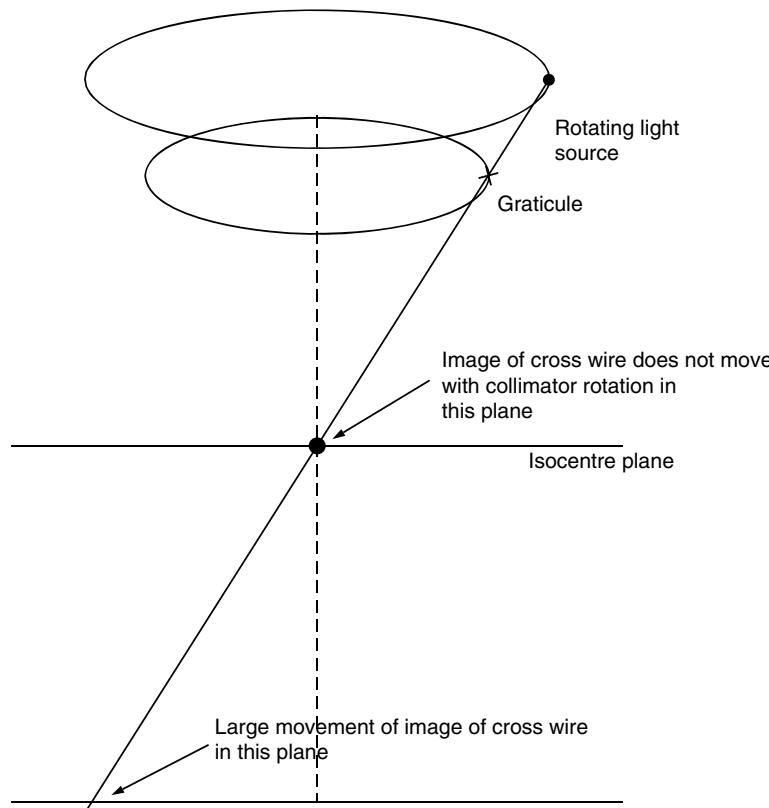

The advantage of this approach where a jig is attached to the gantry is that beam parameters can be measured at any gantry angle. This is also possible with electronic systems containing arrays of ionisation chambers or diodes.

### *38.2.2.4 Interpretation of Alignment Checks*

The results of some of the preceding tests may indicate a problem in alignment of the unit. Examples of possible alignment problems together with the symptoms that they will produce are described below. If one of the tests identifies a problem it is important to carry out all the associated tests before trying to make a diagnosis. The causes of misalignment can be quite complex and it is easy for misalignment of one component of the system to be compensated for by a misalignment of another component. The examples given below should not be regarded as an exhaustive list of possibilities. The first step in aligning the system is to ensure that the projection of the crosswires does not move when the collimator is rotated.

*The Crosswire or the Light Source is Not on the Collimator Axis:* The light source and the crosswire must both be located on the mechanical axis of rotation of the collimator (the collimator axis). The testing procedure and its interpretation would be somewhat different depending upon whether the light source is designed to rotate with the collimator (as in Elekta and Varian linacs) or not (as in Siemens linacs).

If the crosswire is not on the collimator axis, its projection will always move as the collimator rotates. If the light source is fixed, movement of the crosswire projection is always an indication that the crosswire is misplaced and it should be adjusted until its projection is static. If the light source rotates, it could also be responsible for the movement of the crosswire projection. Indeed, if both the crosswire and the light source are misplaced, it could happen exceptionally that at a given distance the projection does not move (see [Figure 38.6](#)) but this would not be true for another distance. One method to decide whether it is the light source or the crosswire that must be adjusted, is to measure the diameter of the projected circle at two different distances. If the diameter increases in proportion to the distance to the source, the crosswire is misplaced; if it increases in proportion to the distance to the crosswire, the source is not on the collimator axis. Another particularly effective method is to suspend a 50 cm focal length lens on the axis of the beam so that a sharp image of the light source is projected onto the floor (or a wall). The exact position is not critical. As the collimator is rotated this image of the light source will not move if the light source is on the axis of rotation.

**FIGURE 38.6**

Misalignment of the crosswire or light source can be compensated for in one plane, but not in all.

When a light source that does not rotate is misplaced the projection will still not move if the crosswire is on the collimator axis. One solution to detect this situation is to set the collimator base to be horizontal with a spirit level (i.e. the gantry vertical) and to check with a plumb line if the optical axis is vertical.

*The light source is not at the correct distance from the isocentre:* In this case, the field size at extended source skin distance (SSD) will not be in correct proportion to the field size at the isocentre and coincidence of the radiation and the light field will not be correct at the extended SSD.

*The light source mounting is loose:* If the light source moves as the gantry is rotated the alignment of the light source will be different at different orientations of the gantry. This can be detected by checking that the coincidence of the radiation and light field remains the same as the gantry rotates\*, for example at 0° and 180°.

*The optical field trimmers protrude too much or too little into the beam or are asymmetric:* Older machines used optical penumbra trimmers<sup>†</sup> to allow exact coincidence between the radiation and light field to be established. Optical trimmers can be very confusing as they can easily mask a more fundamental misalignment. Incorrectly set trimmers will be manifested by a difference in field size between the radiation and the light field. If they are set asymmetrically, the light

\* If the light source rotates with the collimator, this may be more conveniently detected by checking the movement of the projection of the crosswires as the collimator is rotated with the gantry at 0° and 180°.

<sup>†</sup> This was particularly necessary if the optical field was to be set to show the 80% dose level. However, this field size convention is impractical with modern equipment because of the use of asymmetric fields and with MLCs optical trimmers are impractical.

field will be asymmetric and the asymmetric jaw will move round as the head is rotated through 180°. If there is doubt about this it is useful to adjust the light-field trimmers so that they do not protrude into the beam at all and then ensure that the correct radiation field size is set before adjusting the light field.

*The radiation source is not on the central axis of the machine:* The radiation source does not move with collimator rotation. If it is not on the axis of rotation of the collimator there will be an asymmetric radiation field compared to the light field. This asymmetry will be equal and opposite for opposing jaws that are themselves correctly set up and will be offset in the same direction as the collimator is rotated. This can be confirmed as described in [Section 38.2.2.1](#). The misalignment of the radiation and light field will be emphasised by taking radiographs at different SSDs. A more sensitive test of a misaligned beam is the beam flatness (see [Section 38.3.5](#)) because if the radiation beam centre is not aligned with the beam flattening filter there will be a significant asymmetry in the middle of the beam.

*The electron beam is striking the target at an angle other than 90°:* If the electron beam strikes the target at the wrong angle this may result in an asymmetric beam. The flatness scans will also show a misalignment of the minimum in the centre of the beam with the geometric centre (provided that the scanner is set up correctly so that the indication of the central axis is correct) and poor beam flatness (see [Section 38.3.5](#)). There may also be an energy change associated with the need to compensate for the incorrect angle. These problems will result in an asymmetric beam profile at the edges. Because of this possibility it is important to check the beam profile before adjusting the optical field and to check the light and radiation field coincidence after any beam adjustment.

*The collimators are asymmetric:* The asymmetry of both the optical and the radiation field relative to the isocentre will change sides as the collimator is rotated through 180°.

*The collimator sides are not aligned with respect to the source:* If the collimators are not aligned with the edge of the diverging beam an increase in the width of the penumbra will be seen. It should also be possible to detect significant angulation by visually inspecting the collimator.

*The gantry sags or there are distortions in the drum or gantry bearings:* Gantry inaccuracy will be demonstrated by a longitudinal misalignment of the beam at 0° and 180°. This can be demonstrated with a mechanical front pointer or by marking up a film with the gantry at 0° and exposing it with the gantry at 180°. The former is the most effective way to demonstrate problems with the gantry bearings as sudden jumps of the pointer may be seen.

*The collimator bearings are faulty so that it does not rotate correctly about its axis:* Erratic movements of the central cross will demonstrate errors in the collimator bearings when the collimator is rotated.

*The rotation axis of the gantry and collimator differ:* This will result in a shift in the transverse direction (i.e. perpendicular to the gantry rotation axis) as the gantry is rotated through 180°.

---

### 38.3 ALIGNMENT AND QUALITY CONTROL OF MULTILEAF COLLIMATORS

MLCs require particular QC measures depending on their application. Some recommendations for these are given in IPEM Report 81 (1999), the report of AAPM Task Group 50 (Boyer et al. 2001) and in SFPM Report 40 (2003). For simple field shaping the requirements are less demanding than for intensity-modulated radiotherapy (IMRT, see also [Chapter 43](#) and [Chapter 44](#)), where errors in leaf positioning can lead to errors in the delivered dose. With the growing importance of leaf calibration because of IMRT a number of authors have developed methods of testing involving EPIDs (Boyer and Li 1997; Samant et al. 2002; Vieira et al. 2002, 2003; Chang et al. 2004; Baker et al. 2005; Budgell et al. 2005b) and Wiezorek et al. (2005) describe the use of other electronic test tools for this purpose.

### 38.3.1 LEAF CALIBRATION

When establishing the leaf calibration there are two stages: setting the mean position of the whole set (or bank) of leaves and then setting the position of individual leaves (sometimes referred to as minor offsets). The relationship between the mean position of the leaves and the position of the backup jaws (if any) must also be established. Several factors must be considered when setting up the MLC leaf calibration:

- For MLCs with rounded leaf ends (as those of Varian and Elekta) the part of the leaf which defines the field edge varies as the leaf is tracked across the beam and it is therefore necessary to test leaf alignment at different positions relative to the centre of the beam (Graves et al. 2001).
- It is not possible to adjust the light field by using light field trimmers so that once the optics have been adjusted so that the (virtual) light source is on the central axis of the beam no further adjustment of the relationship of the optical field to the radiation field is possible.
- As discussed by Jordan and Williams (1994), when leaves are used to define rectangular fields in conjunction with backup jaws (as in the Elekta design) the position of the 50% isodose line will be different in relation to the leaf position compared to when the leaves define the edge of the field alone. For IMRT the most critical factor is the relationship between opposing leaves as this is fundamental to being able to create composite fields by the combination of multiple small segments by dynamic jaw movements.

A universally useful test is to expose a single film using a series of adjacent strip fields, usually 20 mm wide. Any error in leaf position will show up as a non-uniformity in the resulting film. The exact technique for setting up leaf calibration is dependent on the particular MLC. The procedure for Varian MLC's is described by Chui et al. (1996) and Mubata et al. (1997), for Elekta MLC's by Hounsell and Jordan (1997) and Sastre-Padro et al. (2004), and for Siemens MLC's by Samant et al. (2002) and Bayouth et al. (2003).

### 38.3.2 ALIGNMENT OF THE MLC TO THE TREATMENT MACHINE AXES

The MLC leaves must be aligned so that they are respectively parallel and perpendicular to the standard collimator jaws. In addition the centre of the leaf bank must be aligned with the central axis of the machine. This is principally an issue at commissioning, but with the Varian design where the leaves are mounted on a moving carriage it is possible that they may become misaligned during use. This can be checked on an occasional basis as described by Mubata and others (1997). When using a detachable mini MLC it is necessary to carry out this test each time the collimator is fitted. A rapid method of doing this is to set up a field in which the top left and bottom right quadrants of the field are open while the other two quadrants are shielded. A portal image is then taken, ideally using an EPID. After rotating the collimator through 180° a second image is taken. If using an EPID, this must then be added to the first image, but a film is simply left in place to record both images. The overlap of the two images indicates how well the MLC is aligned.

### 38.3.3 DYNAMIC LEAF MOVEMENTS

When dynamic leaf movements are to be used for IMRT it is necessary to verify the speed of movement of the leaves. If one leaf moves faster than is intended compared to the opposing leaf, the dose delivered will be either greater or less than intended depending on which leaf is moving too fast. Testing procedures involve trying to deliver a uniform dose to a film using different leaf speeds (Chui et al. 1996) or by measuring the dose delivered to an ionisation chamber by scanning a thin slit across the field (LoSasso et al. 1998, 2001; Chauvet et al. 2005).

Dynamic therapy carried out with a tomotherapy machine (see [Section 43.3.4](#)) has a number of additional special requirements which must be considered (Fenwick et al. 2004, 2005) including issues such as the ability to recover after a fault which occurs in mid treatment.

### 38.3.4 LEAKAGE BETWEEN LEAVES

Interleaf leakage is one of the important criteria in the design of an MLC (Jordan and Williams 1994). Where backup jaws are provided it could be argued that the interleaf leakage is less important, but at present only the Elekta machine is designed so that the backup jaws track the maximum leaf opening at all times. For the Siemens machine there are no backup jaws in the direction of leaf movement and for the Elekta *beam modulator* there are no backup jaws in either direction. For other MLCs it is usual for the main jaws to be left in a fixed position during IMRT treatment. MLC leakage is principally measured at commissioning, but it is also necessary to check from time to time that leakage has not increased due to wear (Hounsell and Jordan 1997). A procedure for measurement can be found in SFPM Report 40 (2003).

### 38.3.5 VARIATION WITH GANTRY ANGLE

The leaves in an MLC are heavy and it is potentially possible for a number of parameters to vary with gantry angle. These include leaf calibration, interleaf leakage and the speed of leaf movement. Occasional tests should therefore be carried out with the gantry at 90° or 270° and with different collimator rotations (Mubata et al. 1997; Hounsell and Jordan 1997). The dynamic slit test ([Section 38.3.3](#)) can also be carried out at different gantry angles (Chauvet et al. 2005).

## 38.4 FLATNESS AND SYMMETRY OF PHOTON BEAMS

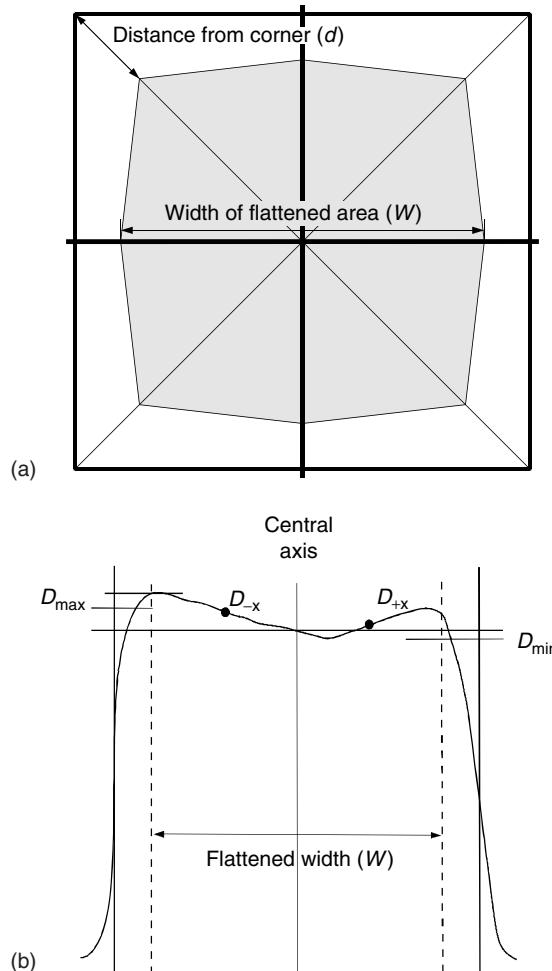

The flatness and symmetry specification according to the IEC (1989) is as illustrated in [Figure 38.7](#). *Flatness* is defined as  $F = D_{\max}/D_{\min}$ , where  $D_{\max}$  and  $D_{\min}$  are the maximum and minimum absorbed dose values in the central 80% of a dose profile in a plane transverse to the beam axis (the *flattened area*). Other definitions of flatness are used in some countries (e.g. NACP 1980).

For routine QC tests, it is normal to measure the flatness along the major axes of the largest field. These checks are usually combined with symmetry checks where *symmetry* is defined as: “The maximum value of the ratio of the higher to the lower absorbed dose at any two positions symmetrical to the radiation beam axis inside the flattened area” (IEC 1989).

When more extensive QC checks are made, for example post service and annual checks, it is advisable to extend the flatness and symmetry checks to include the diagonals of the largest field and all four major gantry angles (0°, 90°, 180° and 270°).

The most accurate measurement of flatness is made using an ion chamber in a water tank normally with the ion chamber at 10 cm depth (at 100 cm source-to-detector distance) and the surface of the water at 90 cm. However, this method is mainly used when rigorous testing is required and for annual QC.

A less rigorous method (which was used extensively in the Continuous Hyperfractionated Accelerated Radiotherapy (CHART) multi-centre trial QA program (Aird et al. 1995)) is to use a linear *in-air* scanner. The ion chamber is set into a block of water equivalent plastic. When this scanner is attached to the head of the accelerator it can be used at any gantry angle. The resulting profiles are very similar to those in water except for the edges of the beam that are not part of the definition of flatness.

**FIGURE 38.7**

(a) IEC (IEC 1989) definition of flattened area (shaded).  $W$  is 80% of the field width for field sizes between 10 cm and 30 cm. For sizes below 10 cm it is 2 cm less than the field size and for sizes larger than 30 cm it is 6 cm less than the field size. Along the diagonal, the distance from the corner,  $d$ , is 20% of the field width for field sizes between 10 cm and 30 cm. For smaller sizes, it is allowed to be 2 cm, and for larger sizes it is 6 cm. (b) IEC definition of flatness and symmetry. Flatness is the ratio of  $D_{\max}$  to  $D_{\min}$  expressed as a percentage. Symmetry is the absolute maximum value of the ratio of  $D_{-x}$  to  $D_{+x}$  (where  $D_{-x}$  represents the value of the dose rate at a distance  $x$  on one side of the central axis of the beam and  $D_{+x}$  is the dose rate at the corresponding point on the other side of the beam axis). The maximum asymmetry may be at any point within the flattened area, i.e. it will not be at the point indicated in the diagram.

Some centres use this principle of *in-air* scanning but with less build-up material above and around the ion chamber. The resulting profiles are different from *in-water* scans, mainly in having larger *horns* at maximum dose due to the measurement reflecting mainly primary radiation flux. This type of measurement is satisfactory provided the results are interpreted against base-line measurements made at the same time as water-tank measurements.

Similarly, when film is used to measure flatness and symmetry, the interpretation must be made with care, particularly because film is less accurate than measurement with an ion chamber. However, film does have the advantage of producing a 2D map of dose across the entire transverse plane of the beam.

Excellent diode or ion chamber arrays are now available to measure flatness and symmetry. In order to measure the whole field a linear array is needed, but for day-to-day use it is sufficient to measure only the central part of the beam with the (usually) smaller 2D arrays.

The Sun nuclear profiler allows two 20 cm square arrays to be bolted together to enable the whole field to be measured if required. Software for such devices allows automatic interpretation of the results in terms of the IEC measures of flatness and symmetry. An electronic device also allows the variation of flatness with time, as the beam stabilises, to be observed. This aspect can be very important for situations requiring a fast beam rise time, such as IMRT. Some multi-detector arrays have a detector at an increased depth (achieved in one such device using a stainless steel absorber) to have a simultaneous measure of energy.

The portal imaging device can also in principle be used as a quick check of flatness. There are some problems with this as portal-imaging software is designed to correct imperfections in the beam and it is usual for the imager to be calibrated to show a uniform field. For the purposes of a quick constancy check or if the manufacturer specifically supports this use it can be very convenient.

### 38.4.1 CONSIDERATIONS RELATING TO BEAM FLATNESS AND SYMMETRY

Flatness and symmetry are important parameters to maintain within tolerance as they can have a major impact on the accuracy with which treatment can be given. They are also useful parameters diagnostically when determining faulty functioning of the accelerator, particularly with bent beam machines. Although the monitor ion chamber with its associated electronics is intended to maintain flatness by servo control in these machines (see [Section 11.7.3.2](#)), the ion chamber currents and control amplifiers can drift.

The depth at which flatness is measured is important to consider. If the check is to be made against the specification of the machine or a base-line measurement made at acceptance, then it is normal to make the routine check at 10 cm depth. However, some low energy accelerators may be used mainly for head and neck treatments, in which case a depth of 5 cm for beam flatness may be more appropriate.

Any adjustments of flatness or symmetry that may be needed should be made in collaboration between the maintenance engineer and the physicist. It is important that they are aware of the interaction of the various beam control systems (centring, steering and energy) that will affect the flatness and symmetry. Protocols should be written as part of the QA system to ensure that adjustments are made in the correct order to avoid mismanagement of these important parameters.

When assessing the cause of a beam asymmetry, it may be useful to carry out a scan with the flattening filter removed, but care must be taken to restore the filter to normal position, and to check that this is in place, before returning the equipment to clinical use. With a computer controlled accelerator, removing the flattening filter can often be achieved by typing a command at the keyboard. The resulting scan will show clearly whether the peaked dose distribution is correctly centred and whether it is symmetrical.

---

## 38.5 ENERGY CHECKS

While x-ray beam energy can be specified in terms of nominal MV, this is not a parameter that can be directly measured. As discussed in [Section 18.5.5](#), beam quality is usually specified for dosimetry purposes in terms of the quality index or  $TPR_{20,10}$ . The percentage depth dose at a standard depth is useful as an energy specification for a particular accelerator type. The percentage depth dose is more easily related to the clinical data in a treatment-planning computer, but a measure related to the quality index may be easier to use as a quick check as it can be easily measured with high precision. Any convenient ratio of two ion chamber readings made with the ion chamber fixed but at two different depths can be used. The ideal system uses blocks of water equivalent plastic of 10 and 20 cm above the chamber (with at least 5 cm below the chamber) to measure the  $TPR_{20,10}$  directly.

### 38.5.1 CONSIDERATIONS RELATING TO BEAM ENERGY

Measurement of quality index is a very sensitive and very precise test of energy (reproducibility should be around 0.2%). However, it is unusual to observe changes in energy of greater than 1% unless the testing follows a major service when beam control currents have been altered. Beam energy changes will also be noted when flatness is measured, because the flattening filter is optimised for one energy. If flatness changes at the beam edge are observed—particularly significant if scans are made at  $d_{\max}$  instead of at 10 cm deep—it is very likely that the energy has changed.

---

## 38.6 QUALITY CONTROL OF ELECTRON BEAMS

### 38.6.1 ELECTRON FLATNESS AND SYMMETRY

The optimum way to study the flatness of electron beams is in a water tank. However, if flatness is to be measured regularly, possibly at various gantry angles, it is necessary to use a scanning jig (or array) rigidly attached to the treatment head, but normally with the measuring probe at a slightly extended distance, say 5 cm, from the end of the applicator. If an ion chamber is used in a water-equivalent plastic block at the depth of peak dose, the flatness profile is very similar to that in water. When changing beam energy, it is essential to remember to change the depth in the water-equivalent plastic to get the correct value for uniformity and symmetry. However, it is unusual for uniformity to change unless there is a large change in energy, so for routine measurements it is more important to concentrate on symmetry. This can be done using a compromise depth for several energies where the depth is always below or near the peak dose. The tolerance given by several groups is 3% for symmetry. The IEC definition of flatness refers to the ratio of the maximum dose in the field at the depth of dose maximum to the dose on the central axis rather than to the minimum dose (as in [Figure 38.7](#)). However, as pointed out by McKenzie in IPEM Report 81 (IPEM 1999), this does not satisfactorily deal with a situation where, for example, the dose maximum is on the central axis and the dose falls off rapidly at the beam edges. He therefore recommends that if the off-axis dose within the flattened area is less than that on the central axis the greatest difference from the central axis should be recorded.

### 38.6.2 ELECTRON ENERGY

Electron energy is of fundamental importance. It determines not only the treatment depth and depth of penetration of the electrons—which may be crucial when critical structures are close to the practical range of the beam—but also the ion chamber calibration factors used for absolute dose measurements.

#### 38.6.2.1 *Energy Selection*

In the typical radiotherapy linear accelerator, the energy of the electron beam is determined by filament temperature, waveguide frequency and bending current. For a 90° beam bending system (e.g. Philips SL75-type machines) the 90° bend was used as a spectrometer, so that only electrons of a narrow spread of energy around the nominal energy selected by the bending current would escape from the bending system. For achromatic bending systems other methods of energy control are applied (see [Section 11.3.6](#)).

Prior to selection by the bending magnet, the electron current (governed by the filament temperature) and the waveguide frequency are adjusted so that electrons reaching the drift tube and entering the bending magnet have approximately the correct energy.

The energy reaching the surface of the patient is modified by the various objects in the beam and at the edges of the beam as it traverses the treatment head and exits through an applicator. The only true measure of energy relevant to treatment is the depth ionisation or depth dose curve in a water phantom. The energy can then be determined using the Equation D.10 or D.11 respectively given in [Appendix D](#). Any check measurement used for QC must be performed on the same occasion so that a baseline can be established against the appropriate depth dose or depth ionisation curve.

### 38.6.2.2 *Quality-Control Energy Check*

There are various methods of checking energy constancy that use film or ion chambers. The simplest, that also gives an immediate answer not dependent on film development, is to use an ionisation chamber at 2 or 3 depths. It is not necessary to move the chamber between different depths since it is only the slope of the curve that is used to determine the energy, not the absolute depth dose. Using 3 depths can give more information and be more accurate. A further parameter that should be measured, at less frequent intervals, is the level of the contaminating bremsstrahlung at a depth beyond the electron range. Commercial devices are available with multiple detectors that give an instant reading of the energy.

Tolerance on energy can be critical. A 0.5-MeV energy variation will cause a depth dose shift of about 2 mm.

Each electron energy should be checked monthly at a gantry angle of 0°. In addition, energies should be checked annually at gantry angles of 90° and 270°.

### 38.6.3 APPLICATOR FACTORS

The measurement of applicator factors is more part of commissioning than QC, but more stress needs to be put on regular checking than is the case with photon-field-size factors, since there is more opportunity for electron-applicator factors to change. These factors are very sensitive to any change in material in the beam, such as the thickness of the plastic foil at the end of the treatment head, or to the position of the secondary diaphragms. A similar argument applies to electron end-plate factors. For most field sizes the ratio of the output at the standard calibration depth to the output at the same depth with the standard field (usually 10 cm × 10 cm) is sufficiently accurate. However, for small field sizes, especially for higher energies, it will be necessary to measure at the true position of dose maximum. These ratios should be checked annually, or following any maintenance or alterations to the head that might change the ratios. If there is uncertainty about this a quick check to decide whether to measure all sizes or not is to check the applicator or end-plate that gives the largest change. At the time of the annual check some checks of the depth of dose maximum should be made.

---

## 38.7 THE MEASUREMENT OF PERCENTAGE DEPTH DOSE

Measurements of percentage depth dose are also part of the commissioning process (see [Section 19.2.2](#) and [Section 19.3.2](#)). However, they must be repeated from time to time, especially after accelerator maintenance. Some hints are given below.

Depth-dose measurements are made in a large water tank in which all movements of the measuring probe are remotely driven. If the operator is unused to a particular tank it is vital to become familiar with its operation and to know how to set it up accurately.

The following is a minimum list of checks that should be made before attempting to measure percentage depth dose:

- The field size calibration should be checked (using film).
- Is the scanning mechanism rigid in the tank and does the depth movement move truly vertically?
- Are the scanning movements, particularly the depth movements, smooth and accurate?
- Has the calibration of the movement been checked?
- Is the tank set horizontally after it was filled with water? It is best to allow time (15–30 min or longer if the water is not at room temperature) after filling the tank for the support system to settle.
- The vertical scale must be set so that the zero position is correct with respect to the water surface bearing in mind the position of the sensitive volume of the detector.
- An appropriate correction should be made in the software for the effective point of measurement (see [Section 18.5.3](#)).
- The water will gradually change its level during a day of measurements as it evaporates and the tank settles further. It is important to check the surface distance periodically during the day.
- Is the appropriate detector being used? (Ion chambers are best for the reference photon depth-dose measurements, but otherwise diodes are satisfactory and provide better resolution. For depth dose measurements with electrons the most appropriate detector is an unshielded diode.)
- Is the reference probe at an appropriate position (i.e. giving sufficient signal but not interfering with the measurement by attenuating the beam)?
- Is the gantry exactly at 0° so that the beam is coming out of the head travelling vertically down?
- Use simple profile scanning at depths to check the beam path.
- Even when everything looks perfect it is important to test that the measuring probe moves vertically down to 30 cm or 40 cm.
- For electron beams with ionisation chambers appropriate conversions must be made between ionisation and dose.

When the percentage depth dose has been measured, the dose at particular depths should be compared to those recorded at commissioning. For electron beams, automatic analysis software will usually be available to extract significant values such as  $R_{85}$  and  $R_{50}$ , etc. (see [Section 24.2.2](#)).

---

## 38.8 OUTPUT MEASUREMENT

The measurement of radiation output and output stability is fundamental to the QC of treatment units. Absolute dose determination will follow a calibration protocol (e.g. IPEMB 1996a, 1996b; IAEA 1997a, 1997b, 2000a; Almond et al. 1999; Ma et al. 2001; Thwaites et al. 2003c) as discussed in [Chapter 18](#) and [Appendix D](#). The protocol must be followed exactly when carrying out the definitive calibration of the unit, but simpler approaches may be defined for the purposes of day-to-day calibration. In this section we consider the practical aspects of maintaining correct calibration.

### 38.8.1 STRATEGIES FOR QUALITY CONTROL OF TREATMENT UNIT CALIBRATION

Three different levels of calibration can be defined:

- Definitive calibration: where there is no link to a previous calibration so that there is a possibility that a serious miscalibration may go unnoticed. Examples of such situations are

when a new machine is commissioned, when a new monitor ionisation chamber is installed in the accelerator or a new source installed in a cobalt unit.

- Routine calibration: when the machine is calibrated using a procedure that provides traceability to a national standard.
- Constancy check: when a quick check device is used to establish that the machine output does not have a significant error.

Each of these situations will be considered in turn.

### 38.8.1.1 *Definitive Calibration*

In the U.K. the requirements for *definitive* calibration were laid down following an incident in which a cobalt source was incorrectly calibrated (Bleehen 1991; IPEM 2002). The calibration should be carried out by an experienced physicist, who should ensure that all other QC procedures that may have an impact on the calibration have been satisfactorily carried out. This is essential because parameters such as isocentre indication ([Section 38.2.1](#)) or beam flatness ([Section 38.4](#) and [Section 38.6.1](#) and also [Section 11.7.3](#)) can adversely affect the calibration. A national or international protocol (see [Chapter 18](#)) should be carefully followed and a dosimeter with a calibration traceable to a secondary standardisation laboratory should be used. The calibration should be repeated with an independent dosimeter and by an independent physicist, thus providing *defence in depth* (IAEA 2000b). The equipment used for the calibration should be removed completely between these two calibrations.

In the circumstances of a definitive calibration, the link with previous calibrations has been broken and it is therefore possible for a large error in the calibration to be made. Wherever possible appropriate cross checks should be made (IAEA 2000b). For example with a new cobalt source there will be a source certificate. The ratio between the quoted output for the old source and the standard calibration dose rate can be compared with the corresponding ratio for the new source. With a new accelerator it may be possible to compare the calibration settings in the accelerator with those of other accelerators of the same type. While these will probably not be identical they should be reasonably close. When no other cross check is available it is wise to make use of a mailed dosimetry service such as the thermoluminescent dosimetry (TLD) services run by the IAEA and ESTRO or the alanine service run by the National Physical Laboratory. Alanine has particular advantages being almost energy independent and having a calibration accuracy on the order of 1%, which is traceable to the national standard.

When deciding on a calibration protocol to follow it is advisable to follow the recommendations of the national professional body. These will have been made in conjunction with the national standardising laboratory and should be self-consistent. For example in the U.K. the National Physical Laboratory provide a calibration factor in absorbed dose to water as defined at the centre of the chamber at a depth in water. It would not be appropriate to include a correction for the effective point of measurement as specified in the IAEA air kerma based code (IAEA 1997a) when using a dosimeter calibrated in this way.

### 38.8.1.2 *Routine Calibration*

The second level of calibration is the routine calibration usually done at least weekly. This should be carried out in a way that allows traceability of the calibration, but may use a simplified set-up with appropriate corrections. Such corrections might include a correction for the use of a small PMMA phantom rather than a 30 cm cube of water. It is important that such corrections should not be arbitrary (i.e. it should be possible to estimate the correction factor from first principles) or significantly different from unity as otherwise there is the possibility for a systematic error. Staff carrying out such calibrations must have adequate training in the principles of dosimetry.

### 38.8.1.3 Constancy Checks

The third level of calibration is the *constancy check* that is usually carried out on a daily basis. This can be as simple as an instrument that shows a green light if the output is within the defined limits, but it is preferable to have a numeric output which will allow the monitoring of trends. The distinguishing factor of a *constancy check* is that a comparison must be made to the standard calibration method to establish the expected reading. This comparison should be carried out at the time of definitive calibration and repeated at appropriate intervals.

A number of constancy devices are available which may use diodes or ionisation chambers that can be rapidly placed in position. However, it is important that such devices should maintain their calibration with a degree of reliability as otherwise much time can be wasted in dealing with false indications that the treatment machine is out of calibration. Some would argue that it is very little extra work to perform a proper calibration with a thimble ionisation chamber rather than use a less precise method. However, many constancy check devices have more than one detector and can therefore provide information about the beam flatness as well. Following an incident in Poland where a power failure caused damage to a treatment machine the IAEA recommends that a constancy check should be carried out whenever an unexpected power failure occurs (IAEA 2004b) although it is acknowledged that the accelerator concerned did not meet current IEC requirements (IEC 1998).

### 38.8.1.4 Frequency of Checks

The frequency with which output checks are made varies from centre to centre. Most centres measure at least weekly. Each centre needs to review its findings regularly. If outputs are very stable then there is no need to change practice. If outputs seem to be drifting, more checks may be needed. In particular it may be important to investigate whether outputs are changing throughout the day. An action level of 3% is appropriate to use.

## 38.8.2 USE OF IONISATION CHAMBERS FOR OUTPUT CALIBRATION

Ionisation chambers are the most reliable method of measuring the dose delivered by a radiation beam and are the recommended instrument for this purpose. For absolute dose measurement in a photon beam, a chamber with a graphite cap is preferred. Each department should have a particular ion chamber and electrometer that is maintained as the departmental standard and calibrated against a secondary standard instrument with a calibration traceable to a standards laboratory. A strontium check source should be available for use with the chamber and this should be used to check its constancy on a regular basis whenever a definitive calibration is required (see [Section 38.8.3](#)).

Most ionisation chambers used in radiotherapy are unsealed, so measurements need to be corrected for temperature and pressure using the standard formula based on the *ideal gas* law (see [Section 15.4.4](#)):

$$\text{CF}_{T\&P} = \frac{101.33}{P} \times \frac{\theta + 273}{293}$$

where  $P$  is the pressure in kPa and  $\theta$  is the temperature in °C. Note that this assumes that the secondary standard dosimeter to which the chamber was compared was calibrated to read at 20°C. Care must be taken to ensure that the pressure used is the pressure at the height of the department and not corrected to mean sea level. A common practice is to ring the local airport to obtain a check of the pressure. However, this can lead to errors as the pressure may be different or be quoted at a different height and it is therefore better to use a properly calibrated aneroid barometer or a well-maintained Fortin barometer. It is also important to note that the temperature must be that of the chamber when it is placed in the phantom. If the phantom is kept in a cold cupboard and not in the treatment room, it is possible that there may be a considerable temperature difference, which is to be avoided. For accurate measurements, it is

essential that the phantom and chamber be allowed to reach room temperature before measurements commence.

### 38.8.3 PRACTICAL ISSUES IN PHOTON CALIBRATIONS

For the calibration of photon beams the chamber is placed in reference conditions as defined in the protocol. This is at a depth beyond the depth at which electron contamination of the beam can occur—at least 5 cm for energies up to and including 10 MV and 7 cm for higher energies.

There is no universal agreement as to how the accelerator monitor unit should be defined (see [Section 20.1.2](#)). Some centres choose to define 1 MU as indicating 1 cGy at the isocentre at the reference depth (10 cm) for a 10 cm square field. Another common choice is to define 1 MU as delivering 1 cGy at the depth of maximum dose with the phantom surface at 100 cm from the radiation source. Even if this definition is chosen, the measurement must still be made in the reference conditions and the standard clinical depth dose tables used to convert the dose measured at the reference depth to the dose at the depth of maximum dose. Some may be tempted to use a measurement of the percentage depth dose for calibration purposes that is independent of the clinical data; but this is not a good idea.

A linear accelerator is required to have a dual dosimetry system in which there are two independent measures of the machine output. One of these channels will be responsible for terminating the treatment and the other will be a backup. The two channels should be independently calibrated rather than made equal to each other. Occasional checks should be carried out that the second channel will terminate the beam in the expected way. If changing the calibration factor of one of the channels can only do this it is best to change the secondary channel rather than the primary. Such a check should only be carried out under very careful supervision.

The monitor ion chamber may either be sealed or should have a built in temperature and pressure correction\*. A sealed chamber may become unsealed and it is useful to compare both the fully temperature and pressure corrected reading with the uncorrected reading on a regular basis. If the calibration changes with the changes in atmospheric pressure it is a sign that the chamber has become unsealed. Recombination corrections (and polarity corrections for electrons) should also be applied to the readings of the measurement chamber (see [Section 15.4.1](#), [Section 15.4.2](#) and [Section 38.9.1](#)). If different dose rates are used, their influence on the monitor calibration must be assessed.

In addition to the weekly check, a check on the variation with gantry angle should be done at least annually with the variation between outputs at gantry  $0^\circ$  and gantry  $\pm 90^\circ$  not exceeding 2%. This should include checks of output factors with wedges. In addition a full calibration following the definitive calibration procedure should be carried out annually.

### 38.8.4 CALIBRATION OF UNITS CONTROLLED BY A TIMER

It is common practice for kilovoltage x-ray units and cobalt-60 units to be controlled by a timer rather than by a transmission dosimeter. Usually the dose rate will take a finite time to stabilise so that the dose delivered in 1 min will in general differ from the dose rate in mid exposure. This difference is called the *timer end error* (see [Section 10.4.2](#)) or, in the case of cobalt units, the *source-transit time* (see [Section 12.3](#)). Two approaches to the measurement of this correction are possible. In the dual exposure method the output dose is measured first for 1 min and then for 2 min. The instantaneous dose rate is then the difference between the two readings and the timer correction is the difference between the instantaneous dose rate

\* Some older units had unsealed chambers with no such correction. In this case the variation may be reduced by correcting the readings to the average room conditions.

(in cGy/min) and the dose measured for a 1-min exposure. It is essential when using this method that the electrometer is able to record the 2-min exposure using the same range as the 1 min exposure and that periods of exactly 1 and 2 min are used. In the second method, the beam is first turned on and then the dose delivered in a fixed period is measured using the start and stop buttons on the electrometer. For some electrometers the dose-rate range is directly related to the dose range and can therefore be used to make a direct measurement of dose rate with the beam on.

### 38.8.5 ELECTRON OUTPUT

For the reasons explained in [Part D](#), a plane-parallel chamber must be used for absolute electron measurements except at the higher energies when a cylindrical chamber can be used. Comparisons to an absorbed dose to water standard made at the NPL (du Sautoy et al. 2003) have resulted in a recommendation that only the Roos (Roos 1993) and NACP (Mattson et al. 1981; NACP 1981) chambers should be used for absolute dose determinations. It is necessary to ensure that the measurement is made at the correct depth and for this purpose it is useful to have a small water tank with a device to allow the chamber to be moved vertically by remote control. Making measurements in liquid water obviates the problems associated with charge storage in plastic phantoms. However, for routine calibrations a water equivalent plastic phantom selected to be water equivalent for electrons is convenient. This should be made of thin slabs rather than being a solid block.

Because of the rapid fall-off in dose with depth and because of the change in electron energy with depth which results in a change in the chamber calibration factor it is important that absolute calibrations are carried out at the correct depth as defined in the calibration protocol. However, for rapid checks of constancy it is convenient to use the same depth for a number of energies with a direct comparison being carried out to establish a *phantom factor*. For this purpose a cylindrical ionisation chamber may be used for all energies.

For small fields the depth of dose maximum may change significantly from the standard value for large fields and it is useful to be able to move the chamber remotely to find the depth of the maximum. The shape of the beam profile must also be considered as for small fields the dose often falls off towards the edge of the field. A chamber such as the Roos chamber may not be suitable in these circumstances because of its large area and it may be appropriate to use a Markus chamber that has a much smaller area.

At least each week a check should be made on the output for each electron energy used clinically. Some centres build this into their daily QC by measuring some of the range of available energies each day. The output check can be performed in a phantom that is also used for x-ray output checks so that no time is wasted changing phantoms and chambers. This can be achieved easily if the phantom is made of water equivalent plastic sections with holes at different depths and if a compromise depth, for example 1 cm, is used for all outputs. A standard 10 cm × 10 cm applicator is normally used. A combined calibration factor for the dosimeter and ion chamber should be determined for each energy on the same occasion that the definitive calibration was made with the appropriate ion chamber in water. It is important that a typical treatment level of dose is delivered, for example, 2 Gy or 3 Gy. The measured dose should be within 2% of the calibrated dose, although some centres use an action level of 3% (or even 5% for a daily constancy check).

---

## 38.9 CHECKS ON DOSIMETERS

### 38.9.1 IONISATION CHAMBERS

It is important to maintain regular checks and calibration data on all dosimeters used for output measurements or checks. Most ion chambers can be disconnected from their

electrometer (although it is preferable for routine checks to leave the chamber connected at all times). It is vital to have appropriate labels made showing the calibration factors for the ion chamber serial number together with its electrometer serial number.

Strontium-90 checks are useful on a regular basis to check the maintenance of the sensitivity of the ion chamber/electrometer combination. Six monthly checks of this nature should show a consistency of better than 1%. However, it is important to recognise that the sensitivity of a chamber to  $^{90}\text{Sr}$  beta particles may remain constant even when the sensitivity to photons, particularly at low energy, has changed markedly. Alternatively such checks could be made using a standard reproducible setup on a cobalt unit where available. In all cases, it is fundamental to correct the reading according to the decay of the reference source used (either  $^{90}\text{Sr}$  or  $^{60}\text{Co}$ ).

Cross calibrations against the secondary standard should be made regularly at between 1 year and 3 year intervals (or if any doubt is raised about a particular ion chamber and/or electrometer). At the time of cross calibration, checks of polarity correction, recombination correction and the stem effect should also be made. Measurement of recombination correction can be carried out with the dual polarising voltage method (Boag and Currant 1980; Weinhaus and Meli 1984), but it is advisable to verify that this works with the particular chamber by measuring at several different voltages—a linear plot should be obtained of the correction against the polarising voltage. The ion recombination correction is typically about 0.5%. This correction is only valid if the response of the ionisation chamber is close to linear with applied voltage. There is some evidence that this may not be the case with some parallel-plate chambers used at polarising voltages in excess of 100 V. Recombination corrections should, strictly speaking, be applied both at the time of dose measurement and at the time of comparison with the secondary standard. Alternatively if the dose rate (or dose per pulse) for the measurement will be the same the recombination correction appropriate to the secondary standard instrument can be applied to the field chamber at the time of measurement.

Visual checks and sensitive touch, of the thimble particularly, to ensure no breakage should be carried out before each use. Graphite thimbles have been known to crack when knocked and the crack only to become apparent some time later when the chamber falls apart.

### 38.9.2 THERMOLUMINESCENT DOSIMETERS

TLD can provide accurate dosimetry if an appropriate calibration method is employed. Details are contained in [Section 16.2.4](#). The calibration scheme adopted will depend on the accuracy that is required of the measurements. Whatever system is adopted, it is vital to handle TLD materials with great care and attention to detail. The light output will change considerably if the disc or chip surface is contaminated with grease or any other substance. Chips can easily be damaged and are best handled with vacuum tweezers.

TLD work is notoriously fraught with problems. For a particular use it is vital to adopt good procedures for handling, read-out and annealing at the start and refine the calibration process. Otherwise the source of error is very difficult to find, since there are so many possibilities. Some of the points to keep in mind and check are:

- Oven temperature for readout and anneal
- Cleanliness of TLDs and trays
- Care with storage of TLDs

### 38.9.3 DIODES

Issues that must be considered in connection with the calibration of diodes are described in [Section 16.3.4](#). Regular calibration is essential both for diodes used for patient dosimetry and for diodes used for QC measurements. Different calibration factors are required in different

situations—for example for entrance and exit measurements—but the relative values can be expected to be constant over a long period of time. However, the standard dose calibration should be checked on a regular basis whose frequency is determined by the amount of dose delivered to the diode. The temperature correction factor for diodes used for in vivo dosimetry should also be checked regularly\*.

Arrays of diodes may be used for beam flatness measurements either for photons or electrons. In these situations it is only necessary to verify that each diode in the array maintains its sensitivity and that any radiation damage affects each diode by the same amount. However, the amount of radiation received by the central section of the array will inevitably be much greater over a period of time than the total dose received at the edges of the array. A regular check that should be made is to measure a beam with an intensity gradient (produced, for example, by a wedge), then rotate the array through 180° and check that the outputs of the two array positions are identical. An alternative approach is to use a method that shifts the whole array by one detector distance. Dose per pulse may also affect sensitivity and should be checked. A more stringent check that should be made at least annually is to check the sensitivity of each diode by using a narrow beam of radiation.

When using a diode to measure depth dose in photon beams it is vital to check the sensitivity with depth, field size and energy since the amount of scatter of different energies varies with these parameters. It is advisable to compare these depth doses with those from an ionisation chamber on each occasion when fundamental commissioning data are measured. It is inadvisable to use diode depth dose data as the primary measurement for photon beams except where it is essential, such as for very small field sizes. There are no such reservations for electron beams where the response of diodes is almost constant for 5 MeV to 25 MeV beams. However, it is still advisable to check the corrected ion chamber depth dose against the diode readings for a range of energies.

---

## 38.10 PHANTOMS AND PHANTOM MATERIALS

The particular dosimetry protocol used will state the preferred options for phantom materials. For the U.K. protocol water is preferred and the minimum phantom size 30 cm × 30 cm × 30 cm. The chamber should be fitted with a thin waterproofing sheath made from PMMA and not more than 1 mm thick.

For plastic materials (mainly PMMA and polystyrene) appropriate corrections must be made. Water-equivalent-plastics made from resin-based materials should be avoided for definitive calibrations. They are acceptable for relative measurements including routine output checks. However, even for these checks care must be taken to use the same block(s) of water equivalent plastic for QC, since there may be variation in composition and density between blocks.

Most modern protocols point out the problems of non-water phantoms, but some of the problems to be aware of are:

- Density and electron density of material will affect depth dose, stopping power etc.
- Different scattering properties affect electron fluence build-up.
- Many of these plastics are insulators and exhibit charge-storage effects which can modify the measured ionisation. The effects are minimised by using phantoms made from a number of sheets rather than a solid block.

---

\* If diodes are used such as to require monthly recalibration, the temperature correction should be checked annually.

## 38.11 PORTAL IMAGING DEVICES

The QA of EPIDs used for verification of patient positioning and transit dosimetry should cover:

- Monitoring of the quality of image produced by such devices during the commissioning stage and their variations over time
- The monitoring of the mechanical aspects of the devices to ensure safety of patients and staff
- Checking the integrity of storage facilities for digital images

Procedures or protocols to monitor these three aspects of the electronic portal imaging system are necessary to ensure that the information obtained from the system is accurate.

With solid-state imaging systems, it is important to ensure that systems are in place to prevent irradiation of the electronics that can cause rapid deterioration of the images. Ideally, software to assist in this function should be provided by the manufacturer.

### 38.11.1 IMAGE QUALITY ASSESSMENT

A general definition of image quality addresses the effectiveness by which the image can be used for its intended task. The image acquired by the detector is a representation of the distribution of attenuating properties of the different structures of the human body or phantom under investigation. The performance of the detector is measured by the detectable contrast between these different tissues, the spatial resolution and detector noise. The performance of the EPID can be assessed by analysing images of known objects. The analysis can either involve the participation of human observers (subjective), or the use of mathematical models (objective) that are evaluated using computers.

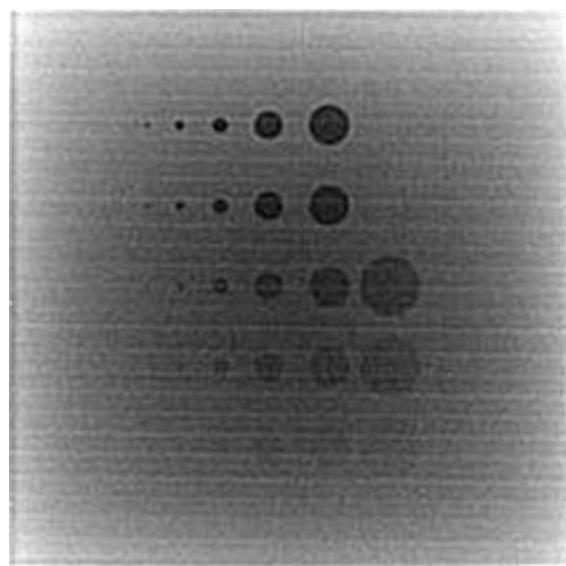

#### 38.11.1.1 *Subjective Image Analysis*

One of the earliest image quality testing tools was developed by Lutz and Bjarnegard (1985). The test tool consists of a series of objects with different contrasts. The evaluation process involves identifying which objects are visible. The contrast detail phantom of Harrison and Lambert (1994) or the “Las Vegas” phantom (Leszczynski and Shalev 1989) consists of a block of aluminium with holes of different diameters and depth. A typical image obtained with the Las Vegas phantom is shown in [Figure 38.8](#). However, unless specific software is being used, the analysis of images from these phantoms is not entirely objective. As one gets familiar with the hole pattern, it is easy to see holes that are not there. In case of direct visual analysis, a more comprehensive procedure requiring receiver operating characteristic (ROC) image analysis methodology (ICRU 1996) is required for the interpretation of the hole patterns in order to increase the objectivity of the results with the Las Vegas phantom.

#### 38.11.1.2 *Objective Image Analysis*

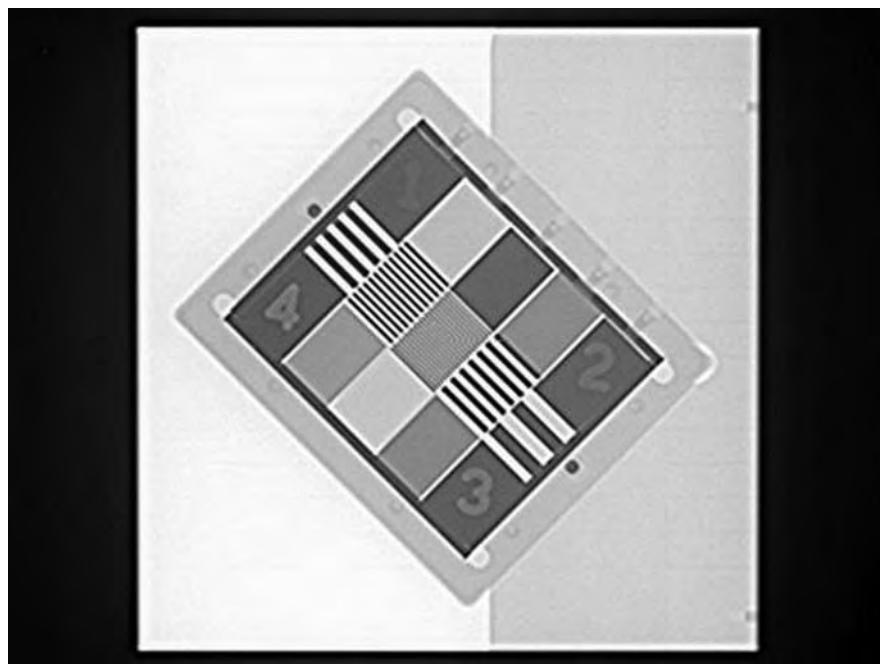

Shalev and others (1997) have proposed and designed a phantom that provides a totally objective test. The images acquired are analysed by a computer program and the results compared to the manufacturer’s specification or to a base line obtained at commissioning. The image quality index is therefore not prone to human perception.

An image obtained from a test phantom constructed according to this design is shown in [Figure 38.9](#). The phantom consists vertically and horizontally layered slabs of PMMA and lead of different thickness chosen to provide spatial resolution in the range 0–1.5 line pairs/mm, and contrast ranging from 20% to 80%, respectively. The phantom is placed on the detector at an

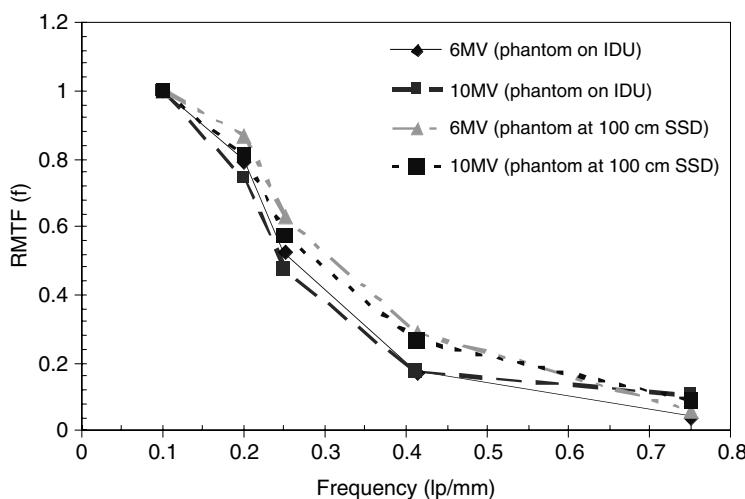

**FIGURE 38.8**

A typical image acquired with the "Las Vegas" phantom showing images of holes of different diameters and depths.

angle of 45° to avoid the artefacts associated with scanning electrodes in matrix chambers. Analysis of the images can be carried out using computer programs. Computer software such as PIPS of Shalev and others (1994), or in-house developed programs, can then be used to determine the frequency dependant square wave modulation transfer function (SWMTF) from which the frequency at 50% modulation,  $f_{50}$ , is derived. The SWMTF is determined by the

**FIGURE 38.9**

An image acquired with a test phantom constructed based on the Shalev and others (1997) design. The numbers 1–4 represent the regions with different lead and PMMA combinations to produce different contrasts. The spatial resolution is determined from the line pair patterns in the middle regions spanning lengthwise.

**FIGURE 38.10**

Typical RMTF curve for 6 and 10 MV photon beams, with the phantom at 100 cm SSD and on top of the image detector unit (IDU). The detector was positioned at 140 cm source detector distance.

MV method used by Droege (1983) and Rajapskshe (1996):

$$\text{SWMTF} = \frac{\Delta E(f)}{\Delta E_0}$$

where  $\Delta E_0$  and  $\Delta E(f)$  are the modulation input and output from the system. The above equation can be modified to obtain a relative measure of the modulation transfer function (RMTF), just for monitoring purposes, given by:

$$\text{RMTF}(f) = \frac{\Delta E(f)}{\Delta E(f_1)}$$

In this case,  $\Delta E(f_1)$  is taken as the highest output frequency modulation. The  $f_{50}$  is obtained from linear interpolation of the RMTF ( $f$ ) versus frequency data.

This modulation transfer function provides a measure of the spatial detail transfer characteristics of the imaging system. The analysis is carried out on the original image with no signal manipulation. A typical RMTF curve is shown in Figure 38.10, for 6 MV and 10 MV photon beams, obtained using the Varian liquid-ionisation-matrix chamber. From Figure 38.10, the  $f_{50}$  values of 0.278 lp/mm and 0.252 lp/mm for this detector can be extracted. Typical values for other detector types are shown in Part C, Table 14.1. The  $f_{50}$  values can be measured over a period of time to monitor the stability of the system using this simple and reproducible test.

### 38.11.2 MECHANICAL STABILITY

QC procedures on the image detection unit assembly depend on holder mounting design and partly on image processing software. Part C, Table 14.1 lists the mounting designs for some of the commercially available detectors. For detectors that have to be attached to the gantry temporarily when in use, such as the now superseded Philips SRI-100, QA checks have to be carried out on the integrity of the interlocking system. This has to be carried out at various gantry angles to ensure safety of patients. Reproducibility of the positioning of the detectors is only critical if the geometric centre of the image detector unit is used during image analysis. This may be more critical when the absolute output at every pixel position is required as in exit and transit dosimetry. The calibration in this case would be affected by beam characteristics such as flatness.

### 38.11.3 QUALITY CONTROL OF IMAGE DATA

Portal imaging devices require a comprehensive image handling system that is used to manipulate, store, import and export images. The images are stored on the system in lossless compressed format. The integrity of the stored and retrieved data can be checked by monitoring the pixel values for an acquired and stored image over a period of time. This can be achieved using the image analysis tools supplied with the system. A region of interest can be chosen and the statistical results obtained using the system tools and recorded over a period of time. There are other methods of checking the accuracy of file storage and retrieval such as performing checksums on the image files.

## 39.1 THE TREATMENT PLANNING PROCESS

### 39.1.1 DEFINITION OF TREATMENT PLANNING

The term *treatment planning* is often used in a restrictive manner to refer only to the production of isodose distributions associated with the choice of a treatment plan (*dose planning*). However, it is also used to describe the whole technical process, from patient data acquisition to treatment verification (Fraass et al. 1998). It is this second definition that is used here. The whole sequence of events is given, in a simplified form, in Table 39.1.

The sequence in Table 39.1 is subject to variations according to different practices. However, it is recognised as being the most consistent one, especially in conformal therapy (see Chapter 43.1) when one is aiming at a precise match between the shape of the target volume and the high-value isodose envelopes. It is often an iterative process since, in a number of instances, a correction to a previous step must be made as a result of a subsequent one. This is the case in the dose-planning phase when the beam parameters are subsequently modified to get the desired dose distribution. It is also the case when discrepancies are found at verification requiring review of some of the previous steps. The way in which this fits into the overall treatment process can be seen in Figure 37.1.

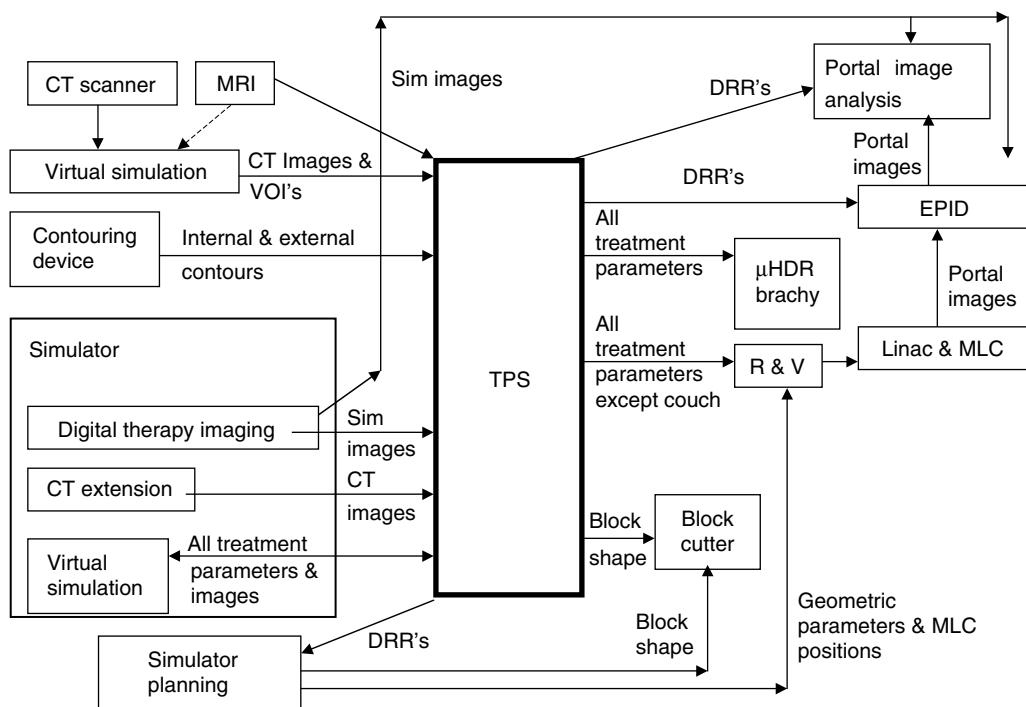

### 39.1.2 DATA EXCHANGE IN RADIOTHERAPY

The radiotherapy process involves the use of a number of different pieces of equipment, as listed in Table 37.2. For each piece of equipment, specific quality assurance (QA) procedures are designed as discussed in Chapter 38 through Chapter 41 but, in addition, special attention must be given to data exchanges between different pieces of equipment, such as shown in Figure 39.1.

**TABLE 39.1**

Main Steps of the Treatment Planning Process

- Patient positioning and patient data acquisition
- Definition of the treatment beams
- Calculation and evaluation of the dose distribution
- Verification before the actual plan implementation

**FIGURE 39.1**

Example of communication between equipment in a radiotherapy department (slightly simplified from a real department).

It is essential to ensure a coherent quality-control system for the whole treatment planning and delivery process.

### 39.1.3 QUALITY ASSURANCE IN TREATMENT PLANNING

A comprehensive QA programme for the whole process implies taking into account many constituents, such as definition of clear aims, appropriate staffing level and qualifications, definition of responsibilities, existence of detailed written procedures, etc. (see [Section 37.2](#)). The main issues discussed here are related to QA of the treatment-planning equipment. It must also be ensured that, for individual patients, errors due to wrong data input, incorrect interpretation of results, or inadvertent/undetected failure of equipment will not appear. Therefore, QA procedures related to individual plans must also be devised.

For further detail, the reader is referred to the American Association of Physicists in Medicine Report of Task Group 53 (TG53 Fraass et al. 1998), the Institute of Physics and Engineering in Medicine Report 81 (IPEM 1999), the ESTRO booklet on QA of treatment planning systems (ESTRO 2004) and the IAEA report TRS 430 (IAEA 2004a).

---

## 39.2 PATIENT POSITIONING AND ACQUISITION OF ANATOMICAL DATA

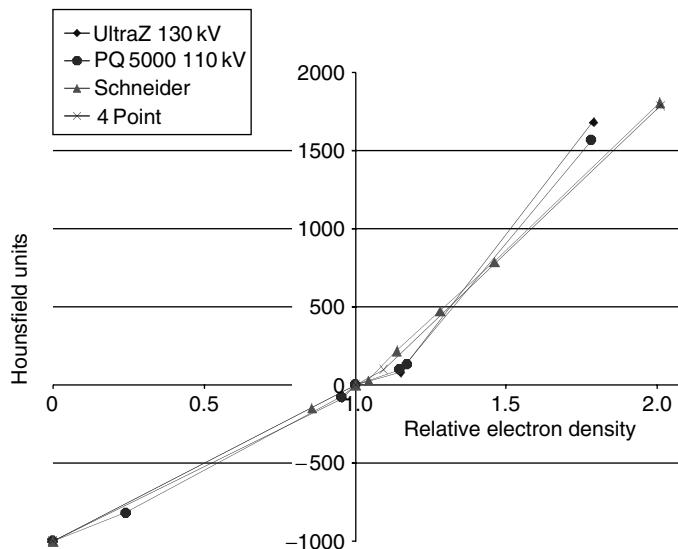

The importance of QA in this phase is often overlooked. Some of the points that deserve special attention for the consistency and accuracy of the planning process are discussed below. However, one crucial point is the interpretation of the patient data by the treatment-planning system (TPS), which will be discussed in more detail in [Section 39.3.5](#). Another important point is that the devices used for data acquisition have been properly calibrated.

### 39.2.1 QUALITY ASSURANCE OF EQUIPMENT USED FOR PATIENT DATA ACQUISITION

The equipment used for patient data acquisition has been described in [Chapter 30](#). The data acquired can be classified as providing geometric or density information.

If the anatomical data consist of a series of contours obtained from mechanical or optical devices, eventually combined with some imaging data for internal structure, the important point is to make sure that these contours have accurate dimensions within a tolerance range on the order of 2–3 mm. The simplest solution to check it, is to use a standard solid block of simple geometry and known dimensions (e.g. a cube or a cylinder), ideally including internal inhomogeneities, and to acquire the corresponding contour(s) and internal structures as if it were a patient. The shape and dimensions should be the same as expected within the stated tolerance.

If CT density data are to be used for inhomogeneity corrections, then it is necessary to carry out a calibration to establish the relationship between the Hounsfield Units (HU) and the corresponding tissue densities (Constantinou et al. 1992; Schneider et al. 1996; Guan et al. 2002). This relationship is somewhat scanner-dependent. It could also, to some extent, depend on the type and quality of radiation used for treatment: for high-energy photon beams, where the Compton effect is prominent for most patient tissues, one should preferably use the electron density instead of the mass density (see [Chapter 4](#)). For particle beams (electrons and protons), the relevant quantity for *density corrections* should be the tissue stopping power or scattering power coefficient (see [Chapter 3](#)). However, in most cases, the direct use of the mass density results in sufficient accuracy to correct the dose for patient inhomogeneities. To perform the CT calibration, one can use commercial phantoms in which a series of materials of different known densities are embedded. The CT console is used to measure the average HU in a representative area of each of these sample materials. Typically, a curve similar to the one represented in Figure 39.2 is obtained. Actually, this curve is normally linear between the density of air (used as a reference for  $HU = -1000$ ) and the density of water (used as a reference for  $HU = 0$ ). Therefore, this part of the curve is

**FIGURE 39.2**

Example of the density calibration curve for two different CT scanners. The curve attributed to Schneider et al. (1996) corrects for the real composition of bone compared to the phantom materials used to measure the curve. The four-point curve is a simplified representation of the data. (After Guan, H. et al., *Phys. Med. Biol.*, 47, N223–N231, 2002.)

independent of the scanner type and CT acquisition parameters. This is not the case in the upper region of the curve, which is much more sensitive to these parameters and even to the phantom size or sample position within the phantom. The reason is that for high-atomic number material (typically bone), some photoelectric effect takes place during CT imaging which depends strongly on local x-ray quality\*. Nevertheless, it is generally acceptable to consider that above roughly 100 HU, there is a second linear portion of curve with a steeper slope based on the average of measurements performed with bone equivalent materials.

Other CT parameters are important for ensuring an accurate patient reconstruction from a series of CT slices. These are essentially comprised of the following:

- Capability to reproduce actual dimensions of objects
- Absence of distortion
- Reproducibility and accuracy of slice position
- Accuracy of slice thickness
- Accuracy of gantry rotation and table swivel scales (preferably fixed at 0°)
- Alignment of laser positioning devices (if any)

The methods to check these points can be developed from the procedures used for mechanical checks of treatment machines and quality control of CT scanners for radiological purposes. Most of them are relatively simple to implement using simple solid phantoms with radio-opaque markers and performing appropriate measurements on the CT console display. The requirements are more stringent than for diagnostic applications, and the accuracy goal is typically between 1 mm and 2 mm or between 0.1° and 0.2° (Motic et al. 2003).

### 39.2.2 PROCEDURES FOR PATIENT DATA ACQUISITION

The patient setup at the time of data acquisition must be such that the same position can be used in further steps of the process, i.e. simulation (if any) and treatment. A distinction could be made between *immobilisation* devices, which aim to ensure that the patient does not move during the corresponding procedure but do not guarantee a reproducible setup, and *repositioning* devices, which help to restore the patient's position at the time of anatomical data acquisition. The use of skin markers, combined with the skill of experienced radiographers, is a more primitive, although often rather efficient, system for patient repositioning. Systematic pictures (i.e. taken with a digital camera) can also be quite helpful. Ultimately, devices such as stereotactic frames ensure both efficient patient immobilisation and accurate repositioning. In all cases, the devices used for treatment should be used also for patient data acquisition, including the table top of the imaging system which should resemble, as much as possible, the table top of the treatment couch and positioning aids such as laser pointers.

Patients' internal movements are also a potential source of inaccuracy. Techniques are developing to take these movements into account, especially for treatment in the lung area. This may be done either by using the *deep inspiration breath hold* technique, where the beam is delivered only while the patient is holding a deep breath under passive or active control of a spirometer, or by using free-breathing *gated radiotherapy*. For this latter technique, the respiratory movements are analysed by an appropriate sensor which triggers the irradiation when the organ position or cycle is within a given range (Ford et al. 2002; Ozhasoglu and Murphy 2002). In such instances, the patient data acquisition should be consistent with the average organ position in the beam-on cycle (see the Introduction to Part I). In the standard situation, the patients are asked to breathe normally, as they would do during treatment, in order to get data

\* For this reason, the higher-density inserts should be of equivalent chemical composition to the patient tissues that they represent.

representative of the whole patient anatomy in the treated region. In all cases, some evaluation of the magnitude of internal movements should be established in order to include them in the planning target volume (PTV) margins (see [Chapter 29](#) and [Chapter 30](#)).

Another potential source of inaccuracy is the use of contrast media that change the local tissue density when the images are acquired, but are no longer there when the patient is treated. If contrast media are considered necessary and if the dose calculation algorithm makes direct use of the HU information, some corrective procedure must be implemented at the dose-planning stage.

## 39.3 TREATMENT PLANNING SYSTEM

Bringing a treatment planning system into clinical use can be implemented in five phases:

1. Specification and purchase of the system
2. Assessment of the system for completeness against the specification
3. Commissioning the beam data
4. Testing the calculation accuracy and algorithms
5. Clinical implementation

Each of these phases will be considered in turn, but it is first necessary to be clear about the components of the system.

### 39.3.1 COMPONENTS AND FUNCTIONS OF A TREATMENT PLANNING SYSTEM

Computerised treatment planning systems have evolved significantly as computer technology has become more and more sophisticated. However, since the 1970s—when the first computer with real time display and graphics possibilities became available—the main components have remained essentially the same. They are shown in [Figure 39.3](#).

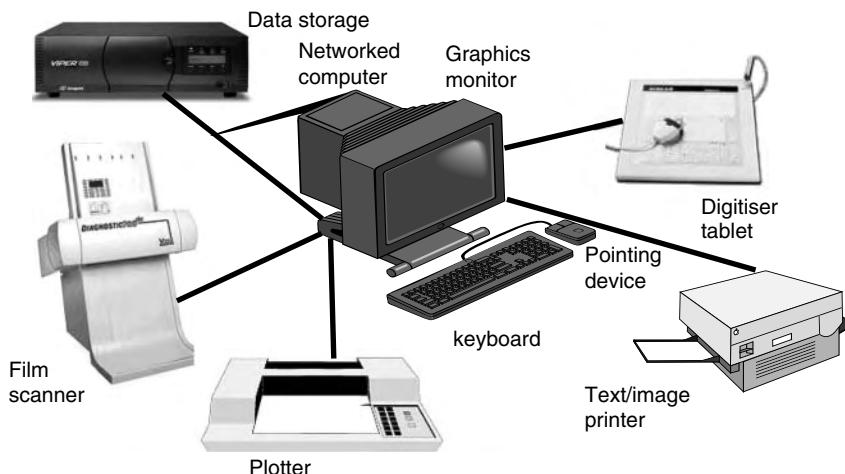

Besides the computer itself—which typically includes the processor, memory, and hard disk drive—a monitor is used to display contours, images, and dose distributions, allowing real-time interaction to perform the plan optimisation. The other pieces of equipment and their main characteristics are described below.

#### 39.3.1.1 *Curve Digitiser*

Curve digitisers are used for input of patient contours as obtained from mechanical contouring devices (see [Chapter 30](#)). They are also useful in defining the shape of the field from radiographs for dose calculation purposes, or for designing the actual field shaping (for transfer to a block-cutting device or to the controller of a multileaf collimator (MLC)). Typically, it should be possible to acquire curves with accuracy better than 0.5 mm. With the increasing use of digital images and networking solutions, curve digitisers are progressively becoming obsolete.

#### 39.3.1.2 *Film Scanner*

A high-quality film scanner used to be an essential part of a planning system, but images are increasingly available in digital format. The most important feature of such a scanner is geometric linearity. It is not recommended to use them to digitise CT images printed on films, since the images are often small and subject to geometrical distortion.

**FIGURE 39.3**

Main components of a typical treatment planning system. Most of the components shown in the figure can be networked and shared between several workstations. It is particularly useful to have a central patient database and a full connection to the rest of the equipment as indicated in [Figure 39.1](#).

### *39.3.1.3 Plotter/Printer*

Although most data and results can be archived on storage devices and displayed on monitors, it is still a common practice to use hard copies of the plans for easier transmission between the various people involved in the planning process and for filing purposes.

Various technologies are available, yielding differences in speed, image resolution, geometric accuracy, and stability. Some printers are limited to text, and others to text and lines (pen plotters). Many modern devices (e.g. inkjet or laser printers) support text, graphics, and images. They are controlled through appropriate drivers, and the compatibility with the planning software must be ensured.

As the paper printout is often used for direct geometrical measurements, the magnification factor must be known and should be controlled in both directions with accuracy better than 0.5 mm.

### *39.3.1.4 Storage Devices*

Three-dimensional (3D) image manipulation places great demands on storage capacity. Storage devices are evolving rapidly, and the more recent technologies offer a wide choice of solutions. It is necessary to clearly define the needs, both for data backup and for archiving. In assessing these needs, it is necessary to:

- Differentiate clearly between the short term (i.e. while the patient is under treatment) and long-term requirements, and to evaluate the relevant needs for storage and access
- Decide whether it is necessary to keep all images used for contouring
- Decide at what stage and in which format (e.g. original CT, treatment planning system format, compressed or uncompressed)
- Define the procedure to restore archived data (e.g. where direct access to the images is required or whether it is sufficient to restore backup versions when the images are needed).

Alternatively, a connection with a picture archive and communication system (PACS) could be provided.

### 39.3.1.5 Network Interfaces

More and more frequently, the treatment planning system is part of a network which consists of several consoles accessing a common dedicated server, with special protocols for data exchange with other pieces of equipment (see [Figure 39.1](#)). To have good communication between these various devices, it is essential to optimise the physical and logical characteristics of the network. It is, therefore, necessary to establish contact with the relevant specialists who are in charge of the hospital network and to make sure that the network infrastructure is adequate for the treatment planning system requirements. If necessary, a local network could be partially isolated from the general hospital network through proper bridges.

### 39.3.1.6 Software Functions

Besides the hardware components, the software is obviously fundamental to obtaining the required functionality. Originally, the functions of a treatment planning system were mostly limited to dose calculation for a given beam arrangement, taking into account the beams and patient characteristics. The requirements have been considerably expanded and now include a wide variety of features necessary for the preparation of a clinical plan. A list of the main features needed is given in [Table 39.2](#).

This table does not reflect the ease of use of the given features. A well-designed user interface is important. This should allow maximum flexibility to change any parameter at any time and immediately see the effect on the dose distribution.

Additional functions and tools are required: for instance, to prepare and check the basic beam data that are processed by the dose calculation algorithm in order to ensure consistency with the measured beam data.

---

**TABLE 39.2**

Typical Main Functions of a Modern Treatment Planning System

**Patient anatomy**

- Transfer of images from the CT scanner (and other imaging devices)
- Registration of images from different modalities
- Automatic delineation of the external surface of the body (for dose calculation)
- Automatic delineation of inhomogeneities and/or density mapping
- Manual or semi-automatic delineation of target volumes
- Manual or semi-automatic delineation of organs at risk
- Automatic addition of 3D margins around structures

**Beams**

- Manual or automatic beam positioning (coplanar, non coplanar)
- Manual or automatic delineation of beam aperture
- Inclusion of beam modifiers (blocks, wedges, bolus, compensators, etc.)
- Definition of beam contributions (beam weights)

**Evaluation/optimisation of the dose distribution**

- Dose computation for various points, planes and in 3D
- 2D isodose display with superimposition on anatomical images
- 3D surface rendering of anatomical structures and isodose surfaces
- Calculation/display of dose volume histograms for volumes of interest
- Calculation of biological indices
- Optimisation (i.e. inverse planning for intensity modulated radiotherapy)

**Aids for patient setup**

- Print-out and automatic transfer of beam parameters
  - Print-out and automatic transfer of individual shielding block shapes
  - Print-out and automatic transfer of multileaf collimator (MLC) settings
  - Generation and export of digitally reconstructed radiographs (DRR)
-

Another important issue, which will be discussed later (see [Section 39.3.4.2](#)), is the accuracy with which the treatment planning system reproduces the actual dose distribution within the patient, considering both the geometric and dosimetric uncertainties.

### 39.3.2 SPECIFICATION AND PURCHASE PROCESS

The acquisition of a new treatment planning system should begin with the careful preparation of a specification. This specification should form the basis of the assessment of the performance of the equipment and the design of the QA system. Different arrangements may be appropriate, depending on the local organisation, but in any case, it is essential to appoint a group of people to prepare the specifications of the future system. This group should be experienced in treatment planning and directly involved in the future use of the system. It could consist, for instance, of a physicist, a dosimetrist, and a radiation oncologist. The basic requirements should be identified in conjunction with the existing or foreseen imaging and treatment devices and with the present or foreseen procedures applied in clinical practice (e.g. conventional photon beams, electron beams, isocentric or fixed Source Skin Distance (SSD) treatments, arc therapy, beam modifiers, stereotactic irradiation, brachytherapy, etc.). [Table 39.2](#) is a useful reference to check the main characteristics that should be considered.

One must sometimes choose between a single multi-purpose treatment planning system and several independent systems dedicated to specialised techniques, such as brachytherapy or stereotaxy. While a multipurpose system may be a cheaper option, other important aspects must also be considered. The single system may be less well-adapted to the whole range of situations. There may be a requirement for a number of people to access different aspects of the system at the same time. This may be easier if there are dedicated systems or, conversely, a single system with multiple terminals may provide greater flexibility. There may also be an issue of accessibility. As a multi-terminal planning system expands, issues of maintaining and upgrading it without disruption can become more difficult.

Before preparing the detailed specification, it is useful to organise visits or demonstrations of some of the systems currently available on the market. It is then much easier to figure out what could be offered and to write specifications at the right level to cover local needs while also taking into account the existing commercial products.

As underlined in the AAPM Report of Task Group 53 (Fraass et al. 1998), creating the specification for a modern 3D treatment planning system is a huge task, and only some general guidelines can be given. The main items that should be considered are the following:

- Computer hardware description\*:
  - Number of consoles
  - Input and output peripherals
  - Connections with other equipment
  - Storage capacity and access for backup data and for archiving
- Software requirements:

These should be described with enough detail to avoid any ambiguous responses. Table 39.2 or the tables given in [Chapter 4](#) of the TRS 430 report (IAEA 2004a) can be used as an aide memoire. The details must be adapted to local requirements. The questions should normally be phrased to require a yes-or-no answer, but in many situations, it is also useful to allow for some comments from the manufacturer.

\* In most situations, it is not appropriate to specify a given type of computer or operating system, since the important point is to make sure that the system is capable of fulfilling its purpose, whatever technical solution is chosen by the manufacturer.

**TABLE 39.3****Functions Requiring Particular Attention in Testing**

Automatic delineation of structures
Automatic expansion of structures (margins)
Automatic isocentre positioning
Automatic field shaping
Dose calculation with shielding blocks
Dose calculation with inhomogeneities
Dose calculation with wedge filters
Dose calculation with asymmetric fields
Dose calculation with multileaf collimators

- Performance requirements:

Requirements such as accuracy or speed should be expressed in such a way that they could be actually checked by running an appropriate benchmark test.

An example of a list of requirements for a relatively basic treatment planning system can also be found in Appendix C of IAEA TECDOC 1040 (IAEA 1998).

It is not practical to conduct an exhaustive test of a treatment planning system before purchase, and it is, therefore, important that a sufficiently detailed specification of the requirements is prepared so that the manufacturer has a clear commitment to provide what is expected. The manufacturer or the vendor may be asked to conduct preliminary tests (following, for instance, the published benchmark tests) and to demonstrate them to the user during the purchase or the acceptance phase (ESTRO 2004). Typical areas in which detailed specification and assessment are necessary are listed in Table 39.3.

### 39.3.3 ACCEPTANCE OF THE TREATMENT PLANNING SYSTEM

Acceptance testing involves testing the function of the hardware and assessment of the system for completeness against the specification. It is unreasonable to expect to carry out a full evaluation of the system at this stage, but sufficient tests should be conducted to identify major deficiencies. It is also wise to test connectivity to other equipment at this stage, but it is unlikely to be possible to test the calculation accuracy unless the manufacturer is able to supply standard beam data for the published test data given in AAPM Report 55 (1995) or Venselaar and Welleweerd (2001). It is similarly important to check the documentation provided with the system. This must include comprehensive details of the data required and the algorithms used, as well as the standard instructions for use. These instructions must be read carefully, as a treatment planning system can produce unexpected results if not used in the intended fashion (IAEA 2001). The manufacturer must also provide appropriate training particularly of the physicist responsible for the planning data.

### 39.3.4 OBJECTIVES OF TREATMENT PLANNING SYSTEM COMMISSIONING

#### 39.3.4.1 Aim of Commissioning and Risk Analysis

Here, *commissioning* is understood as the steps required to prepare a new treatment planning system, a new software release, or a new set of beam data so that it may be used safely for patient planning. In contrast to the approach of IPEM Report 81 (IPEM 1999), the process of data collection and data entry into the planning system is treated as one process. Since there are many risks associated with the use of a treatment planning system, qualified and experienced staff must perform commissioning, and sufficient time must be allocated to carry out the whole process.

More and more frequently, the systems being sold and installed are subject to some kind of certification by accredited bodies. Examples are the Food and Drug Administration (FDA) system in the U.S.A. and the CE marking in Europe. Depending on local regulations, such certification is mandatory for clinical use. However, the testing required for certification is limited to ensuring that the system is well-documented and that it behaves as described. Such testing does not prevent large uncertainties or errors in local clinical practice (IAEA 2001). With the increasing complexity of treatment planning systems, not all situations can be covered, and computer glitches with severe implications can be found from time to time. Published recommendations often contain an exhaustive list of tests to detect possible problems. The author believes that, for commercial software, this extensive testing is primarily the responsibility of the manufacturer, with the help of clinical beta test sites (ESTRO 2004). Users should concentrate on the points where their own interaction can induce inaccurate or erroneous results. These are linked to parameter definition by the user on the one hand and to misinterpretation in using the software on the other hand. The full testing of in-house software or software which has not been released commercially remains the responsibility of the user. The possibility of undiscovered software programming errors (so-called bugs) will remain in spite of the most exhaustive testing, and a quality control system for individual plans is also necessary (see [Section 39.3.9](#)).

Any system requires some form of parameter definition. Some of the parameters are used only as *preferred options* and have no influence on the dose calculation. Some are fundamental, especially those related to machine and beam characteristics that must be consistent with the local data. The commissioning phase is the unique opportunity to adjust these parameters with great care and to check their value in terms of overall accuracy for a number of clinically relevant situations. This will be discussed in more detail in the following paragraphs.

Another aim of commissioning is to achieve a thorough understanding of the various functions of the treatment planning system and the underlying assumptions and limitations. It is also necessary to establish that the accuracy is within acceptable limits.

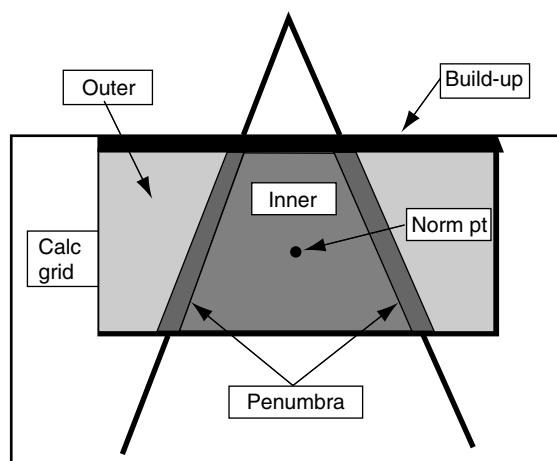

### 39.3.4.2 Accuracy and Tolerances

The accuracy of the planning system should be compared against an agreed-upon standard for both geometric and dosimetric accuracy. The goal is that the treatment planning system should not introduce significant additional errors to the errors already existing in the chain, starting from beam calibration and ending with treatment completion. This leads to figures which are typically between  $\pm 2$  mm and  $\pm 3$  mm for geometry and between  $\pm 2$  percent and  $\pm 3$  percent for doses (see [Section 37.4](#) and [Section 37.5](#)). However, the accuracy required depends on the clinical objective. For instance, a plan for a stereotactic case would be much more demanding than one for a palliative treatment. In addition, for practical reasons, it may be acceptable that a larger tolerance is accepted in complex situations or specific regions (see below). Ultimately, it is the user's responsibility to decide in particular circumstances if the results are clinically acceptable.

The appropriate tolerances for different regions of the beam have been considered in several publications (Van Dyk et al. 1993; TG53: Fraass et al. 1998; Venselaar et al. 2001; ESTRO 2004). It is generally agreed that the regions of the beam should be divided up as illustrated in [Figure 39.4](#) and described in [Table 39.4](#).

In defining tolerances as percentages, it is necessary to be clear about the definition of the normalisation (100%) point. For the dose at the normalisation point, the only sensible way to define the tolerance is in relationship to the measured (or expected) absolute dose for a given number of monitor units (MU)\*. At other points, a number of different

\* For a discussion of the definition of MU, see [Section 38.8.3](#) and [Section 20.1.2](#).

**FIGURE 39.4**

Regions of a single beam in for which tolerance levels can be set. More detail is contained in [Table 39.5](#). (From Fraass, B. A. et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 42, 651–659, 1998.)

choices become possible. TG53 (Fraass et al. 1998) recommends that all criteria be a percentage of the central-axis normalisation dose. Venselaar et al. (2001) suggest that this can lead to an unrealistically lenient requirement in areas of low dose. They recommend that the normalisation is to the local dose (i.e. the measured dose at the point of interest) for the inner region and to the dose on the central axis at the same depth for low-dose regions (i.e. outside of the beam limits or under shielding blocks). It will be seen that these definitions will result in significantly different values of the assessment criteria, even if the recommendations actually agree in principle.

Table 39.5 gives an example of the possible criteria, based on the table by Venselaar et al. (2001). In an ideal world, the tolerance should not depend on the complexity of the treatment, being instead based on the clinical requirements, but the widening of the tolerances is necessary in order to be achievable. Note that the tolerance in the outer region is similar to that in the central region if expressed as a percentage of the

**TABLE 39.4**

Description of Regions of a Beam as Shown in Figure 39.4

Region Name	Definition	Dose Level	Dose Gradient
Build-up region	Depth < dose maximum	High	High
Inner region	Central high-dose part of beam	High	Low
Penumbra region	5 mm inside and outside the geometric limits of the beam	High	High
Beam fringe	50–90% region of penumbra	High	High
Outer region	Outside the penumbra or areas where the dose is <7% of the central axis dose	Low	Low
Central axis	Centre of open field	High	Low
Normalisation point	Point at which absolute dose is defined	High	Low

Source: Definitions following Fraass et al. (1998) and Venselaar et al. (2001).

**TABLE 39.5**

Example Criteria for Tolerances

Region	Homogenous, Simple Geometry	Complex Geometry (inhomogeneity, wedge, asymmetry, blocks or MLC)	More Complex Geometries (more than one complexity)
Build-up region	2 mm or 10%	3 mm or 15%	3 mm or 15%
Inner region	2%	3%	4%
Penumbra region	2 mm or 10%	3 mm or 15%	3 mm or 15%
Beam fringe	2 mm	3 mm	3 mm
Outer region	30% (3%)	40% (4%)	50% (5%)
Central axis	2%	3%	4%
Normalisation point	0.5%	1%	2%

For the outer region, tolerances are shown as the percentage of the local dose with the percentage of the central axis dose in brackets.

Source: Adapted from Venselaar et al. (2001) taking into account also Fraass et al. (1998).

central axis dose. When a point is in a high dose gradient, it is appropriate to use a distance criterion.

### 39.3.4.3 Tolerance Specification in Non-Uniform Dose Distributions

In areas where the dose distribution is varying in an unpredictable way, such as with Intensity Modulated Radiation Therapy (IMRT) fields, it may be misleading to use a strict dose percentage criterion. In these circumstances, a combination of a dose criterion and a percentage criterion may be appropriate. For this purpose, the concept of the *gamma index* has been proposed (Low et al. 1998; Van Esch et al. 2002; Depuydt et al. 2002; Bakai et al. 2003). Here, the tolerance is expressed as the maximum distance to a point of agreement or the maximum percentage difference, whichever is greater. To determine whether a tolerance in terms of gamma is exceeded at any point, the calculated dose is first compared with the measured dose, and the difference ( $\Delta$ ) calculated. Next, the nearest measured dose point that matches the calculated dose is found, and the distance ( $\delta$  mm) to this point is calculated. A gamma criterion of 3% or 3 mm is met (i.e. the gamma index is smaller than 1) if  $\Delta < 3\%$  and  $\delta < 3$  mm. The mathematical definition of the gamma index by Low et al. (1998) and a comprehensive presentation of the possible solutions to express the deviations between computed and measured dose and illustrative examples can be found in the ESTRO booklet (2004).

### 39.3.5 GEOMETRIC ASPECTS OF TREATMENT PLANNING SYSTEM COMMISSIONING

The nondosimetric aspects of treatment planning system commissioning have often been neglected in the past. Since the publication of TG53 (Fraass et al. 1998), they are considered to be an important part of the commissioning process, especially with the development of conformal radiotherapy, in which geometrical issues are fundamental. The tests listed here are purely an indication and are not exhaustive. The principal benefit of going through these different tests is to explore the various functions of the software. This helps the user to understand the possibilities, limitations, and pitfalls, rather than to discover the bugs in the software.

**TABLE 39.6**

Examples of Tests to Check the Validity of Anatomical Data Entry into the Treatment Planning System

Item	Scope	Procedure
1. Digitisation of contours	Check scale and linearity	Digitise simple shapes of known dimensions. Measure these with the TPS ruler functions. Apply beams to the shapes and verify that their sizes are as expected
2. Identification	Check that image identification by the TPS is correct and unambiguous	Understand the identification structure of the imaging device (i.e. patient/examination/series/-image). Using all the available protocols, transfer images to the TPS and verify how these relate to the TPS image identification
3. Series of images	Check consistency	Generate a series of scans with mixed characteristics (e.g. duplicated slices, different field of view, different orientation, with and without contrast, etc.) and make sure that the TPS rejects, generates warnings, or processes the inconsistencies
4. Patient orientation	Check that orientation is correctly understood and processed by the TPS	Use a test object (e.g. a cube with engraved or protruding markers on different sides) and scan it in different patient orientations (e.g. supine/prone, head/feet first). Check how this is displayed in 2D or 3D reconstructions performed in the TPS
5. Geometrical representation of images	Check that there is no significant modification of distances or distortion	Compare the distances measured on the imaging console to those measured on the TPS using appropriate tools (a solid phantom of known dimensions could also be used) as in item 1
6. Tissue density for CT	Check that the density calculation by the TPS is consistent with original HU data	Compare original HU on the CT console to the HU measured on the TPS (preferably using a density phantom) and to the density derived manually from the HU to (electron) density curve (see <a href="#">Section 39.2.1</a> )

A number of these tests could be performed on dummy clinical cases as part of the training programme.

### 39.3.5.1 Anatomical Data

The suggested tests for the accuracy of anatomical data are summarised in Table 39.6. The general precautions to be taken during patient data acquisition have already been discussed in [Section 39.2](#). The object of these tests is to make sure that anatomical data are transferred and interpreted correctly by the treatment planning system.

During the planning process, these data are subject to further processing, which could be explored with tests such as those listed in [Table 39.7](#).

**TABLE 39.7**

Examples of Tests to Check the Processing of Anatomical Data

Item	Scope	Procedure
1. Delineation of structures	Check that the various options of manual or automated delineation give accurate results	Using either patient or phantom images, practice 2D contouring using the different tools available. Look at the position of the resulting contour overlaid onto the original image. Check known dimensions on phantom images using measurement tools. Analyse the behaviour for bifurcated structures (i.e. the same structure separated into different contours on a single slice)
2. Image reconstruction	Check if image reconstruction in planes, such as sagittal or coronal, is accurate	Using either patient or phantom images in which sufficient landmarks can be identified in each plane, check that distances are correctly reproduced and that the position of each plane is satisfactorily displayed. Check also the position of reconstructed contours in relationship to the reconstructed images
3. Expansion of structures (Volume growing)	Check that adding margins around a given structure is a 3D process based on actual values of these margins	Starting from a given simple structure, create other structures with either symmetric or asymmetric margins for different slice thicknesses. Look at the result in different reconstruction planes (e.g. a point-like original structure with symmetric margins should expand to a sphere). The volume obtained by applying four successive 10 mm margins should be the same as that obtained by applying a 40 mm margin in one step. A beam's-eye view is also a useful way of checking 3D margining
4. Bolus <sup>a</sup>	Check if the bolus coverage and thickness are correct and if they can be associated with individual beams	Use either patient or phantom data and create bolus of a given thickness. Check how it is displayed and how it affects the depth, SSD, and dose distribution of the associated beam(s)
5. Image registration	Check if images from different modalities can be merged within a single consistent patient model	Use either patient or phantom images with sufficient landmarks identifiable in both modalities to compare their position in the two series after registration. The comparison is easier if the two series are viewed in different orientations (e.g. sagittal and coronal). It can also be useful to have two data sets with a known geometric relationship

<sup>a</sup> Bolus can be considered either as an addition to the patient *anatomy*, or as a beam accessory.

### 39.3.5.2 Machine Parameters

The treatment planning system should model both the geometric and dosimetric characteristics of the treatment machine. These characteristics include:

- Machine identification, available energies and modalities, scale definitions, accessories, etc.
- Dosimetric coefficients and tables for each beam configuration.

These data are stored in the machine beam data library. Software should be provided to facilitate the construction, verification, and maintenance of these data. This section considers the geometric parameters; the dosimetric parameters are considered in [Section 39.3.6](#).

With the development of record-and-verify systems and networking, it is becoming more important to model the machine geometry exactly (see Section 41.1.3). If even one parameter is not correctly represented in the treatment planning system, it will not be possible to use digital data transfer. In spite of the efforts to reach an agreed-upon international standard (IEC 1996), there are still many departments where machines from different manufacturers, or even different generations of machine from the same manufacturer, have inconsistent scales. Depending on the treatment planning system, some degree of customisation will be possible. However, it can lead to confusion if a patient is treated on two differently-configured machines so that the scale conventions are different for different beams of the same plan\*. Some compromises may be required in order to achieve a consistent representation within the planning system. The major areas of difficulty are collimator jaw settings (especially in asymmetric mode), wedge conventions, and table rotations.

Another important issue is the definition of the allowed range for these various data. Ideally, it should be impossible to prepare a plan that cannot be implemented. Time will be wasted if a plan is prepared which cannot be achieved on the machine. A potentially more-serious problem is that a machine facility may be selected which has not been validated, resulting in an incorrect treatment. However, it may not be possible to reproduce the limitations of couch movements exactly as the exact position of the patient on the treatment couch can vary. Each machine parameter should be examined to ensure that it has been correctly set up.

### 39.3.5.3 Beam Definition and Representation

For an individual plan, beam parameters have to be specified, including the following:

- Machine, mode, and energy
- Treatment technique (SSD, isocentric, arc)
- Beam orientation and position
- Collimator settings, including MLC leaves
- Additional beam-limiting devices or beam-modifying devices

[Table 39.8](#) gives some examples of tests that should help to understand and check the treatment planning system behaviour for beam-related features. Some of these tests are relevant only if the corresponding technique is being used. More extensive testing may be appropriate where special techniques, such as conformal radiotherapy or intensity modulated radiation therapy, are implemented.

Although the primary aim is to investigate non-dosimetric characteristics, it is convenient to use the generic data supplied with the planning system to display the dose distribution

---

\* With modern machines, it is usually possible to change existing machines to the new scale conventions retrospectively. This may involve some physical changes, but if a record-and-verify system is in use software changes are very simple. The added convenience and safety will more than repay the effort involved.

**TABLE 39.8**

Examples of Tests to Check the Processing of Beam Data

Item	Scope	Procedure
1. Beam positioning	Test the various means to define the beam position and orientation	Use a patient or phantom model to position the beam using various techniques, with different beam orientations and positions. Check the graphical or numerical position of the entry point (on the skin) and the isocentre depth. Check that movement of the beam in the longitudinal direction is correctly represented, including for different slice thicknesses. Simulate non-coplanar beams and check the graphical and numerical display of table rotation
2. Collimator settings	Test the conventions used for collimator opening and rotation	For the different techniques and different SSDs, set a rectangular field of known dimensions and check the graphical and numerical display. Understand how the field size is defined (at what distance). Check maximum and minimum field sizes, symmetric and asymmetric modes, use of electron cones, etc. Check also how the display reproduces the changes induced by collimator rotation in different planes
3. Wedge filters	Test the wedge selection and orientations	Add a wedge to an open beam. Change the wedge orientation or rotate the collimator. Select another machine/energy while the wedge is on. Check changes in display and wedge identification
4. Conformal fields	Test the beam's-eye view design of field aperture	Prepare customised field shapes either manually or automatically, using the various available means (e.g. film digitising, manual or automatic contouring, editing of an existing shape), and check the shape and size of the resulting aperture. Check how it reacts to modifications of machine, technique, collimator rotation, distances, etc. Check how the information is transferred and used for construction of individualised blocks
5. Multileaf collimator (MLC)	Test the internal and external consistency of generated MLC files	From given explicit or virtual field shapes (i.e. automatically obtained from BEV projection of structures), generate MLC leaf positions for different leaf fitting options and collimator rotations. Check graphically that leaf positions are as expected. Test the minimum and maximum aperture limits, including rules about interdigititation. Check the relationship to the primary jaws. Check consistency with main jaws or backup jaws position
6. Beam weight <sup>a</sup>	Test the exact meaning of weight (generally associated with a <i>beam normalisation point</i> )	Investigate the meaning of beam weight for single and multiple beams. Establish how weights are related to total dose, fraction dose, and MUs. For percent and fractional weights, establish what is the associated reference value and whether beam characteristics such as wedge, shielding blocks and trays, inhomogeneities, etc. are included in the weight. Check the position of the beam weight (or normalisation) point and its relationship to the overall normalisation. Consider also the case of several weighting points in different slices

<sup>a</sup> This parameter is linked to the beam but it is also, strictly speaking, a dosimetric quantity. It has been however arbitrarily included in this list which deals with understanding how to handle the whole series of beam parameters.

for both photons and electrons, to check if it is qualitatively consistent with what is expected (see also Section 39.3.6.1). Furthermore, it is a good opportunity to understand the exact meaning of the planning system definition of beam weights and the relationship to the resulting dose distribution.

#### 39.3.5.4 Transfer of Beam Data to Simulator or Treatment Machine

If simulator or treatment machines are under the supervision of a *record-and-verify* system (see [Section 41.2.1](#)), it is important that the plans can be transferred directly from the treatment planning system to the simulator and/or treatment machine(s). Transfer from the simulator to the treatment planning system may also be possible.

Data transfer usually involves translation between the data structure of the treatment planning system and that of the treatment machine. This may involve user-defined data translation tables. In addition to establishing the physical connection between the two computers, it is essential to verify that all the parameters discussed in [Table 39.7](#) are correctly transferred. A major risk is that a systematic error will be made for all treatments on a given machine, rather than the occasional errors that might otherwise occur. Tests should include dose and MU parameters and MLC settings. It is important to vary these parameters within the clinically significant range to check the various interlock features. Checksum controls embedded in the transferred files have been found useful to confirm data integrity. This issue is discussed further in relation to the DICOM transfer protocol in [Chapter 42](#), Section 2.7 and [Section 4.2](#).

### 39.3.6 DOSIMETRIC ASPECTS OF TREATMENT PLANNING SYSTEM COMMISSIONING

#### 39.3.6.1 Qualitative Check of Dose Computation Features

Some testing of the dosimetric possibilities and limitations of the treatment planning system software can be carried out using *generic* beam data that should normally be supplied with the system. As mentioned in [Section 39.3.5.3](#), these data are useful to explore the treatment planning system functions related to beam definition and processing. They can also be used to assess the possibilities and limitations of the dose computation algorithm (Rosenwald 1995). For example, one can define a reference situation (e.g. using a flat semi-infinite water-equivalent phantom) and then change the phantom configuration or beam position to explore qualitatively if the expected change occurs in the dose distribution. This approach has been used successfully to assess the treatment planning system ability to correct for field blocking, missing tissues, or the presence of inhomogeneities (Simonian-Sauve and Smart 1998). Used in the framework of a European intercomparison, it has given unexpected results for systems that used dose algorithms believed to be sophisticated enough to handle relevant corrections (Panitsa et al. 1997).

Such investigations are useful to introduce the new user to the operation of the planning system, but can equally be completed by the manufacturer or by a users' group. If relying on such tests carried out by others, it is important to check that the same software version was used.

#### 39.3.6.2 Basic Beam Data and the Construction of the Beam Data Library

The central part of the commissioning process is the establishment of a complete beam data set corresponding to the local treatment machines and the validation of the treatment planning system representation of these data. This is the function of the beam data library and associated utility software.

The dosimetric data which are included in the library are very much dependent on the dose calculation algorithm (see [Part F](#)), and have as their basis the minimum set of experimental data

specified by the treatment planning system vendor. Even for fundamental models such as Monte Carlo algorithms, the basic experimental data will include depth dose curves (or tissue phantom ratios), off-axis profiles, and output factors. If not used as direct input to the algorithm, these data will be required to support the iterative process whereby dose calculation parameters (including energy spectra) are adjusted, until the computed doses match the experimental data (Starkschall 2000). Specific measurements may be required to enable the influence of the flattening filter, the shape of the collimating device, the transmission of blocks or trays, etc. to be modelled. The relative dose distribution must be linked to the absolute dose through the treatment time or MU calculation, and the appropriate data for this must be measured (see [Chapter 23](#) and [Chapter 26](#)).

A computerised 3D water phantom is essential to perform these measurements, and the data can be transferred as electronic files to the treatment planning system (see [Chapter 19](#)). However, it is important that the whole set of measurements is self-consistent and representative of the *normal* behaviour of the treatment machine. Some re-normalisation and smoothing of the data may be necessary to achieve this. For example, small asymmetries in the measured data should normally be averaged out.

The process of measuring, entering, processing, and checking the beam data is time-consuming. To assist this process, a number of software tools are required to enable interactive adjustment of the coefficients to yield an acceptable match between the experimental and the computed dose distribution. The most straightforward approach to comparing these distributions consists of superimposing plots of computed and experimental depth-dose curves and profiles with appropriate scales. As discussed in [Section 39.3.4.2](#), the associated tolerance levels are the responsibility of the user. Venselaar et al. (2001) have suggested that more stringent criteria (i.e.  $\pm 1\%$  tolerance) be used when comparing the computed depth-dose data or profiles to those measurements that formed the basis of the beam dose-model. They also defined an *upper confidence limit* as

$$\Delta = AD + 1.5 SD$$

where the average deviation, AD, is the average of the modulus of the difference between calculation and measurement for a number of data points and SD is the standard deviation of the differences. This methodology is sensible and the suggested tolerance values are realistic, but they may not always be achievable. The process of creating a beam model is dependent on the algorithm and on the degree to which the model can be controlled by adjustments of the various parameters. Because these parameters are generally interdependent, the final outcome tends always to be a compromise.

Great care must be exercised in carrying out this procedure, since the result will have a significant influence on the quality of all subsequent dose calculations. It must be conducted by well-trained staff who take full responsibility for the results. It must also be fully documented, since it will be used as a reference for future software releases or changes to treatment machine characteristics or accessories.

The number of basic measurements that are required to build the model is system-dependent. Measurements of dose distributions for rectangular fields and for different SSDs, collimation or beam modification devices, etc., may be required. If they are not part of the essential basic data, such measurements are still necessary to confirm the global validity of the dose calculations. These additional measurements are often called *reference data* instead of *basic data*.

### 39.3.6.3 Quantitative Checks for Simple Situations Using Reference Data

It is difficult to give precise recommendations for the extent of additional comparisons between measurement and computation. Some lists of cases have been suggested by various

authors (Van Dyk et al. 1993; Fraass et al. 1998; IPEM 1999) without convincing justification for their choice. Their approach was to cover the range of clinical situations as fully as possible but, in order to limit the workload (and so accept a larger uncertainty), a *minimum* subset of situations measurements was specified. However, commissioning a treatment planning system is not a task that can be satisfactorily achieved by following a predefined list of actions. The rationale for the choice of such comparisons should be based on the following: "Is there a risk that my beam data library, as used by the dose calculation algorithm, will cause discrepancies in situations which have not been explored during the model-building process?" Rather than being prescriptive, [Table 39.9](#) seeks as far as possible to answer this question. For this reason, the consideration of issues such as obliquity or inhomogeneity corrections has been excluded and will be addressed later (see [Section 39.3.6.4](#)). The items to test and the range of parameters should be chosen according to the existing or intended treatment techniques.

The format and the presentation of the measured data set (1D, 2D, 3D) is very much dependent on the tools and methodology used for comparison. Ideally, one would produce a series of 3D matrices of measured doses and have an automatic comparison with 3D computed dose distributions. Software tools may be limited to a series of 1D comparisons on the basis of depth dose curves and off-axis profiles, but the methodology is likely to evolve towards automated comparisons, using evaluation criteria such as the gamma index (Van Esch et al. 2002). Several automated 2D and 3D comparison tools using film or multiple diode dosimeters are becoming available (Jursinic and Nelms 2003; Renner et al. 2003; Létourneau et al. 2004). These are particularly necessary for IMRT dose distributions.

To assess the discrepancy between calculated and measured doses precisely, the comparison should ideally be in terms of absolute dose for a given number of MU. This approach—which includes, for example, the influence of the output factor or the transmission of accessories—is highly recommended. It can be implemented by calculating the MU required to deliver a given dose to the *weight point* and displaying the dose distribution as absolute dose per MU. However, the comparison of relative dose distributions (properly normalised) is easier to achieve and allows a better understanding of the reasons for discrepancies. The tolerance range could be the one suggested by Venselaar et al. (see [Table 39.5](#)). In that case, the additional discrepancy due to the MU calculation should be included in the assessment.

### *39.3.6.4 Quantitative Checks for Complex Situations*

Here, the phrase *complex situations* means those cases of clinical interest which can present significant discrepancies between computation and reality, but are not in principle influenced by the adjustment of the beam data library. Such complex situations include tissue inhomogeneities, loss of lateral scatter, and oblique incidence. It is, of course, of interest to recognise the limitation and inaccuracy due to the algorithm, and several approaches have been suggested:

- One approach consists of using an extensive published reference data set, together with all the data needed to build a beam data library (AAPM 1995; SGSMP 1997; Venselaar and Well-eweerd 2001; NCS 2006). The problem is then that the treatment planning system user would have to spend a huge amount of time adjusting the parameters of a beam data library that he will never use clinically. Such an approach is unrealistic for individual users, but could be carried out as a cooperative endeavour by groups of users of a given treatment planning system. Alternatively, the vendor could supply the corresponding beam data libraries, together with the series of test cases and ideally, with proper tools for analysis.
- Instead of using published data, the user could perform a series of measurements to create a similar data set for the same set of test situations as the published data. These data would then be consistent with the local treatment machines. However, such measurements are difficult, time-consuming, and perhaps unrealistic for most centres.

**TABLE 39.9**

An Example Reference-Beam Data Set

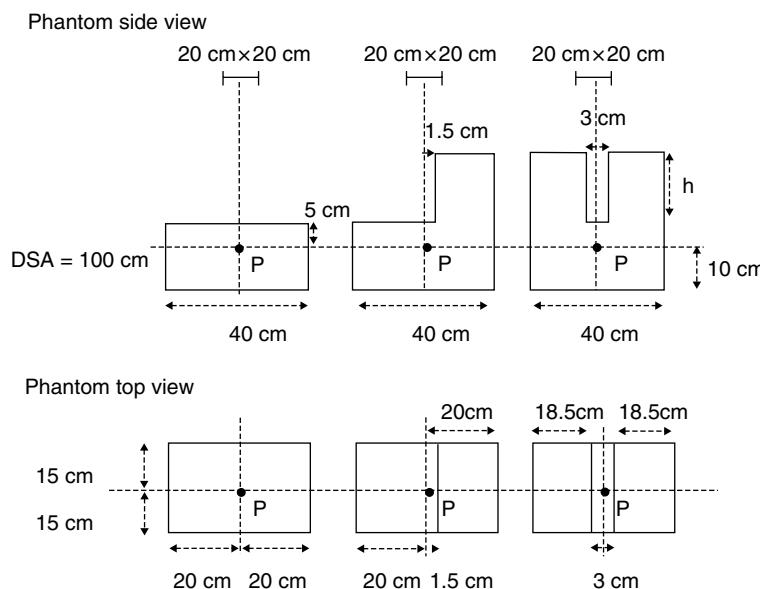

Item	Scope	Range and Analysis
1. Open fields (photons)	Check basic dose distribution and MU (or treatment time) calculation over clinical range	Minimum to maximum field sizes, including some rectangular fields. SAD and SSD technique, including extended SSD. Special attention should be paid to small fields Dose distribution in central planes or planes perpendicular to the beam axis. Variation with field size of the MU required to deliver a given dose to a point. Variation of MU with technique and distance
2. Wedges	Check dose distribution and MU (or treatment time) calculation for wedges (including motorised and virtual wedges)	Dose distribution with wedges for at least one field size (preferably the same range as for open fields). Special attention should be paid to larger field sizes with different widths and lengths Dose distribution in wedged and unwedged direction. MU calculation for different field sizes with and without wedge (inverse of wedge factor). Special attention should be given to the relationship between wedge output and field width and length for virtual wedges
3. Blocks	Check influence of blocks and tray	For each energy, dose under block for fields smaller and larger than block size, compared to dose without block Influence of tray (mostly MU calculation). Penumbra at the edge of block. Simplified mantle-type geometry could be used, making sure that blocks used for measurements are similar to blocks used clinically
4. Asymmetric jaws	Check influence of asymmetry on dose distribution and MU (or treatment time) calculation	For a limited number of asymmetric fields, dose distribution in central or perpendicular plane(s) Changes in MU for a given dose on the field axis, as a given square field is scanned from the centre to the periphery (including diagonal)
5. Multileaf collimator (MLC)	Check influence of MLC presence and shape on dose distribution and MU (or treatment time) calculation	Use some of the values for the open field, but delimited by MLC with 0° and 45° collimator rotation Dose distribution in planes perpendicular to beam axis. Penumbra region. Dose under the leaves, influence of main collimator, or backup jaws. MU calculation as for open field and asymmetric fields
6. Electron beams	Check dose distribution and MU calculation	Same as open field for photons, with special attention, if cones and inserts are being used, to the position of x-ray jaws Special attention should be paid to small fields

In both cases, if any significant discrepancy is found (provided that the experimental data are fully validated), the cause is a priori related to a combination of beam-library data (which have already been validated in the so-called simple situations) and the dose calculation algorithm (which cannot be changed by the user).

An alternative approach has been proposed by Caneva et al. (2000), in which the ability of the algorithm to deal with inhomogeneities, etc. is tested independently of the beam data. The principle is to quantify the dose perturbation resulting after a modification (mostly of phantom shape or composition) from a reference situation. By measuring the perturbation in a number of beams of different energy, it can be expressed as a function of the beam quality index. If there is a smooth variation, independent of the other machine characteristics, the correction factor for any beam quality may be inferred. It is then straightforward for any user to simulate the same reference and modified situations on their treatment planning system, compute the corresponding perturbation factor, and compare to the perturbation factor expected for the same quality index. This approach has been implemented successfully for photon beams and used for treatment planning system intercomparisons for missing tissue perturbation (Caneva et al. 2000), electronic disequilibrium after an air slab (Caneva et al. 2006), and penumbra enlargement in a low-density medium (Tsiakkos et al. 2004). This approach is illustrated in Figure 39.5.

Another possibility is to use a computed reference data set instead of an experimental one. Such a possibility, which is more and more attractive as Monte Carlo algorithms are developing, is especially useful in cases where measurements turn out to be inaccurate or impractical. However, as a preliminary step, a comparison between such dose calculations and experimental values is always required for the *simple situations* referred to above, where measurements are still mandatory.

Due to the difficulty of exploring these complex situations, in many centres this will not be included in the commissioning process. Instead, the users will generally rely on the QA system

**FIGURE 39.5**

Experimental configurations designed to investigate the modification of the dose at the point of measurement, P, when there are changes in phantom lateral scatter. A series of measurements is made once for each of the phantoms and for a number of beam energies. These data allow the ratio of each test configuration to the reference configuration to be determined as a function of the beam quality index and these ratios have been published. For a beam quality, it is then possible to predict the value of this ratio and to compare it to the ratio computed with a given treatment planning system. (From Caneva, S. et al., *Med. Phys.*, 27, 1018–1024, 2000. With permission.)

implemented by the treatment planning system manufacturers with the support of their beta test sites. However, it remains the user's responsibility to ensure safe treatment of the patients in their centre. Users should not embark on complex treatments unless they have been able to establish that adequate verification of their version of the planning system algorithm has been properly tested for that treatment configuration. This is particularly true for IMRT treatments (see [Section 39.3.9.3](#) and [Section 44.3.5](#)).

### 39.3.7 CLINICAL VERIFICATION

The last important step before allowing the treatment planning system to be used for clinical plans consists in conducting an overall verification of the whole chain.

If not done previously, this would start with phantom scanning or direct use of patient scans, including transfer to the treatment planning system. After that, a number of typical plans should be created which are as far as possible representative of the current clinical practice. This should be followed by data transfer to the external pieces of equipment (block cutters, milling machines, MLC, record and verify systems, etc.).

Overall verification of the absolute dose is particularly important. This consists, for instance, of preparing a plan for a simple phantom geometry, aiming to deliver a stated dose at a reference point (normally the *weight point*), and calculating the corresponding MU (or treatment time). The dose is then measured in the phantom and compared to the expected dose. Such measurements should be repeated for the various energies and for a significant range of beam parameters (especially with or without blocks, wedge filters, MLCs, etc.). Most planning systems allow a patient plan to be recalculated using a standard phantom, and it is convenient to use this facility for the first patients for whom plans are created on the new treatment planning system.

While performing the clinical verification, special attention should be given to the various displays and documents associated with the treatment plans. One should make sure, for instance, that the identification of all documents is unique and can be related unambiguously to the corresponding plan and the correct patient. The 2D and 3D dose distributions should be compared to ensure that they are consistent, together with the corresponding dose volume histograms (DVH). If there is any doubt, or if clinical decisions are to be based on the DVH, further tests can be conducted to assess the accuracy of DVH calculations, which are likely to be sensitive to such parameters as grid size, number of sampling points, or dose gradient in the investigated structure (Panitsa et al. 1998).

### 39.3.8 PERIODIC CHECKS OF THE TREATMENT PLANNING SYSTEM

#### 39.3.8.1 *Regular Quality Control Checks*

After the treatment planning system has been fully commissioned and is in clinical use, the user must remain vigilant. There is not much risk that a change would appear spontaneously. One must, however, recognise the risk of drift of input or output devices such as the plotter or digitiser, which should be checked periodically and recalibrated if necessary.

As far as the computer itself is concerned, it is likely (but not certain) that any file corruption will result in a program crash or other evident error. It is unreasonable to set up a time-consuming systematic quality control programme for an incident which is very unlikely and which could happen at any time. However, an automatic checksum verification can be carried out with little effort if the necessary software is available.

It is, nevertheless, good practice to prepare a number of typical composite plans (*reference plans*), taking advantage as much as possible of the various options and situations currently encountered in clinical reality, and to use them as a reference for further tests. It is then quite easy to *replay* them systematically at given intervals (say, every 6 months) or in case of doubt.

These reference plans are also very useful to trace the treatment planning system history during its evolution.

### *39.3.8.2 After Changes to the Beam Data Library*

From time to time, it is necessary to update the beam data library. The reason can be a major change, such as a new treatment machine installation, but it can be also the modification of an accessory (e.g. tray thickness) or a change in parameters to improve dosimetric accuracy. In any event, one must be very careful, since even minor changes have generated unexpected changes in the resulting dose or MU calculations. Ideally, a full recommissioning should be done, but this is unrealistic.

To avoid major errors, the reference plans referred to above can be repeated and any small differences between the original and the new version reconciled. Good documentation during commissioning is invaluable for this purpose. In any case, all changes to the beam data library and the results of the associated tests should be carefully documented and recorded.

### *39.3.8.3 After a New Software Release*

The problem is somewhat similar after installation of a new software release. In the case of a major release, it is probably necessary to go through many of the steps of the acceptance and commissioning process. Some simplifications could be acceptable; for instance, if the dose calculation algorithm has been announced as unchanged, and if this is confirmed for some of the reference beams, it could be assumed that it will be the same for the other beams.

The number and types of tests to be done is very much a question of personal appreciation of the risks associated with the software evolution. The detailed list of the changes that have been made from the previous version should normally be supplied with each new release. It is very helpful to tentatively identify the critical points that deserve further attention. However, this does not prevent unexpected errors elsewhere, since treatment planning system software is highly complex and contains modules which are very much interdependent.

Again, it is essential to document and record systematically what is done during and after each new software release. This could also be extended to hardware problems, replacements, or upgrading. Finally, one must be careful when starting the clinical use of a new release where it is highly recommended that qualified physicists follow very closely the plans prepared with the new version. They should also be responsible for ensuring that the local procedures are updated to conform to any changes in the software.

## **39.3.9 INDIVIDUAL PLAN CHECKS**

### *39.3.9.1 Rationale*

In spite of the QA programme set up by the manufacturer for the development of the treatment planning system, and in spite of the local commissioning efforts, there is a significant risk that some individual patient plans are erroneous. The two main causes of error are software error and data error.

A software error (bug) is likely to remain undetected until a specific sequence of operations leads to an untested part of the system. This will mostly happen when new people are using the software or when special clinical cases require the use of unexplored procedures or functions. In the best case, the system will crash and the error will be evident. In other cases, the plan will be completed but erroneous.

A data error will happen if an incorrect parameter is entered into the system. There are many causes for such errors, from a simple mistyping to an inadequate imaging procedure. The consequences of the errors can be very serious, and procedures should be implemented to try to

detect them. While a totally error-free system is unachievable, the risk may be significantly decreased by implementing systematic review of individual plans and by applying an independent method for the most critical data.

### 39.3.9.2 *Methodology*

The plan review should be carried out by experienced specialists, who have a deep understanding of the influence of the various parameters and of the expected dose distributions for clinical cases. The review can be conducted on the printed documents or using the computer display, provided that an electronic signature mechanism is available. For complex plans, reviewing the plan on the computer may be essential.

The reviewer should make sure that the plan version being checked is the final one which has been approved or (preferably) is about to be submitted to the responsible physician. The patient and plan identification should also be checked. The review mainly consists of scrutinising all the available data, checking their internal consistency, and comparing all the associated documentation. Special attention should be given to the beam parameters (including the presence of accessories), to the prescription values (dose, weights and weight point positions, normalisation, etc.), and to the graphical displays of anatomy, beams, and isodoses.

The MU (treatment time) calculations deserve special consideration, since they will directly affect the final dose given to the patient. For this reason, it is recommended that an independent dose calculation is performed. This calculation may be less accurate than the planning system calculation, but with experience, the magnitude of such differences is predictable. If an independent calculation is not possible, reference to a table of expected values may suffice.

Altogether, the QA of the dose planning process is very much a question of state of mind. In addition to well defined procedures, one should always be questioning the validity of what one is doing. Computer output in particular should never be regarded as immune from error. Special attention should be paid to any situation that is not standard current practice.

### 39.3.9.3 *Clinical Verification of IMRT Treatments*

The QA of IMRT is discussed in [Section 44.3.5](#), but it is important to contrast the QA of the complex situation described there with the considerations described in this chapter. The accuracy of IMRT treatments depends not only on the treatment planning system, but also on the treatment delivery (Kung and Chen 2000; Budgell et al. 2001; Dong et al. 2003; Budgell et al. 2005a). When calculating an IMRT dose distribution, a number of factors, such as small field dosimetry and MLC leaf modelling, become much more important than in standard therapy. In addition, there are often special parameters used in IMRT dose calculation that are not considered when standard plans are calculated. For this reason, the fact that the beam data library produces satisfactory results in the conditions described in [Section 39.3.6.3](#) is no guarantee of satisfactory dose calculations for IMRT beams. It is, therefore, recommended, at least until consistent accurate results are found in the centre, to check individual plans by comparison between the planning system computation and measurements. This can be performed for each modulated beam, applying the beam setting used for the patient (but with vertical incidence) to both compute the dose distribution at a given depth of a flat phantom and measure it (Van Esch et al. 2002). Another solution is to compute and measure the dose for all beams together, keeping the beam directions but using a simple geometrical phantom. Such plans where the patient is replaced by a phantom are sometimes named *hybrid plans*. It must be recognised that an individual beam which only partially irradiates the detector may give significantly different doses from those calculated (Woo and Nico 2005). The combination of beams will, in general, smooth the differences. However, even for such a combination, the phantom should approximate the shape of the patient, because if the

**FIGURE 39.6**

Delta4 phantom containing an array of diodes along the coronal and sagittal axes, used to measure 3D dose distributions in real time.

dimensions are very different, the relative contributions of the different beams may be so distorted that the dose is no longer uniform. It is a common experience that the measured dose differs for IMRT beams more than for standard beams (Low et al. 1998; Kung and Chen 2000; Mohan et al. 2000; Arnfield et al. 2001; Cadman et al. 2002) and a systematically low result by 1–2% has been reported (MacKenzie et al. 2002; Francescon et al. 2003; Budgell et al. 2005a).

There are two aspects to the verification of IMRT that are equally important: the absolute dose and the dose distribution. For the dose distribution, the position of the edge of the treated volume is particularly important, and film dosimetry is a convenient way of approaching this (Esthappen et al. 2002; Ju et al. 2002). Here, the gamma approach to simultaneous assessment of dosimetric and geometric accuracy is very useful (see [Section 39.3.4.3](#)). Software is available to compare the dose grid calculated by the planning computer with either film measurements or arrays of detectors (usually diodes). A new device (Delta4, manufactured by ScandiDos) has been developed under the EU Invorad project; it consists of an orthogonal array of 1069 diode detectors in a cylindrical phantom, enabling real-time measurements in three dimensions (see Figure 39.6). With this device, there is freedom to examine individual beams and the composite dose and to look at both absolute dose and the dose distribution all at the same time.

As experience grows with IMRT delivery, users will become more willing to use standard IMRT plans measured at regular intervals rather than individual patient dose measurements. Independent dose calculations are also now available to reduce the possibility of an unpredictable error in the treatment planning system calculation. However, in the initial phases of the introduction of IMRT, phantom measurements for a number of individual patient plans are essential. It is also essential to complement the quality control of the treatment planning system with detailed quality control checks of the linear accelerator. Leaf position accuracy (especially in relation to the other leaf of the pair) is particularly important, and for dynamic delivery, it should be tested in dynamic mode (Chauvet et al. 2005). For step and shoot delivery, the accuracy of dose for small numbers of MUs should also be checked. Niemierko (2004) and Budgell et al. (2005a) discuss the issues and criteria for transition from individual patient measurements to a system based on an independent calculation together with special machine quality control.

## 40.1 ELECTRONIC PORTAL IMAGING DEVICES

### 40.1.1 INTRODUCTION

The technology of electronic portal imaging devices (EPIDs) was discussed in [Chapter 14](#). The development of these devices has opened up new possibilities for quality assurance of treatment technique and for verification of treatment accuracy. The clinical usefulness of EPIDs depends on the availability of good quality images for analysis and the availability of methods of analysing the images obtained at the computer software level. The analysis should yield a quantitative verification of treatment quality. This verification may be in terms of patient positioning or dosimetry.

Here we consider the use of EPIDs for treatment verification. First, the use of image processing to enhance the information content in the image such that it may be used for treatment accuracy measurement is discussed. Then, the tools needed for investigations of positional accuracy are considered. Such tools allow the comparison of an electronic portal image taken on the treatment machine with a reference image. From this comparison, the positional accuracy of the treatment may be evaluated. Dosimetry with EPIDs is then discussed. Such applications often yield dose measurements or measures of patient thickness. Finally, other uses of EPIDs are considered such as in the verification of intensity-modulated treatments.

### 40.1.2 IMAGE ENHANCEMENT

Electronic portal images are generally of low contrast. This is mainly because the primary x-ray interaction process leading to image formation at radiotherapy treatment energies is Compton scattering. The cross-section for Compton scattering is proportional to the number of electrons available for scattering. For the low-Z atoms constituting biological material, the ratio of the atomic number to the mass number ( $Z/A$ ) is constant. Therefore, the scattering probability is proportional to the density of the material. This situation should be contrasted with that for lower, diagnostic energies, where the photoelectric effect dominates. The photoelectric effect has a very high  $Z$  dependence, leading to large intrinsic contrast (for a given dose and spatial resolution), particularly between tissues such as soft tissue and bone.

Because of this low intrinsic contrast, it is often desirable to apply image enhancement techniques to electronic portal images to extract or enhance important features in the images, which may then be used for image matching, as discussed in [Section 40.1.3](#). Image enhancement generally falls into three classes of operation, which will be described in the following sections.

#### 40.1.2.1 Point Operations

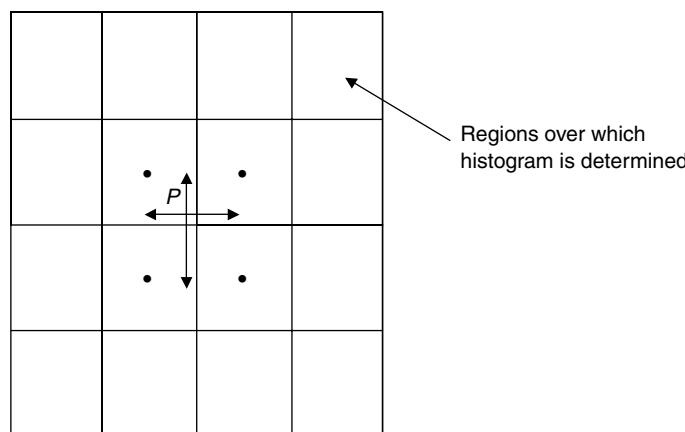

Point operations are carried out on the histogram of image intensities. The most common example is windowing or contrast stretching. The relationship between intensity in the measured detector signal and displayed intensity is modified to accentuate an intensity range corresponding to features of interest. The simplest form of this is histogram equalisation, in which the goal is to obtain a uniform histogram for the output image, i.e. the number of pixels is the same for each displayed intensity range.

There are various methods that have been developed, based on this technique, which involve analysis of the histogram of the image on a region-by-region basis. These are known as local histogram equalisations. One of the most common of these is the adaptive histogram equalisation (AHE) (Pizer et al. 1984). In this technique the image is divided into a set of square regions of typically  $16 \text{ pixels} \times 16 \text{ pixels}$ . The histogram of each region is determined. The transformation to equalise the histogram in each region is then computed. For each point in the image, bilinear interpolation of the transformations for the four neighbouring regions is used to determine the output intensity. This is illustrated in Figure 40.1. There are variations on this technique, which are often used in electronic portal image processing. These include contrast limited adaptive histogram equalisation (CLAHE), in which intensity levels above a predefined clipping level are reduced. The purpose of this is to prevent the overenhancement of noise (Leszczynski et al. 1992).

#### 40.1.2.2 Spatial Operations

Spatial operations are carried out on points or groups of points. Usually, a spatial filter is convolved with the image. The filter will usually be high-pass, low-pass, or band-pass.

Filters usually have kernel sizes of  $3 \times 3$  or  $5 \times 5$ . High-pass filters are generally used to enhance edges, such as those in bony anatomy. Examples are the Laplacian and Sobel filters. Low-pass filters are generally used to reduce noise in the image. Examples are filters that

**FIGURE 40.1**

Illustration of image segmentation and interpolation in adaptive histogram equalisation. The image is segmented into 16 regions in this example. The histogram mapping for the point  $P$  is determined using bilinear interpolation of the mappings of the four closest regions, illustrated with the arrows. The four large dots indicate the centres of the closest regions.

average the values of adjacent pixels, median window filters (in which a pixel is replaced with the median of the surrounding region) and Gaussian filters.

#### 40.1.2.3 Transform Operations

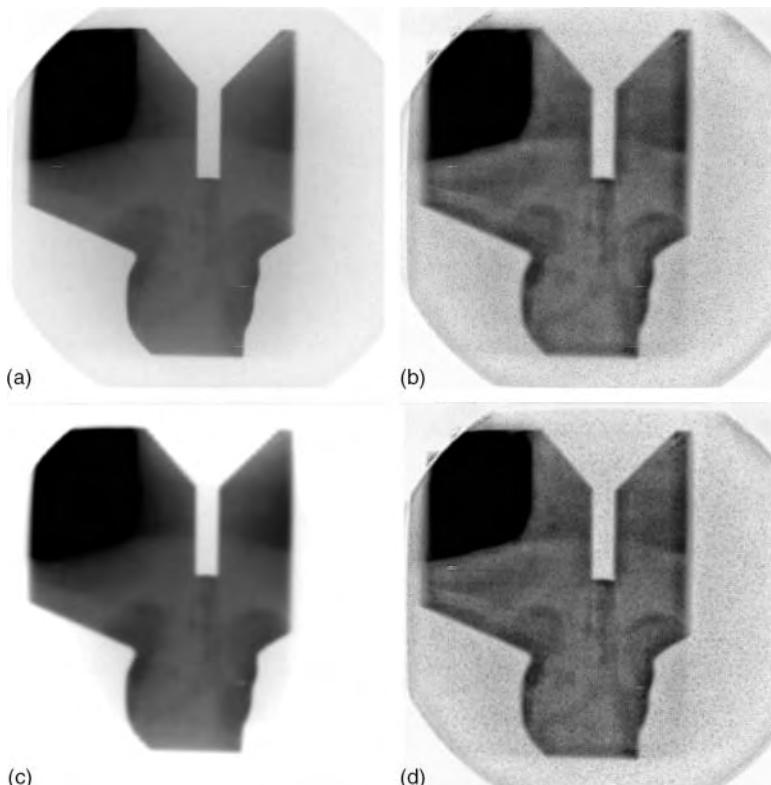

Transform operations involve taking a transform of an image and applying a filter to the transformed image. The inverse of the transform is then applied to yield a filtered image. The transform most commonly used is the Fourier transform. The frequency space filter used is generally a high-pass or low-pass filter.

Figure 40.2 shows an example of a mantle image with various filters applied to it.

#### 40.1.3 IMAGE COMPARISON TECHNIQUES

Measurement of treatment setups using EPIDs generally consists of several distinct steps or components:

1. A reference image must be established to define the *ideal* setup.
2. The reference image and the treatment image are analysed to find the field edge and important anatomical detail.
3. The images are compared and the difference in positioning of the anatomy relative to the field edge is measured.

**FIGURE 40.2**

Illustration of filtering applied to electronic portal images: (a) original image; (b) application of adaptive histogram equalisation; (c) application of a  $3 \times 3$  smoothing filter; (d) application of Sobel edge-enhancement filter in  $x$  and  $y$ . Note the similarity between (b) and (d); the Sobel filter enhances contrast by enhancing edges and the histogram equalisation boosts contrast between regions and hence edges.

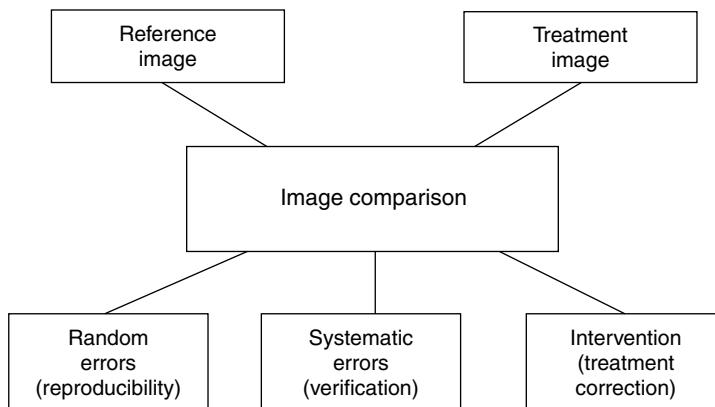

**FIGURE 40.3**

Illustration of the use of image comparison. A treatment image is compared with a reference image. The result is used to measure treatment reproducibility, for verification, or to correct treatment setup.

The results of such comparisons may be used in three ways:

1. *Treatment reproducibility can be measured* by comparing a series of images acquired at various times during the treatment course. The measured variations in patient positioning are often referred to as random errors.
2. *Treatment accuracy can be verified* by comparing a reference image with a treatment image. The measured differences between such images are often referred to as systematic errors.
3. *Treatment errors can be corrected* using intervention protocols. There are two ways intervention may be implemented. Each treatment may be corrected on-line. Alternatively, the measurement of the errors in one treatment may be used to modify future treatments.

The image comparison process is illustrated in Figure 40.3.

#### 40.1.3.1 Reference Images

The reference image will come from one of three sources:

1. *A treatment image* could be used either from a digital detector or from a portal film. Film should ideally be digitised, to enable simple and quick image analysis with appropriate software.
2. *A simulator image* may be obtained from film (again with the possibility of digitisation) or from an x-ray image intensifier. Image intensifiers generally suffer from radial distortion, given by the expression:

$$r' = r + Dr^3 \quad (40.1)$$

where  $r'$  is the radial distance of a point from the centre of the image intensifier field with distortion and  $r$  is the distance it would be if no distortion were present (i.e. its correct distance).  $D$  is a parameter describing the distortion. This distortion may be removed using a calibration process involving images of a test phantom containing a set of regularly spaced objects of known size and placement (Rudin et al. 1991). This distortion may well be dependent on the gantry angle used to obtain the simulator image\*. Distortion is not a problem with solid-state imaging panels.

\* The reason for the dependence of the distortion with respect to the gantry angle is the inevitable presence of the earth's magnetic field. However this may be compensated using corrective coils.

3. A *Digitally Reconstructed Radiograph (DRR)* can be computed from the CT data. Although simulation images are often taken as the reference for patient positioning studies, they clearly do not represent the true, planned position, since in effect a simulation setup is a special case of a treatment setup and hence prone to similar random errors as the treatment. The planned position is best represented by a DRR; a virtual simulation film generated from the treatment plan and the planning CT data (see [Section 32.4.5](#) for more detail). This also has the added advantage that it is digital in nature. However, the spatial resolution of a DRR is limited by the slice separation in the CT data set. Hence there is the need for closely-spaced slices to produce a clinically useful DRR.

#### 40.1.3.2 Field Edge Determination

The field edge is usually defined as the position of the 50% isodose contour. An estimate of this may be found simply by finding the 50% intensity level in the image (Evans et al. 1992). However, this will be inaccurate if the patient thickness varies across the field.

Other techniques developed include:

1. *A double exposure technique.* An image is taken of the treatment field. This is then divided by an *anatomical* image of a larger area of the patient. The net result is an image of the field edge (Meertens et al. 1990b).
2. *Histogram analysis.* The field edge may be defined as the region of maximum gradient. This corresponds to a minimum in the histogram. The histogram of the image contains several peaks and minima because of the various regions, i.e. the inside of the field, blocked regions and the area completely outside the field. A minimum corresponding to a first estimate of the field edge is found. The points in this first estimate are shifted to where the local gradient is maximal (Bijhold et al. 1991a).

#### 40.1.3.3 Field Edge Matching

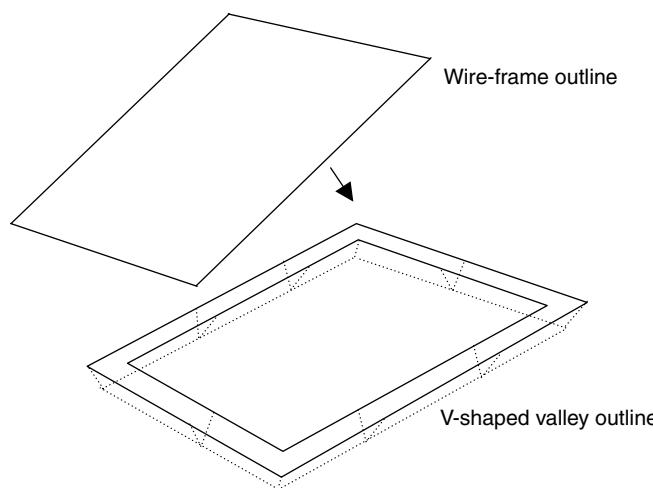

Various methods have been developed for automatic matching of field edges. Methods developed include the calculation of low-order moments in treatment and reference images. The images are moved and scaled until the moments match as closely as possible (Bijhold et al. 1992).

Another method involves the technique known as *chamfer matching* (Gilhuijs and van Herk 1993). In chamfer matching, the field edge in one image is turned into a wire-frame outline. In the other image, it is turned into a v-shaped valley, where the dips in the valley follow the contour of the field edge and the sides of the valley decrease in depth as distance from the field edge increases. The field edges are matched by fitting the wire-frame outline into the v-shaped valley. This is illustrated in [Figure 40.4](#). The v-shaped valley is often created from the reference image, as this is available before treatment and thus may readily be processed prior to treatment. The field edge in the treatment image is generated using one of the automatic methods described above.

The techniques described above produce numerical results describing the goodness of fit and thus may be used to detect gross field definition errors, such as the misplacement of a block. For such an error, the moments will not match very well and the residual root-mean-square distance between points will be large.

#### 40.1.3.4 Segmentation and Matching of Anatomy

Electronic portal images are generally of low contrast. Thus the process of segmenting them is far more difficult than that of finding the field edge. Both manual, operator-dependent and automatic methods have been developed. Some image matching techniques involve no

**FIGURE 40.4**

Schematic illustration of chamfer matching. The best fit of the wire-frame into the v-shaped valley is determined.

formal segmentation step. Hence, in the following discussion, we shall consider segmentation and matching of anatomy together.

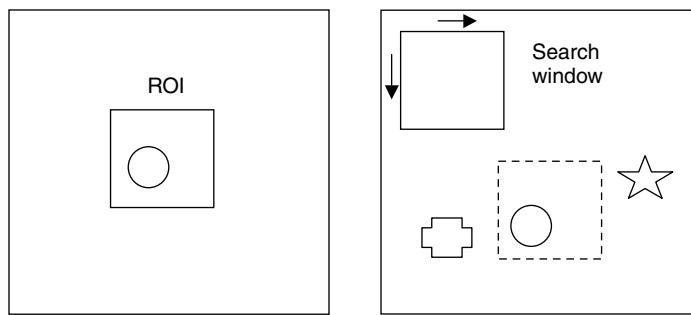

EPID images are, of course, two-dimensional, while the patient is three-dimensional. The differences in patient positioning between one imaging session and another (be they different treatments or a simulation and a treatment) are describable by six degrees of freedom, three translations and three rotations. Three of these, the two translations in the plane of the imager and rotation in the plane of the imager, are easily measured from portal images taken of each field. Translations in the plane perpendicular to the imager will show up as magnification changes. However, the sensitivity of the magnification to out-of-plane translations is very small. A large translation is required before the magnification changes significantly. The other two degrees of freedom, rotations out of the plane of the imager, result in spatial distortion of the image (Bijhold et al. 1991b). In general, it may be difficult to distinguish between such distortion and the effects of patient motion during treatment.

The first image matching method involves the use of fiducial reference markers, which are drawn on the prominent features on one image and the corresponding points in the other (Meertens et al. 1990a; Halverston et al. 1991; Evans et al. 1992; Bijhold 1993; McParland 1993). A method such as singular value decomposition (SVD) (Balter et al. 1992), is then used to find the transformation to achieve the best match between the points. This is usually expressed in terms of translation and rotation in the plane of the image and magnification out of the plane of the image.

Template overlays are sometimes used (Bijhold et al. 1991b; Evans et al. 1992). A wire-frame diagram is drawn around the anatomy in the reference image and either matched on the treatment image or the corresponding template from the treatment image.

The third set of methods falls in the category of visual registration. A two-image movie technique has been used. The treatment image is interactively translated and rotated relative to the reference image, until the best fit is obtained. A difference image technique has been used to compare two treatment images (Evans et al. 1992). Coloured overlays are used to indicate regions of significant intensity difference. One image is rotated and translated until the coloured region inside the field is minimised. Colour overlays have been used in which, for example, one image is displayed in green and the other is displayed in purple. If two maximum grey level regions in both images become superimposed, they appear white (Weinhous 1990; Bijhold et al. 1991b; Graham et al. 1991).

Various automatic image comparison methods have been developed. Gilhuijs and van Herk (1993) described a fully automatic method of segmentation and matching. Firstly, the

**FIGURE 40.5**

Illustration of correlation technique. On the left is a reference image with a region of interest (ROI) drawn around a feature (a circle in this schematic example). On the right is a treatment image. A search window is scanned across this image and the correlation with the ROI in the test image calculated. The best fit occurs when the correlation is maximal (dotted window).

positioning of anatomical edges is found in the reference image. The anatomical edges in the treatment image are then automatically extracted using a morphological transform that looks for features of a certain size and shape. Then chamfer matching is used to register the images as described above. They found their automatic method to yield a success rate in excess of 90% (Gilhuijs et al. 1995).

Jones and Boyer (1991) described a correlation technique allowing for automatic image registration (Figure 40.5). They found their technique to be most effective for most values of translation and small rotations in and out of plane. Other groups have developed similar techniques. In one such technique, the operator selects pairs of features in the reference and treatment image. A correlation technique is then used to register these pairs of features. The centres of the features are then taken as match points for use in the fiducial reference marker technique described above (Moseley and Munro 1994).

#### 40.1.3.5 Measurement of Setup Errors

Once the field edge has been found and the anatomical detail delineated, one of two approaches may be used to calculate the setup error. The field edges may be aligned first and the residual displacement in anatomy equated to the setup inaccuracy; or the anatomy may be aligned first and the positioning of the field edges analysed.

If the first method is used, the quality of fit in the field edge matching procedure must be good; otherwise, the subsequent matching of anatomy will be prone to error. The transformation to match the field edges is also applied to the anatomy. Any residual difference in the positioning of anatomy between the two images is interpreted as a setup error.

If the anatomy is matched first, then the transformation parameters are used to register the reference image and the portal image. Any residual difference in field edge positioning is a setup error. It is important that the anatomy matching stage be accurate. Often the delineation of anatomical landmarks is difficult. Furthermore, image distortion and out-of-plane rotations will lead to inaccuracies.

#### 40.1.3.6 Accuracy of Analysis Techniques

The accuracy of setup error measurement is limited by the accuracy of the techniques presented in [Section 40.1.3.4](#). The determination and matching of the field edge should be highly accurate and reproducible, however, many of the anatomy matching methods require user interaction and thus are subject to inter-user variability.

Meertens et al. (1990a) studied the dependence of the technique using fiducial reference markers on the location of the markers. They found that the reproducibility of the results depended strongly on how far apart the markers were located. If the markers were too close together, then the small discrepancies inevitable in the identification of the markers by different users result in large uncertainties in the rotation required to match them.

Evans et al. (1992) tested several algorithms and found reproducibility of less than 1 mm and 1° for the fiducial reference marker, template overlay and visual registration techniques in a phantom study. For clinical images, only the visual registration technique remained reproducible to within 1 mm and 1°.

Michalski et al. (1993) tested the fiducial reference marker and template overlay technique. They found both methods to be reproducible to within 1 mm and 1° for phantom studies. For clinical images, they found the single user variation to be as small, but the multiple user variation was up to 2 mm and 3°.

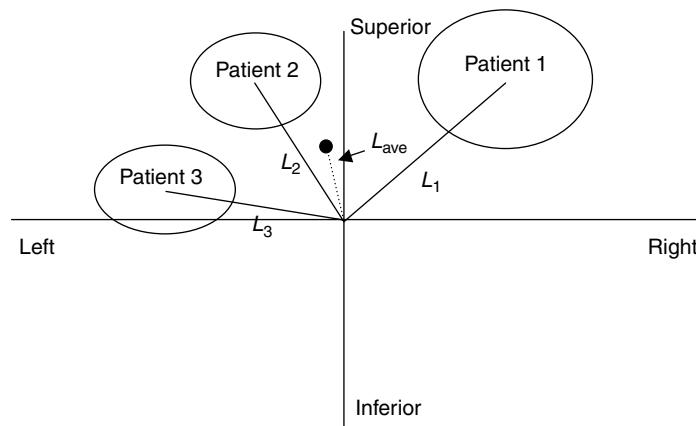

#### 40.1.3.7 Visual Inspection of Images

The methods described in Section 40.1.3.4 are all designed to measure the transformation to match treatment and reference images. However, much information may be obtained by visual inspection of images. For instance, a gross error due to the misplacement of a block will be shown. A set of images may be displayed in a movie loop. This may provide quantitative information on day-to-variations in setup and variations during the course of a single irradiation, due to breathing, etc. (Reinstein et al. 1992).

#### 40.1.3.8 Interpretation of Position Measurements

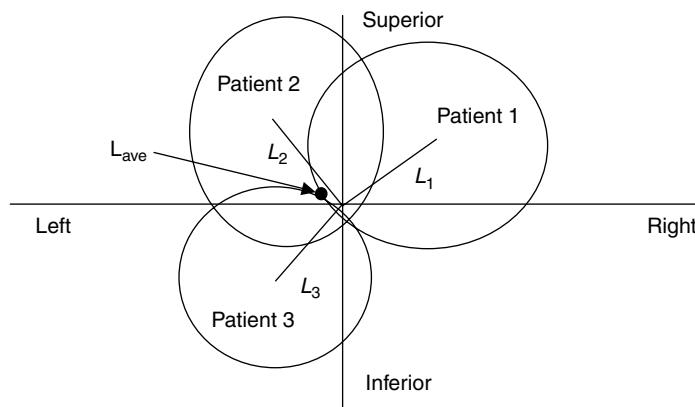

Once a set of position measurements has been made for a set of patients, these may be analysed to extract information on the sizes of the random and systematic errors. Such measurements are the essential first stage in the use of EPIDs. Figure 40.6 illustrates how the accumulated measurements might look for a set of patients when measurements are made in the superior-inferior and left-right directions. Other planes will show similar behaviour.

This graph shows measured differences between a set of treatment images and the reference image for each patient. The data for each patient will fall within an ellipse, whose size indicates the random, day-to-day setup error. The eccentricity of the ellipse indicates the difference in accuracy of setup in superior-inferior and left-right directions. The distance of

**FIGURE 40.6**

2D representation of a set of measurements of random and systematic errors for a hypothetical set of three patients. Here the systematic errors ( $L_1$ ,  $L_2$  and  $L_3$ ) are larger than the random errors (shown by the ellipses).

**FIGURE 40.7**

2D representation of a set of measurements of random and systematic errors for a hypothetical set of three patients. Here the random errors (ellipses) are larger than the systematic errors (individual  $L_1$ ,  $L_2$ ,  $L_3$  and average,  $L_{ave}$ ).

the ellipse centroid from the origin ( $L_1$ , etc.) is the difference between the mean treatment position and the position in the reference image. This is often referred to as the systematic error. This may be different for each patient (as in the example), indicating a random component in the error between simulation and treatment. The average of the  $L_1$ ,  $L_2$  measurements over a large group of patients ( $L_{ave}$ ) is an estimate of the systematic difference between the simulated and treated position and should be close to zero.

In the example shown in Figure 40.6, the systematic errors are larger than the random errors, but the case may be the opposite (e.g. Figure 40.7). Whichever is the case, it is clearly most efficacious to try to minimise the larger source of error first and foremost.

The purpose of any method of improving treatment accuracy is to shrink the ellipses in Figure 40.6 and Figure 40.7 and to get them as close as possible to the origin.

#### *40.1.3.9 Intervention in Treatment Delivery*

Once the setup error is known, the treatment may be adjusted in order to correct the error. This may be done either on-line (during the irradiation) or retrospectively (at the next treatment fraction).

In the case of portal film, only retrospective correction is really feasible, owing to the time taken to develop and analyse the film. If the analysis of the film shows a significant setup error, then this is corrected at subsequent treatment fractions. To determine whether a correction can reasonably be made, it is necessary to have good information on the random and systematic errors associated with a given treatment technique. This is because retrospective correction should reduce systematic errors, but it can have no effect on day-to-day, random variations. Hence, if random errors are relatively large, this technique is likely to be of limited efficacy.

Various decision rules have been developed for retrospective correction. For a given fraction, the decision to adjust the treatment setup is based on the results of the random and systematic error values determined from the previous fractions. Often, these decision rules start with a relatively large threshold for correcting setup, which is gradually reduced as the treatment progresses, i.e. as better statistics on the random and systematic errors for the individual patient are acquired. Examples of decision rules may be found in the work of Bel et al. (1993) and van Herk (2004).

For on-line intervention, an image is taken at the start of the irradiation, using a few monitor units, and the beam is turned off. If the setup error is small, the irradiation is continued. If it is large, the setup is adjusted before the treatment recommences. Another

image may be taken at the end of the treatment fraction to verify the correction. This technique reduces both types of error, but is time consuming and hence has significant logistic implications. Several groups have investigated the feasibility of on-line intervention (Ezz et al. 1991; De Neve et al. 1992; Gildersleve et al. 1994).

An alternative approach to intervention in treatment delivery is to monitor the random errors during the first few fractions and to modify the PTV based on the size of the random variations. This strategy has been called *adaptive radiation therapy* by its proponents (Yan et al. 1997; Martinez et al. 2001).

#### 40.1.4 DOSIMETRIC APPLICATIONS

Portal films (Van Dam et al. 1992; Fiorino et al. 1993; Weltens et al. 1994) as well as EPIDs (Boellard et al. 1997a; Van Esch et al. 2004) have been used for in vivo dosimetry. The purpose of this application is to use an EPID to measure some dosimetric aspect of a treatment. To do this the intensity at each point in the image must be calibrated in a quantitative sense. In other words, the intensity must relate to dose in some way. Therefore,

1. The dose response of each pixel in the detector must be known.
2. The effects of scattered radiation in the detector must be understood.
3. The temporal stability of the detector must be known.

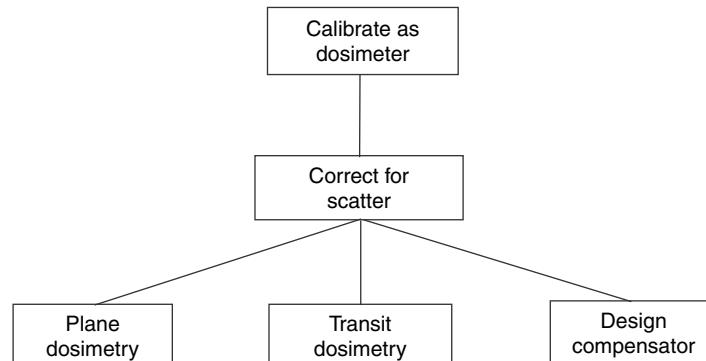

Knowledge of the temporal stability is needed in order that the detector may be calibrated frequently enough.

The information produced by dosimetric calibration may be used to verify the dose distribution or to design compensators to modify the dose distribution. Dose verification may be done by measuring the dose within a certain plane, or by reconstructing the dose distribution within the patient. Figure 40.8 illustrates the process.

##### 40.1.4.1 Dosimetric Calibration

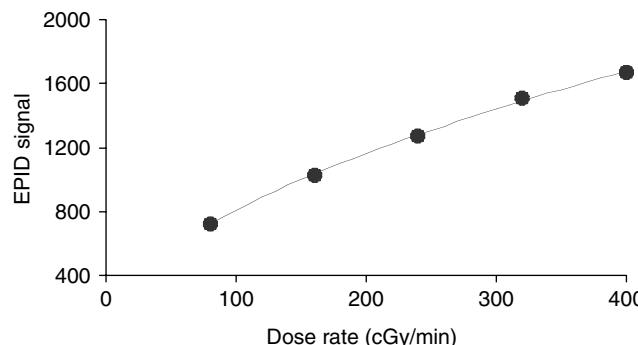

The relationship between intensity and dose may depend upon:

- Gantry angle
- Field size
- Air gap between patient exit surface and detector
- Other parameters

**FIGURE 40.8**

The steps required to extract dosimetric information from an EPID.

**FIGURE 40.9**

Response of the Liquid Ionisation Chamber Varian Portal Vision system as a function of the accelerator dose rate. The dots are measured points. The solid line is a fit using Equation 40.2.

Commercially-available systems fall into three groups detailed below.

*Camera-Based Systems.* These are generally linear in response up to a certain dose at which they start to saturate (Kirby and Williams 1993).

*Liquid Ionisation Chambers.* These usually have a dose response close to the square root of dose:

$$I = a\dot{D}^{1/2} + b\dot{D} \quad (40.2)$$

where  $I$  is pixel intensity,  $\dot{D}$  is the dose rate, and  $a$  and  $b$  are parameters. For dose rates commonly used in radiotherapy,  $a$  is large (over 90% of the contribution) and  $b$  is small. Earlier versions of these detectors are prone to variations with gantry angle, which can be corrected (Boellaard et al. 1996). Figure 40.9 illustrates a dosimetric calibration performed for the Varian Portal Vision system by varying the treatment machine dose rate. As can be seen, a square-root behaviour is a good representation of the detector's response.

*Flat Panel Imagers.* These are usually amorphous silicon arrays. They are generally linear with dose, but the acquisition parameters should be selected to avoid saturation (Berger et al. 2006). There is evidence that they show some *ghosting* effect, which may be a problem when they are applied to dosimetry. This ghost is a long-term image persistence that may last up to 30 min or longer (Siewersden and Jaffray 1999) although Van Esch et al. (2004) found that the effect of ghosting was not clinically relevant.

#### 40.1.4.2 Scatter Correction

Scatter correction is needed to remove the effects of scatter from the patient (Swindell and Evans 1996) and, in the case of camera-based systems, to remove the effects of light scatter within the detector that lead to optical cross-talk between pixels in the image (Heijmen et al. 1995). Such corrections are needed to extract primary fluence for various dosimetric techniques and remove the influence of the air gap on the measured signal.

Scattered radiation from the patient adds a component to the EPID signal that will vary with patient thickness, field size and the air gap between the patient and the detector. Two approaches have been made to the determination of the effects of this scattered radiation. The first method, developed by Boellaard et al. (1997a) involves the measurement of the detector signal for various air gaps. For very large air gaps, the scatter signal is very small and hence, the detector intensity is mainly primary radiation. The relationship between primary radiation intensity and air gap is simply given by the inverse-square law. The scatter signal for smaller air gaps is determined by taking the difference between the measured signal and that expected by applying the inverse-square law correction to data measured with a large air gap.

These measurements are used to calculate a kernel, known as an exit dose spread function, EDSF. The second approach is to use Monte Carlo simulation to estimate the scatter signal (Swindell and Evans 1996). Studies of uniform, homogeneous objects have shown that the scatter signal is, to first order, proportional to the volume of scatterer in the field, with correction terms that are functions of the thickness of the object and the field area. Applying the same model to the calculation of kernels to describe scatter, Hansen et al. (1997) found that as the thickness of the scatterer is increased, the scatter contribution increases in magnitude up to a maximum thickness of typically 200 mm, beyond which the magnitude decreases. This is because as the thickness increases, the probability of scattering occurring increases. However, for large thickness, the probability of the scattered photons being absorbed becomes significant.

The light scattering inside camera-based systems has been extensively studied by Heijmen et al. (1995). They used images of light fields of various size to show there is optical cross-talk within the detector housing and none, or very little, in the CCD camera. From these measurements, they deduced a kernel to describe the optical scatter, which can be used for any field size and shape. Munro et al. (1998) modelled the optical cross-talk as a result of multiple reflection between mirror and phosphor screen. They showed that the distribution of the component of the image signal from light scatter might be very non-uniformly distributed, with a peak close to the junction between the mirror and the screen. This is particularly true for large field sizes.

#### 40.1.4.3 *Plane Dosimetry*

As its name suggests, this involves using the EPID to deduce the dose in a certain plane. Most commonly this is the patient exit surface, the patient midplane, or the plane of the imaging system (what dose would be measured by an ion chamber with full build-up if it were positioned where the EPID is located) (Boellaard et al. 1997b).

This generally involves calibrating the detector for a large air gap and relating the signal measured in this plane to the dose in the desired plan. For instance, in the case of exit dosimetry, it is necessary to correct for the greater amount of patient scatter at the exit plane compared with that in the image plane (Boellaard et al. 1997a, 1998).

If dosimetry in the plane of the imager is performed, the EPID is usually calibrated in comparison with an ionisation chamber, which is the gold-standard for dosimetric measurement. The measured dose images are often referred to as portal dose images (PDIs). Kroonwijk et al. (1998) generated PDIs for a set of prostate cancer patients and compared their results with predicted PDIs from their treatment planning system. They found average agreement between the planning system and measurement of  $\sim 0.5\%$ , with 2% to 3% standard deviation, but off-axis differences could be much larger (up to 15%) perhaps due to organ motion.

Huyskens et al. (1994) used semiconductor diodes to measure the entrance dose and film to measure the exit dose. They interpolated between entrance and exit dose to determine the midplane dose. In phantoms, they found agreement with ionisation chamber measurements to within a few percent.

#### 40.1.4.4 *Transit Dosimetry*

This is a method of estimating the dose distribution within the whole patient using information from EPIDs. It involves a combination of measurement and dose planning. It requires CT information at time of treatment to enable the beam attenuation within the patient to be calculated. Generally this is not available so planning CT data are used. One transit dosimetry algorithm involves the following steps (Hansen et al. 1996):

1. Calibrate portal imager as dosimeter.
2. Subtract the scatter signal to yield a primary fluence map.

3. Back-project this information through the planning CT data to yield a primary fluence distribution.
4. Convolve this primary fluence distribution with dose deposition kernels to generate a dose distribution.

The dose distribution produced may be compared with the original planned distribution.

McNutt et al. (1996) generated PDIs from their planning system. They compared these with measured PDIs from their EPID. An iterative process was then used to adjust the primary fluence in their planning system model until it agreed with measurement. The suitability of amorphous silicon imagers for transit dosimetry is considered by Louwe et al. (2004).

#### 40.1.4.5 Compensator Design

This requires the EPID to be calibrated for radiological thickness. Once a radiological thickness map is available, a planning protocol is used to determine what compensation is needed; e.g. compensation may be applied to equalise doses in the midplane.

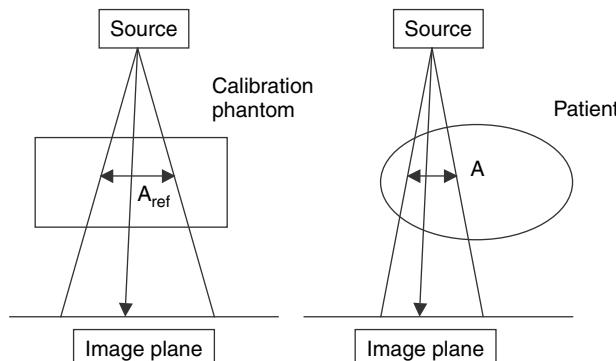

EPIDs have been used to design compensators for lung (Yin et al. 1994) and for breast (Evans et al. 1995). One method of calibrating EPIDs for thickness is shown in Figure 40.10.

A set of uniform calibration blocks of known radiological thickness is imaged and, for each pixel in the detector, the relationship between pixel intensity and thickness is determined. This is done for a large field that covers the whole active region of the detector ( $A_{\text{ref}}$  in the left side of Figure 40.10). The relationship between intensity and thickness is given by

$$I = I_0 \exp(\alpha t + \beta t^2) \quad (40.3)$$

where  $I$  is the measured intensity,  $I_0$  is the intensity for no object in the field,  $t$  is the thickness and  $\alpha$  and  $\beta$  are fitted parameters.

When a patient is imaged, (right side of Figure 40.10), the field size will, in general, be different. The intensity of the patient image ( $I_{\text{meas}}$ ) is firstly corrected for the difference in field size, using a field size factor,  $F$  (equivalent to an output factor). This corrected intensity is then fed into Equation 40.3 to yield a first estimate of thickness,  $t$ . A correction for scatter within the patient is then made to yield an estimate of the intensity value ( $I_{\text{ref}}$ ) if the patient were imaged with field size  $A_{\text{ref}}$ .

**FIGURE 40.10**

Method of calibrating an EPID for patient thickness.

$$I_{\text{ref}} = I_{\text{meas}} F \left( \frac{1 + \text{SPR}(A_{\text{ref}}, t)}{1 + \text{SPR}(A, t)} \right) \quad (40.4)$$

The value for  $I_{\text{ref}}$  is then fed into Equation 40.3 to yield an improved estimate of the thickness,  $t$ .

#### 40.1.5 OTHER APPLICATIONS

EPIDs have other applications than the measurement of treatment accuracy and dosimetry discussed above. These applications include regular QA of treatment machines and the verification of complex treatment techniques, such as intensity-modulated radiation therapy (IMRT).

Kirby and Williams (1995) showed how EPIDs may be used to verify multiple static field treatments using a multileaf collimator (MLC). Partridge et al. (1998) have developed a method of using an EPID, triggered by the linear accelerator pulses, to verify dynamic MLC treatments, in which the MLC leaves scan with the radiation on. A set of frames is obtained, from which the leaf positions as a function of dose delivered are extracted and compared with the prescribed parameters. The use of flat panel imagers to measure the positioning of gold grains implanted in the prostate has been shown to yield good results for localisation (Nederveen et al. 2001).

The use of portal imaging technology to obtain pretreatment megavoltage CT (MVCT) scans was first investigated in the 1980s (Swindell et al. 1983; Brahme et al. 1987). More recently cone-beam MVCT has been demonstrated (Mosleh-Shirazi et al. 1998).

Jaffray et al. (2002) attached a diagnostic x-ray set and flat panel imager to a radiotherapy gantry and have demonstrated CT images with good soft tissue delineation. This forms the basis of the approach known as Image Guided Radiotherapy. The commercial version of Jaffray's device is shown in Figure 40.11. Varian has a similar device with two

**FIGURE 40.11**

(See colour insert following page 590.) The Elekta synergy image guided radiotherapy solution. A similar concept is available from Varian. (Photo courtesy of Elekta Oncology Systems.)

motor driven arms. Siemens have taken the approach of mounting a CT scanner in the treatment room on a floor track which allows the scanner and the treatment machine to use the same couch, and have also developed megavoltage CT.

#### 40.1.6 FURTHER READING

Several reviews are available. A review of the technology of imaging systems has been provided by Antonuk (2002). Herman et al. (2001) have presented a thorough set of recommendations for the clinical use of electronic portal imaging. Hurkmans et al. (2001) have provided a review of current clinical practice.

## 40.2 IN VIVO DOSIMETRY

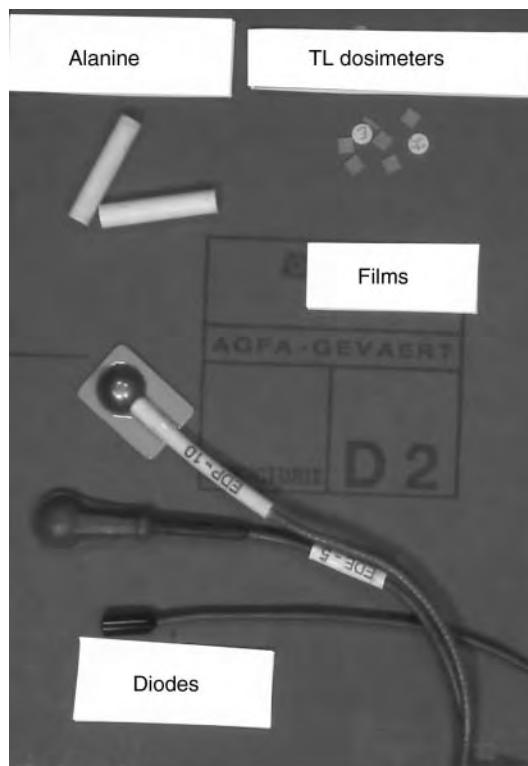

### 40.2.1 INTRODUCTION

Historically, in vivo dosimetry began to be used at the same time as radiotherapy when skin erythema was the only form of dosimetry available. More than 30 years ago in vivo measurements were also recommended for brachytherapy of cancer of the uterine cervix because it was not possible to calculate the dose delivered to the bladder and rectum, which were limiting factors for the irradiation (IAEA 1967). Currently, in vivo dosimetry is most often considered a quality assurance tool useful to identify deviations in the delivery of standard (Van Dam and Marinello 1994; Huyskens et al. 2001; AAPM 2005) or complex treatments such as IMRT, to evaluate the dose to critical structures (lens, gonads, etc.) or when computer calculations are not possible or are questionable (limits of block shielding, junction of non-coplanar irradiation fields, dose at skin or within inhomogeneities, etc.). In vivo dosimetry can also be used to monitor the irradiation for special techniques such as total body irradiation ([Chapter 47](#)) or total skin electron irradiation ([Chapter 48](#)) etc.

Dosimetric investigations in special or anthropomorphic phantoms loaded with dosimeters and irradiated in the same conditions as patients can also be useful to check the validity of special techniques prior to routine practice, to point out problems related to sub-optimal treatment planning systems, errors in irradiation technique or in dose calculations, or simply to validate the method used for in vivo dosimetry. They have also been used by cooperative groups for clinical and dosimetric intercomparison between centres (see [Section 40.2.4.6](#)). The problems to be solved being similar in the above cases, the object of this chapter is to make a review of the principal detectors that can be used and to present methodologies for some applications encountered in normal practice. Although the use of ionisation chambers is possible for in vivo dosimetry (IEC 1997), they will not be considered in this section as they are fragile and require a high voltage that may be dangerous for patients (except for condenser chambers, seldom used nowadays). Only solid state detectors will be considered.

### 40.2.2 CHOICE OF DETECTORS AND ACTION LEVELS

In the first place the material and method should be as simple as possible to reduce time, effort and cost (Kesteloot et al. 1993). Secondly, the tolerance and action levels should be previously established. Generally a maximum dose deviation level must be defined for each treatment situation, and all deviations exceeding this level must be investigated and explained. That means that considerable care needs to be taken in the choice of the detector and associated readout system, which must allow dose measurements with an overall uncertainty lower than the action level desired.

**FIGURE 40.12**

Comparison of some one or two-dimensional solid dosimeters which can be used for in vivo dosimetry.

Overall uncertainty (IAEA 1994) is evaluated by combining the type A uncertainties (i.e. the standard deviation of the mean value, which can, in principle, be reduced by increasing the number of individual readings) and the type B ones (i.e. uncertainties linked to the measuring instruments and methods that may affect the measured value in a systematic way). To minimise all the sources of type B uncertainties, it is recommended to calibrate the dosimeters in situations as close as possible to those used for the patient measurements.

The detectors that can be used to carry out in vivo dosimetry and anthropomorphic phantom measurements (see Figure 40.12) can be grouped into:

- *Point detectors*, which measure the dose at a point, such as alanine, diodes, MOSFETs, and thermoluminescent dosimeters
- *Two-dimensional detectors*, which measure the dose distribution in a plane, such as standard or radiochromic films, plastic scintillators and electronic portal imaging devices
- *Three-dimensional detectors*, such as gel dosimeters which are useful for IMRT verification because they can provide the dose distribution in complex volumes

The main properties of the different detectors yielding advantages or disadvantages for in vivo or anthropomorphic phantom dosimetry are summarized in [Table 40.1](#). Details of detector characteristics are covered in [Part D \(Chapter 16 for TLD and diodes and Chapter 17 for film and gel dosimetry\)](#). EPID dosimetry has already been discussed in [Section 40.1.4](#). For the choice of phantom material, the reader can refer to ICRU Report 44 (1989) and Report 48 (1992) and also to [Section 18.8](#).

In practice, detectors that show an overall uncertainty higher than  $\pm 3\%$  are either of poor quality or have been incorrectly handled. They can only be used to detect large errors such as

**TABLE 40.1**

Main Properties of Detectors That Can Be Used for In Vivo Dosimetry

Detector	Usability for Volume Dosimetry	Measurement Instrument	Cable Linked to Patient?	Readout	Destructive Readout?	Range of Response with Dose	Accumulated Dose Dependent?	Results Dose-Rate Dependent?	Temperature Dependent?	Tissue Equivalence	Directionally Dependent?
Diode	1D	Simple	Yes	Immediate	No	Up to 10 Gy	Yes	Yes	Yes	Limited range	Yes
TLD	1D/2D	Simple	No	Delayed	Yes	Up to $10^2$ or $10^3$ Gy <sup>b</sup>	No	No	No	Large range	No
MOSFET	1D	Simple	No	Immediate <sup>a</sup>	No	1–180 Gy	Yes	No	Yes	Limited range	Can be
Alanine	1D/2D	Specialised laboratory	No	Delayed	No	10–10 <sup>5</sup> Gy	No	No	No	Large range	No
Plastic Scintillators	1D/2D	Specialised laboratory	No	Delayed <sup>c</sup>	Yes	1–10 Gy	No	No	No	Large range	No
Radiochromic films	2D	Simple	No	Delayed	No	0.5–40 Gy	No	No	Yes	Large range	No
Portal films	2D	Moderately simple	No	Delayed	No	A few cGy	No	No	No	Limited range	Yes
EPID	2D	EPID	No	Delayed	Yes	1–20 cGy	No	Yes	No	No	Yes
Gel dosimeters	3D	Use of MRI or optical CT scanner	No	Delayed	Yes	10–70 Gy	No	Not up to 4 Gy/min	Yes	Large range	No

<sup>a</sup> However, not really *on line* because the gate voltage must be determined after the end of irradiation.

<sup>b</sup> Depending on TL material and readout conditions.

<sup>c</sup> Immediate data acquisition is possible.

the forgetting of a wedge filter, a bad position of a compensator, or a serious machine failure. The detection of small systematic errors or verification of the homogeneity of the dose distribution during treatment requires a tolerance and action level less than 5%. This implies the use of detectors of high quality and an experimental method well adapted to the intended application. Whenever possible, a preliminary check of the method in special or anthropomorphic phantoms is desirable.

### 40.2.3 METHODOLOGY

For obvious reasons, the direct measurement of the patient dose is only possible in a limited way and mostly restricted to skin or intracavitory dose measurements. However, it is possible to obtain information on the dose to the tumour or critical structures by combining data from entrance and exit dose measurements for techniques involving a limited number of homogeneous photon beams. The principle of the methodology to be applied is similar for all types of *point* detectors provided that they are correctly handled and their response corrected to take into account their particular characteristics. Use of two-dimensional or three-dimensional detectors requires a complex methodology not considered in this section (but that is discussed in [Section 40.1.4](#)). Nevertheless, the type of detector to be chosen depends on the application to be carried out and on the predefined action level. In vivo measurements must not interfere with the treatment and measurements close to metallic structures, such as dental fillings or a prosthesis, should be avoided because of the interface effect.

#### 40.2.3.1 Skin Dose Measurements

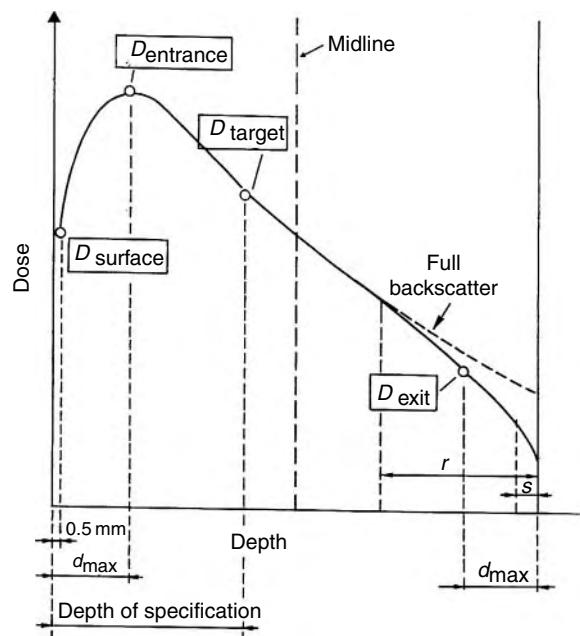

Skin dose measurements are mostly used with electron beams either used alone, or joined at the patient skin to cover a large surface for breast or total skin electron irradiations ([Chapter 48](#)). They can also be used in some limited cases with photon beams in order to explain abnormal cutaneous reactions or to know the dose at a scar, etc.

The *skin dose* or *surface dose* is defined by convention at 0.5 mm below the surface irrespective of the nature and energy of the ionizing radiation used. That implies that it should be measured with very thin detectors such as TL chips or a thin layer of TL powder wrapped in plastic or kapton (Dupont polyimide film) pouches or envelopes made of thin opaque paper, monocoated photographic emulsions or radiochromic films. Diodes, even though they are very thin (such as diodes dedicated to electron beam measurements), must not be used in high-energy photon beams because their response is very much influenced by electron contamination existing in such beams (Sjögren and Karlson 1998). In all cases, the detector is stuck directly to the patient skin taking care to minimise the air space between the skin and the dosimeter wrapping envelope and no build-up cap is required.

If the water equivalent thickness of the detector (sensitive part plus cover) is less than 0.5 mm, a thin layer of tissue equivalent material must be added above it to reach an adequate thickness. On the other hand, when detectors of thickness greater than 0.5 mm are used, correction factors have to be applied to their response to take into account their effective point of measurement, which is not at 0.5 mm below their surface (Kron et al. 1993). The experimental determination of the correction factor is only possible for detectors of constant and known thickness.

#### 40.2.3.2 Entrance Dose Measurements

Entrance dose measurements are made at an equivalent depth corresponding to the dose maximum on the beam axis of photon or electron beams either used alone or in combination with other beams (Huyskens et al. 2001). They are mainly used to check the reproducibility of patient setup and machine output during the different fractions of external beam therapy, the positioning of shielding in relation to the position of the patient or, when adjoining fields are

**FIGURE 40.13**

Dose distribution along the axis of a single photon beam passing through a phantom made of homogeneous tissue-equivalent material of limited thickness. The surface dose ( $D_{\text{surface}}$ ) is defined at 0.5 mm below the entrance surface, the entrance dose ( $D_{\text{entrance}}$ ) at  $d_{\text{max}}$ , the target dose ( $D_{\text{target}}$ ) at the depth of dose specification, the exit dose ( $D_{\text{exit}}$ ) at a distance of  $d_{\text{max}}$  from the exit surface on the beam axis. (After Van Dam, J. and Marinello, G., *Methods for in vivo dosimetry in external radiotherapy*, ESTRO Booklet Number 1, Garant, Leuven-Apeldoorn 1994.)

used, to check the field junction. In combination with exit dose measurements (see [Section 40.2.3.3](#)), they can allow the target or midline dose to be calculated using an appropriate protocol (Van Dam and Marinello 1994).

**Photon Beams:** The individual entrance dose of each beam contributing to the target dose and the case of two directly opposed beams will be considered in turn.

When a medium is irradiated by a *single photon beam*, the dose gradually increases from a low value at the surface up to a maximum value  $D_{\text{max}}$  at a depth  $d_{\text{max}}$  that depends on the energy, the collimator aperture, the source skin distance (SSD) and the presence or absence of modifying devices traversed by the beam or inhomogeneities close to the entrance surface (Figure 40.13). This depth can vary from a few millimetres to several centimetres. As the sensitive part of the detectors is generally very thin, entrance dose measurements cannot be carried out with bare detectors directly placed on the patient skin. A build-up cap made of a tissue-equivalent material must be placed in front of and around the bare detector to achieve electronic equilibrium. The dimensions of this build-up cap are very dependent on the irradiation conditions. For example a different thickness is desirable for open beams or under shielding, both because of the energy variation and the presence of the block tray. The appropriate thickness must be carefully determined for each type of treatment. The thickness of the build-up cap to be used to check external beam treatment will be between 2 mm and 3 mm with cobalt-60 and approximately 10 mm with 4 MV x-rays. For x-rays between 18 MV and 25 MV the required build-up cap thickness will increase from 20 mm to 35 mm as the field size is reduced from 30 cm × 30 cm to 5 cm × 5 cm (Van Dam and Marinello 1994). It should also be noted that the use of very thick build-up caps, although required to provide electronic equilibrium, can lead to an underdosage of the treatment volume together with loss of skin sparing in small areas (Nilsson et al. 1988). This effect can be reduced by using a slightly different detector position for the different treatment fractions, at the expense of some

uncertainties in the dose determination. For this reason and to reduce the size of the detector generally, it is common practice to use a material such as stainless steel in the build-up cap instead of a tissue equivalent material.

When *opposed beams* are used both the contribution of the beams and their respective weights modify the depth  $d_{\max}$ , and therefore the thickness of the build-up cap to be used. The presence of a large inhomogeneity traversed by the beams can also change the conditions of electronic equilibrium considerably (Marinello et al. 1982). Consequently the best solution involves the experimental determination of  $d_{\max}$  in conditions as close as possible to those used for the clinical applications and to deduce from these measurements the optimal dimensions of the build-up cap. However, in practice commercial diodes provided a restricted choice of build-up cap (see [Table 16.5](#) and Huyskens et al. 2001).

**Electron Beams:** Generally the entrance dose of electron beams is determined along the axis of a single beam used alone or adjacent to other beams to cover target volumes of limited thickness. In practice  $d_{\max}$  is reached at depths varying from a few millimetres to several centimetres depending on the energy, the type of electron collimator (cone or tube collimator, or an open collimator, as shown in [Figure 11.28](#)), the source skin distance (SSD), the presence or absence of modifying devices, etc. To have a response representative of the dose at  $d_{\max}$  the bare detector must be surrounded by a certain thickness of tissue-equivalent material but care must be taken because build-up caps more than a few millimetres in thickness can induce a relatively important scattering artefact and may alter the dose distribution substantially because of the high scattering properties of the electrons. Consequently it is preferable to derive the entrance dose from surface dose measurements ([Section 40.2.3.1](#)) using correction factors established in a phantom irradiated in the same irradiation conditions as for the patient. The correction factor to be used is the ratio of the response of the bare detector on the surface to that at the depth of the maximum dose on the beam axis.

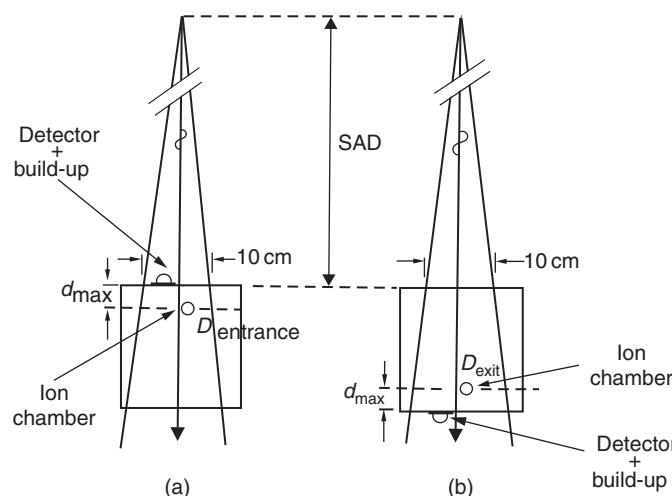

### 40.2.3.3 Exit Dose Measurements

Exit dose measurements are primarily performed for photon beam irradiations, most often at the same time as the entrance dose measurement (except for portal transit dosimetry). In this region there is a *build-down* related to the lack of backscatter radiation from the air behind the patient ([Figure 40.13](#)). As the position at which the exit dose  $D_{\text{exit}}$  should be defined is less obvious than for  $D_{\text{entrance}}$ , it is generally taken at  $d_{\max}$  from the exit surface, i.e. symmetrically with the entrance dose with respect to the midline. For reasons similar to those discussed for photons in [Section 40.2.3.2](#), the detector must be covered with enough material behind and around it to ensure complete electron backscatter (otherwise it would be in too a high dose gradient, which would decrease the accuracy). The dimensions of the build-up cap required for exit dose measurements are in principle different from those used for entrance dose measurements, but it is usual in practice to use the same caps for both situations but to use different calibration factors which must be determined experimentally ([Figure 40.14](#)). This has the advantage that the same setup can be used for opposed beams with appropriate correction factors being used for each beam. When positioning the detectors for simultaneous entrance and exit dose measurements, it is necessary to avoid their shadowing effect by offsetting them slightly from each other.

### 40.2.3.4 Target and Midplane Doses

A very simplified approach which consists of considering the target dose equal to the mean of the entrance and exit doses can be acceptable in some practical conditions but may frequently induce errors of several percent. These errors can be attributed to one of the following reasons:

- Deviation from the linear approximation of dose variation with depth for lower energies and greater patient thickness

**FIGURE 40.14**

Example of method for determination of entrance and exit dose calibration factors of solid state detectors by comparison with an ion chamber. (After Van Dam, J. and Marinello, G., *Methods for In Vivo Dosimetry in External Radiotherapy*, ESTRO Booklet Number 1, Garant, Leuven-Apeldoorn, 1994.)

- Variation of response with change in energy spectrum
- Changes in the effect of the inverse square law

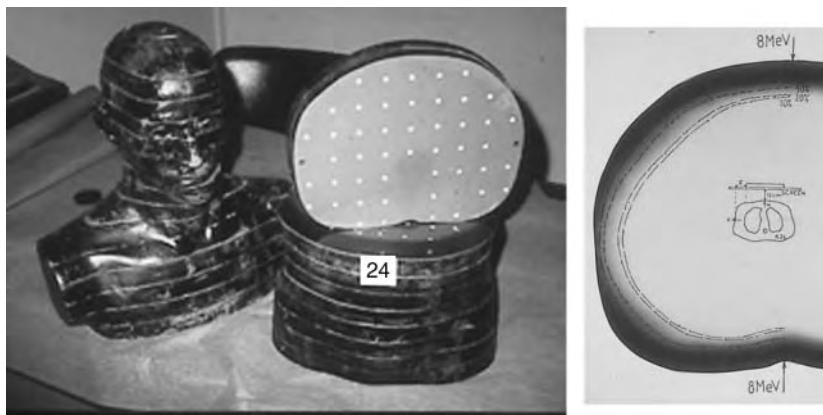

The validity of the method must be checked prior to use for in vivo dosimetry either experimentally or using a calculation method based on data established in irradiation conditions as close as possible to those used for patient treatments.

If the approximate method is not valid, it is necessary to derive the target dose from simultaneous entrance and exit dose measurements using one of the calculation methods published by different authors. Most of them are based on the symmetrical (with respect to the midline point) expansion or compression of the real patient to a thicker or thinner *water equivalent patient* and on the concept of midline and exit transmission curves (Rizzotti et al. 1985; Leunens et al. 1990). Accurate results can be obtained using these methods in regions of the human body which have a symmetrical disposition of the different types of tissue irradiated provided that midline and exit transmission curves are established from tissue-phantom ratios corresponding to the energy and field sizes used for irradiation and that the lack of exit back-scatter is taken into account (Van Dam and Marinello 1994). Symmetry is generally adequate for lateral fields, but unfortunately, except for the brain and skull, the methods are not straightforwardly applicable for antero-posterior beam directions because of the lack of symmetry.

Some authors have proposed new methods to deduce the midplane dose directly in 2D using portal films or an electronic portal imaging device (see [Section 40.1.4.3](#)). They have shown that, under certain conditions, midplane doses could be estimated with a similar accuracy compared to existing conventional methods for in vivo dosimetry.

#### 40.2.3.5 Intracavitary Dose Measurements

In vivo measurements within body cavities such as the mouth, nasopharynx, oesophagus, vagina, rectum, etc. can be performed either for external beam therapy, including IMRT, or brachytherapy. TL dosimeters sealed inside waterproof catheters are the most appropriate for such measurements (Engström et al. 2005). The position of the dosimeters must be checked radiographically using radio-opaque markers. It should be noted that the increase in scattered radiation resulting from the presence of high atomic number radio-opaque markers can cause uncertainties of a few per cent in the absorbed dose to the TL dosimeter, although this can be

**FIGURE 40.15**

Example of an anthropomorphic phantom including tissue inhomogeneities and allowing the insertion of films or solid dosimeters (left) and example of the results obtained with films (right) irradiated in conditions of total electron irradiation (8 MeV decelerated by lucite screens as shown in Part I, Figure 48.6).

allowed for. MOSFET detectors have also been successfully used for this purpose (Cygler et al. 2001; Marcié et al. 2005).

#### 40.2.4 CLINICAL APPLICATION

Irrespective of the type of detector and the method intended to be practiced for in vivo measurements, the validity of the approach should first be checked by carrying out measurements in phantoms made of tissue-equivalent materials and irradiating them in conditions as close as possible to those used to treat patients. Details of suitable phantom materials can be found in ICRU Report 44 (1989) and Report 48 (1992). Body and limb cross sections can be simulated by elliptical, oval or cylindrical phantoms of the appropriate radii but it should be realised that homogeneous phantoms with regular shapes are not a good representation of real patients. It is preferable to confirm the method intended to be used for in vivo measurements with an anthropomorphic phantom (see Figure 40.15) drilled with holes and cut into sections allowing the insertion of dosimeters within it.

The accuracy of the measuring system and the different correction factors to be applied must be previously investigated by comparison with an ionisation chamber calibrated at an energy close to that of the measurements. This is the simplest way to compensate for factors such as dose-rate dependence, directional dependence, temperature effects, etc. which can influence the response of some detectors. If the detector is used for entrance and exit dose measurements, it has to be assigned separate entrance and exit dose calibration factors. One of the methods which can be used to determine them is shown in Figure 40.14.

Different methods for in vivo dosimetry which can be used for standard cases of external beam radiotherapy or in brachytherapy are briefly described below. For a more detailed description of them, the reader can refer to the work of Van Dam and Marinello (1994), the Report of Task Group 62 of the AAPM Radiation Therapy Committee (AAPM 2005) or to the extensive list of references relating to Part H.

##### 40.2.4.1 Patient Dose Verification in External Beam Therapy

The large number of steps and persons involved leads to a large probability of errors in the preparation and execution of a radiation treatment (Leunens et al. 1992; Essers and Mijnheer 1999; Huyskens et al. 2001). Different ways can be used to assess the uncertainty in the dose

delivery. The sequence of the different procedures involved in delivering a dose to a patient (dose calculation, treatment machine calibration, patient setup etc.) can be analysed. The total uncertainty in all the steps may then be considered as the maximum attainable accuracy in dose delivery. In practice the actual accuracy in dose delivery may be less than desirable for any of the following reasons:

- Errors in patient contours
- Patient mobility
- Inhomogeneities
- Organ motion
- Transfer of treatment data from simulator to the treatment unit
- Machine settings
- Positioning of modifiers, etc.

The ultimate check of the individual dose delivered to a patient can only be performed at the patient level, by means of in vivo dosimetry.

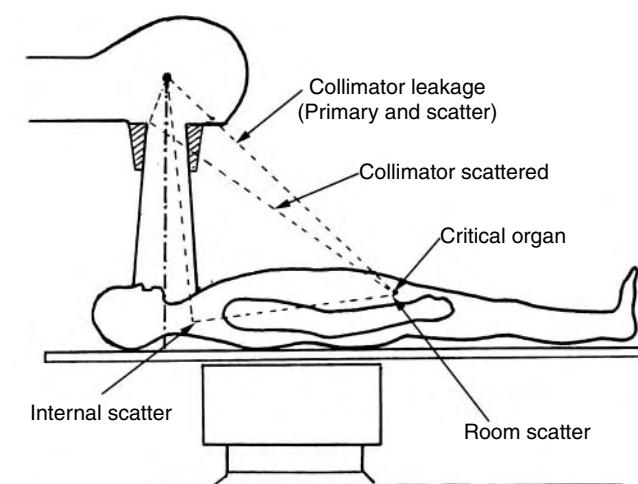

The method most commonly used for standard techniques consists of positioning *point* detectors on the patient's skin and measuring the entrance and/or exit doses in conditions adapted to the type and energy of the beam (see [Section 40.2.3.2](#) and [Section 40.2.3.3](#)). By combination of the two (as discussed in [Section 40.2.3.4](#)), it is then possible to obtain the dose inside the patient (target or midline dose, for instance). The detectors usually employed are diodes and thermoluminescence dosimeters (Van Dam and Marinello 1994; Mayles et al. 2000). Some authors have also used portal films or electronic portal imaging devices as discussed in [Section 40.1.4](#).

Although more demanding to carry out, in vivo dosimetry can be used to detect errors or to check the dose delivered using intensity modulated therapy (see [Chapter 43](#)). Depending upon the objectives to be achieved dosimeters can either be put at the entrance of the different beams at points situated in a low dose gradient area (Ling et al. 1996; Higgins et al. 2003) or put within the target volume using, for example, a nasogastric tube (Van Esch et al. 2002; Engström et al. 2005). When this is not possible, in vivo measurements done in high dose gradient regions are subject to question (LoSasso 2003).

*Diodes:* Diodes allow the detection of important systematic or human errors, with the patient still on the treatment couch which allows immediate corrective actions (Ciocca et al. 1991; Heukelom et al. 1991a, 1992; Mijnheer 1994; Noel et al. 1995; Loncol et al. 1996; Georg et al. 1999; Lanson et al. 1999; Verney and Morgan 2001). Because of their directional effect care must be taken when diodes are used for tangential fields (Heukelom et al. 1991b) and they should not be used in regions of high dose gradient. Some authors (Shackford and Bjarngard 1995) have also mentioned the possible disturbance of diode signals by radiofrequency radiation produced by linacs: although this should not be a problem with properly designed electronics. An overall uncertainty from 3 to 5% can be obtained for routine measurements provided that the constancy of diode response is regularly checked and a separate calibration carried out for each type of beam in which the diode is used. In practice a good solution consists of assigning an electrometer plus diodes to each treatment unit, and assigning them a correction factor for each irradiation condition (for instance a correction factor for standard fields and another one for large blocked fields used for Hodgkin disease etc.).

*Thermoluminescent Dosimeters (TLD)\*:* TLD is also a good tool to detect important systematic or human errors in radiotherapy with an overall uncertainty of  $\pm 3\%$  or less when correctly chosen and handled (Bascuas et al. 1977; Marinello et al. 1992; Loncol et al. 1996).

\* A system similar to TLD, but with the possibility of rereading the detector is optically stimulated luminescence (OSL). This is also available as an on-line device connected via an optical fibre cable (Aznar et al. 2004).

**FIGURE 40.16**

Measurements outside the irradiated volume: different components of the photon beam at the level of point of measurement.

Because of their limited size, their weak energy variation and their absence of directional effect, they are suitable for measurements in most clinical applications. They can be used for small or large fields with or without beam modifiers, irregularly shaped beams, tangential fields, zones of high dose gradient such as the penumbra region (although great care is needed with positioning accuracy), field junction zones, dose within inhomogeneities, IMRT, etc. Because of their insensitivity to dose-rate the dose variations produced by beam modifiers, SSD variations or patient anatomy do not change their response (even in scanned electron beams).

#### *40.2.4.2 Dose to Organs at Risks Close to or Outside the Irradiation Field*

A very common use of in vivo dosimetry is the determination of the dose to sensitive organs for which relatively small radiation doses may be undesirable. Among the most common such measurements are those of the dose delivered to the gonads and to the eyes.

*Dose Delivered to Gonads:* The treatment of seminoma, Hodgkin's disease and non-Hodgkin's lymphoma generally involves irradiation of sub-diaphragmatic nodal areas. Although outside the irradiation field, the gonads will be exposed to low doses of radiation. This is due both to scatter which is of lower energy than the primary beam and may be generated by the irradiated volume, by parts of the machine and the walls of the room, and to leakage through the machine shielding and collimator (Figure 40.16). As shown by different authors who have used them, thermoluminescent dosimeters are the most suitable dosimeters for in vivo measurements in this region because of their high sensitivity in a small volume, their absence of directional dependence and their good energy response in the relevant energy range (Sharma et al. 1981; Marcié et al. 1995). Diodes specially designed for measurements of doses to organs at risk situated outside the irradiation fields are also commercially available (see Table 16.5). The validity of their response must be evaluated using phantom measurements prior to in vivo use because of their directional effect and their enhanced response at low energy (Section 16.3.4.8 and Section 16.3.4.9).

*Dose Delivered to Eyes:* When the dose delivered to the eyes is to be assessed, it must be borne in mind that the sensitive tissue is the lens and not the eyelid, where doses are most easily measured. A phantom study carried out by Harnett et al. (1987) suggests that for lateral irradiation a dosimeter placed on the outer canthus may give a more accurate estimate of lens dose than one placed on the eyelid. If anterior beams are used (Galbraith et al. 1985), the surface dose just outside the beam edge actually overestimates the lens dose because of the

electron contamination of the radiation reaching the dosimeter. Prior to in vivo measurements it is necessary to perform phantom measurements in irradiation conditions close to those used for patients to reduce the unavoidable inaccuracy of evaluation of dose to the lens. Because of their high sensitivity in a small volume and their dosimetric properties, TL dosimeters are again the most suitable dosimeters for such measurements. Diodes can also be used provided that care is taken in interpreting the results because of their directional effect ([Section 16.3.4.9](#)).

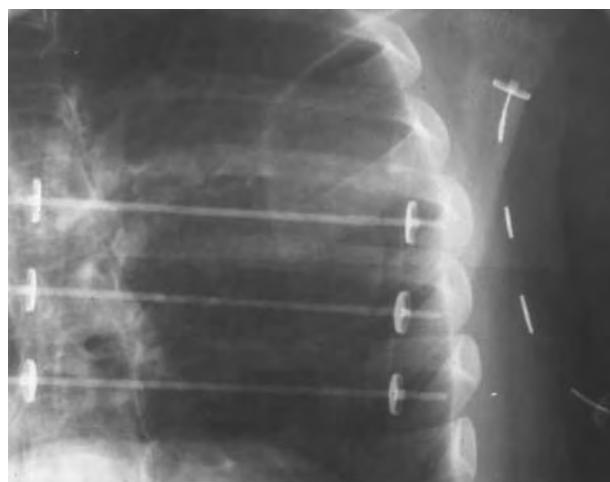

#### 40.2.4.3 Intraoperative Irradiation

Intraoperative radiation therapy is a complex irradiation technique practiced during a surgical operation with either electron beams of energies ranging from 6 MeV to 17 MeV or x-rays of between 50 kV and 300 kV. The entire dose is delivered during a single irradiation in a complex configuration that makes dose control tricky but indispensable. A radiation dose mapping technique based on laser heating of thermoluminescent dosimetric plates has been developed allowing the measurement of a two-dimensional dose distribution of non-planar surfaces with a resolution of  $\mu\text{m}$  which is more satisfactory than film for this particular application (Beteille et al. 1996).

#### 40.2.4.4 Brachytherapy

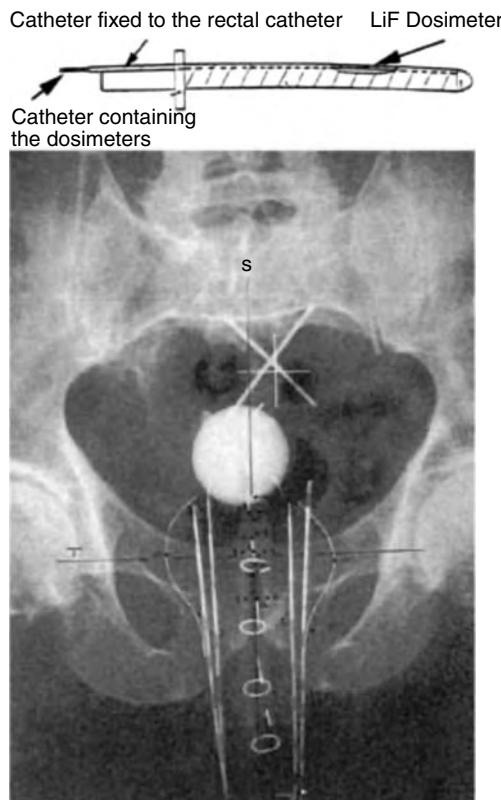

Currently used brachytherapy sources are either beta sources or low energy photon sources (see [Section 51.2](#)). They are characterised by a large variation in their energy spectrum and a high dose gradient existing around them. Consequently the detectors to be used for in vivo or phantom dosimetry must be of very small dimensions, have a response that varies little over the relevant energy ranges and be dose-rate independent. Among the possible solid detectors there are TLD, plastic scintillators, radiochromic film and polymer gels.

TLD. Thermoluminescent rods, chips, or powder included in small plastic tubes or catheters can be used. Care must be taken when using LiF because of its large variation of energy response at low photon energy which is not the case for lithium borate (see [Section 16.2.4.9](#)). TL measurements have been used since the 1970s for phantom or in vivo measurements intended to check the first computer programs (Joelsson et al. 1972). They have also been used by different teams for conservative breast treatments either to check the dose

**FIGURE 40.17**

In vivo determination of the dose delivered to the axilla during endobrachytherapy of breast cancer using LiF powder enclosed in a thin catheter. As LiF is invisible on radiographs, lead markers are necessary to show the position of dosimeters. (After Marinello, G. et al. *J. Radiol. Electrol.*, 56, 791–796, 1975.)

**FIGURE 40.18**

Rectal catheter used for in vivo measurements during HDR brachytherapy of prostate performed using the Paris System. (After Brune, D., Prostate, in *A Practical Manual of Brachytherapy*, Pierquin, B. and Marinello, G., Eds., Medical Physics Publishing, Madison, WI, 1997.)

delivered to the target volume (Hamers et al. 1993), to evaluate the skin dose in the vicinity of the implants (Mechakra et al. 1988) or the dose delivered to the axilla as shown in Figure 40.17 (Marinello et al. 1975). TL dosimeters or sheets have also been used for rectal dose determination during brachytherapy of the cervix (Iwata et al. 1992) or the prostate (Figure 40.18) and of rectal cancer.

**Plastic Scintillators:** Plastic scintillators have been shown to be very convenient to measure the dose distribution around ophthalmic applicators (Flühs et al. 1996) or to check the dose distribution of intravascular sources.

**Radiochromic Film:** Radiochromic films are useful for quality assurance purposes. For instance small samples of film included in vaginal cylinder applicators can be used to check the dose delivered during each fraction by HDR brachytherapy (Pai et al. 1998).

**Polymer Gels:** Polymer gels read out by MRI which have been found to be of the same accuracy as TLD measurements by Knusten et al. (1997) when used in a phantom study of dose distributions in brachytherapy of cervix.

**Diodes:** Diodes should be used cautiously (Piermattei et al. 1995; Alecu and Alecu 1999) but are not recommended because of their poor tissue equivalence in the involved energy range (Section 16.3.4.8).

Irrespective of the detectors chosen for in vivo dosimetry, it is necessary to calibrate the dosimeters in a water or a solid water phantom by comparison with an ionisation chamber of very small dimensions and calibrated for low energy photons or electrons, depending on the intended application. Both the chamber and TLD must be placed at a distance from the source representative of the practical application. The same phantom can be used for calibration at

**FIGURE 40.19**

Use of alanine dosimeters to check the dose delivered to human bone allografts. Thin lead markers are necessary to see the position of the dosimeters within the bone structure because of the good tissue equivalence of alanine that make them invisible on a radiograph. (After Hernigou, P., Marce, D., Julierion, A., Marinello, G., and Dormont, D., *Revue Chirurgie Orthopédique*, 79, 445–451, 1993.)

different distances provided that the holes drilled in the phantom are not in front of each other to avoid the influence of an air cavity on the detector responses.

#### 40.2.4.5 Prostheses Measurements

Implantation of dried bone allografts after freezing and sterilisation by high doses of radiation (25 kGy to 35 kGy) is current practice in osseous surgery. Because of its good accuracy for the evaluation of doses from 10 Gy to  $10^5$  Gy (the saturation dose level being  $5 \times 10^5$  Gy) and its dosimetric properties (Ciesielski et al. 1988, 1993; Olsen et al. 1990), alanine dosimetry is recommended to check the irradiation dose delivered to the prosthesis prior to the implant (Figure 40.19). It is simple to handle, with good long term stability, and its response is independent of the size and shape of the dosimeters. It can be considered as bone-equivalent in the photon and electron energy range used in practice. The relative variation of mass energy absorption coefficient between alanine and bone is less than 5% between 0.3 MeV and 8 MeV for photons. The relative variation of the mass collision stopping power of the material to that of compact bone is less than 2% between 0.2 MeV and 40 MeV for electrons (Mc Laughlin et al. 1991). As the readout equipment is expensive and rather complicated, most centres mail the dosimeters to specialized laboratories for readout.

#### 40.2.4.6 Comparison between Centres: Mailed Dosimetry

Mailed dosimetry, most often practiced with thermoluminescence or alanine dosimeters, is extensively used by different international and national organisations (IAEA/WHO, Radiological Physics Centers in the U.S.A., ESTRO-EQUAL etc.) for quality assurance networks. Generally measurements are performed in a specially designed phantom and are intended to

evaluate the uncertainties in the calibration of radiotherapy machines in the different radiotherapy centres. Since 1989 the European Organization for Research and Treatment of Cancer (EORTC) has also carried out pilot studies including either anatomical phantom measurements [Johansson et al. 1987; Hamers et al. 1991] or in vivo dosimetry in a limited number of patients. A good example is in vivo dosimetry with TLD in the conservative treatment of breast cancer patients treated with the EORTC protocol 22881 in which in vivo dosimetry has been used both for external therapy (Hamers et al. 1991) and for brachytherapy (Hamers et al. 1993).

## 41.1 RECORDING AND VERIFICATION IN EXTERNAL BEAM RADIOTHERAPY

To improve the accuracy of treatment delivery, by eliminating as many errors as possible, checking systems, whether human or computer-assisted are commonly used on radiotherapy treatment machines (Rosenbloom et al. 1977; Klein et al. 1998). Errors can either be caused by human fallibility or machine malfunction, so interlock and checking systems have been devised to help reduce these errors. In contrast with portal imaging and *in vivo* measurements, which are generally not used systematically for all patients and all fractions, record and verify (R and V) systems ensure that the machine settings will be repeated throughout the treatment course. They also ensure that the programmed total dose will not be exceeded. This places a considerable burden on the person entering the data for the first time, as any errors may be repeated throughout the treatment (see [Section 41.2.2](#)).

### 41.1.1 CONTROL OF THE TREATMENT MACHINE

All modern linear accelerators are computer controlled and have electronic monitoring circuits to limit machine malfunction. Parameters such as beam flatness, symmetry, output from dual monitor chambers, dose rate, and mechanical positional interlocks are all under computer control.

Features such as dynamic wedges and IMRT, which involve simultaneous control of motion of collimators and of dose-rate, require close and precise monitoring and verification systems. It is important for the operators and engineers to have a good appreciation of the function, trigger level, and importance of each interlock in the computer controlled systems—which ones are major and which ones may be overridden for later investigation. The issue of overriding interlocks will be discussed in [Section 41.4.3](#) that addresses patient-related verification.

In addition to computer control of the accelerator, R and V systems have been designed to store the details of a patient's treatment and to help prevent errors. The original aim of an R and V system was to compare the daily treatment-setup parameters with the planned parameters, and to inhibit treatment or flag a warning signal if the two did not agree (Rosenbloom et al. 1997). Since then, systems have evolved through recording the parameters actually used, to storing the data required for treatment, controlling the linear accelerator user interface, allowing assisted setup and even automated treatment. At the end of the treatment session, in addition to recording the parameters actually used, the system will record any overrides along with the identification of the operator that performed them, the accumulated dose and the treated fraction.

### 41.1.2 NETWORKING

Record and verify systems can be linked together so that data can be transferred around the department electronically. The networking of the department is discussed further in [Section 41.6](#) and in [Chapter 42](#).

---

## 41.2 IMPLEMENTATION OF THE RECORD AND VERIFY SYSTEM

### 41.2.1 WORKFLOW IN A NETWORKED DEPARTMENT

As soon as a computerised system is installed, it becomes necessary to have a strictly regimented workflow. A typical sequence is as follows:

1. A patient plan is prepared on the treatment planning system.
2. Patient and treatment plan data are entered directly via a network link between the planning system and R and V system, and checked by an independent operator before the patient arrives for simulation of the plan (or the first treatment if verification simulation is omitted).
3. When the patient is simulated, the plan parameter data are recalled from the R and V storage system and used to set up each treatment field for simulation. Any changes at this stage are automatically acquired into the R and V system and passed back to the treatment planning system to check for any dosimetric changes.
4. If the patient requires blocks or multi-leaf collimation, data files containing the relevant parameters may be sent over the network to a block-cutter or the MLC workstation on the treatment machine.
5. When the patient attends for the first treatment the data are accessed by entering the patient's unique ID and the data are then displayed on the R and V console.
6. Each field is called up and the *planned* data are then displayed, together with the *actual* settings from the treatment machine.
7. The setting of different treatment fields is speeded up by use of the assisted setup facility that automates some of the machine's features, such as gantry, collimator, and jaw movements.
8. If, for some reason, some of the actual parameters are not within the tolerance assigned for the planned parameters, a warning is given that requires intervention before treatment is allowed to commence.
9. When treatment is finished, the system records to the database, all the set-up parameters and the doses actually used for the treatment.

The parameters that are verified in a typical system are listed in Table 41.1.

---

**TABLE 41.1**

## Parameters for Verification

<b>Patient identification</b>	Patient number, Date of birth
<b>Prescription</b>	Treatment plan phase Dose Individual fraction data
	Total dose Cumulative dose Fraction number Contribution to target dose Reference point doses (optional)

---

### 41.2.2 DATA ENTRY AND CHECKING

A separate terminal remote from the treatment machines, for data entry and/or checking, is a great advantage in a busy department. In some systems, the data can be acquired directly from the simulator or treatment planning system. It is important that data are entered carefully and then checked by an authorised second person, in a quiet atmosphere. Any mistakes at this stage could be carried through the whole treatment, and therefore have graver consequences than random mistakes made during the course of a treatment.

Machine breakdowns and emergency treatments will mean there are times when it is not possible to enter patient data before the first treatment. In this case, it is possible to treat without the verification system, or to use a direct data entry mode. A minimum of data necessary for defining a field needs to be entered. Some software has a facility whereby the only data to be typed in are patient and field identification, and the system automatically records the machine settings, if requested to, by automatic acquisition. This is not to be encouraged as a regular practice on a treatment machine, but can be useful in the event of a machine breakdown, provided the data are carefully checked before the next fraction of treatment.

After the patient and plan data have been entered into the system it may be useful to print the data so that a careful check can be carried out. There are several ways of doing this: some systems use specialised cards, bar codes, or simply A4 sheets, while some systems are customisable to individual department's requirements. However, hardcopy is often the weak part of the whole system, and the R and V printout is often not a suitable replacement for the existing treatment card system within a department. As R and V systems evolve and benefit from better integration with the hospital information system, it is likely that printed charts will progressively replace manual charts, which may ultimately be phased out altogether in favour of paperless departments.

### 41.2.3 DATA RETRIEVAL

The first step in treating a patient whose data has been entered and verified, is accessing their data using the patient's identity. The field is then selected by number and label, and the screen will display all the planned machine settings that are required. It is useful to have an additional monitor and keyboard in the treatment room, to allow data entry and display the settings. In some systems, it is obligatory to treat the fields in the order in which they have been entered and in all systems, the treatment of the same field twice over is inhibited.

### 41.2.4 COMPUTER-ASSISTED SETUP

Patient setup can be completed considerably more quickly by using the computer assisted setup facility. An auto button either on the handset or on the console can be activated taking the machine to all the required settings simultaneously. If this is not required, then the auto facility can still be used to set up each parameter individually. Various automated movements, such as couch rotation, can be *forbidden*, if required. The usefulness of assisted setup should not replace a visual check of the field positions on the patient before leaving the room. Users must also be aware of the possible danger of a collision and set parameters individually if there is any uncertainty. Some computer-assisted setups can be directed from outside the treatment room to facilitate conformal therapy or IMRT. Some systems can be programmed to deliver the whole treatment with one button press. The faster treatments achieved using computer-assisted setup, can not only improve throughput, but can also improve patient comfort and because there is less time for the patient to move during treatment, reproducibility.

### 41.2.5 RECORD KEEPING

The data entered at the pre-treatment stage is automatically recorded and stored. After the treatment of a field, the actual machine settings used, the monitor units delivered, any overrides, the accumulated dose from that field, and the number of fractions is immediately recorded. The system then sums the accumulated dose from all the fields and compares it with the prescribed value. Treatment is inhibited when either the accumulated dose has been reached or when the number of fractions equals the prescribed value. After a field has been recorded as treated in a particular session, a warning is displayed if it is accessed on the same day (unless explicitly declared as a hyperfractionated treatment). Provision to override the time interval is necessary to allow patients to be treated twice on one day to allow for gaps in treatment.

In an ideal world, the database of the R and V system should provide a complete record of treatment. However, it is common practice to maintain a manual system and to print the treatment details each day when all the patient fields have been treated. Paper systems have the advantage of being able to record signatures and check marks, facilities that are often not adequately catered for in the R and V software.

### 41.2.6 PATIENT VERIFICATION

The advent of electronic portal imaging has allowed routine evaluation and verification of the patient position on treatment and the accuracy of the treatment beam delivery. It also generates large amounts of image data, which need to be incorporated into a general image-viewing network. Images of treatment fields are easy to acquire as part of the individual field treatment delivery, but if the field is small, as in conformal therapy and IMRT, it is sometimes necessary to perform double exposure imaging, which gives extra radiation dose to the patient. It is useful to be able to incorporate this extra exposure into the record and verify system, both to program when images are to be taken and to add in the extra dose delivered to the patient. Control over the machine parameters and number of MU's set are also important as the larger field is not part of the prescribed treatment and needs to be monitored. Diode dosimetry for entrance and exit doses can also be incorporated into the R and V system, both in terms of a reminder as to when doses should be measured and to record the doses that have actually been delivered.

---

## 41.3 SYSTEM MANAGEMENT

A system manager should be nominated to manage the R and V system. The system manager should be very familiar with computers in general and the R and V software, in particular. The manager should also be able to customise the system to the users' requirements, and help to provide maximum use of all the features of a particular system.

### 41.3.1 PASSWORDS

Different levels of authorisation are password protected. [Table 41.2](#) shows a typical example of how password access may be used. If security is to be effective, it is important that the user logs out when finished, unless the system does this automatically. The system should allow a user with a high level of access to enter their password temporarily to execute a particular task. Overriding parameters that are out of tolerance often requires a password, so is only allowed to be carried out by users with certain levels of access.

**TABLE 41.2**

## Hierarchy of Duties Associated with R and V Systems

- 
1. Treat patients without modifying the data
  2. Enter patient data
  3. Enter and verify patient data
    - Delete patient data
    - Override out of tolerance items
  4. Backup and restore patient data using long term storage
    - Edit and enter the tolerance table
  5. Customise machine parameters
    - Backup and restore machine parameters using long term storage
  6. Troubleshooting involving direct access to the database
- 

These duties may be ranked in order by passwords. It is assumed that each level includes authorisation to perform all the lower levels.

---

### 41.3.2 TOLERANCE TABLES

The achievable accuracy of patient setup varies according to the treatment site. For example, head-and-neck tumours are usually treated with the patient in an immobilisation device, which is often fixed to the table in a reproducible manner, but there may be much more variation in patient position on the treatment couch for chest and abdomen patients. It is therefore necessary to assign different tolerances to the agreement between planned and actual machine parameters for different treatment sites. The accuracy required for particular treatments may also vary. Different *tolerance tables* are customisable by the user to specify the range over which parameters can differ from the prescribed value before treatment is inhibited. Tolerance tables are identified by number and need to be assigned to every field. Some systems use a default tolerance table when none is specified. In this case it is strongly recommended that the default table should be the tightest tolerance table, so that inadvertent choice of a wide tolerance will be avoided. Table 41.3 lists reasonable tolerance values for typical sites.

**TABLE 41.3**

## Verification Parameters and Recommended Tolerance Tables for Routine Use

Units	Tolerance Table Number			
	1	2	3	4
Gantry angle	Degrees	0.1	0.2	0.2
Collimator	Degrees	0.1	0.5	0.5
Field X and Y	mm	1	1	1
Couch Height	mm	1	2	10
Couch Lat & Long	mm	1	5	50
Couch Rotation	Degrees	0.1	0.5	2.0
				10.0

Tolerance Table 1: Smallest tolerances: for accurate treatments with the patient immobilised on the couch (e.g. using a stereotactic frame).

Tolerance Table 2: Small tolerances on couch lateral and longitudinal movement: for treatments where patients are immobilised in a shell.

Tolerance Table 3: Tolerances suitable for pelvis/abdomen/chest where separations, etc, are checked daily.

Tolerance Table 4: Maximum flexibility: for static electron treatments.

---

### 41.3.3 BACKUP AND ARCHIVING

The large amount of data requires considerable storage capacity. Backup records of given treatments can be kept on optical disc or some form of data tape. It is useful if the backup system allows individual patient records to be retrieved as well as a full restore of the database. A daily backup of patients on treatment is usually performed (it should be possible to program this so that it occurs automatically during the night).

Old data are permanently removed from the system and transferred to long-term storage during the archival process. It is important that backups of archived data are also maintained. Ideally, archival should be controlled by the R and V system, so that a record of the patient's existence can be retained. Data storage should comply with national regulations relating to patient privacy.

### 41.3.4 SYSTEM RESILIENCE

Retrieval from tape is notoriously problematic, and any backup method should be fully checked (by retrieving patients) before it is actually needed. If data are stored centrally on a server, it is wise to have a backup server so that the system can be brought back online in the event of a serious failure. The backup server must be kept up to date. Transaction logs can be used as a method of restoring very recent data.

### 41.3.5 FAULT REPORTING

R and V systems are constantly evolving and it is important that software suppliers are made fully aware of any problems of use so that they can be rectified. For this purpose, it is helpful if the software stores an audit trail so that the source of any problems can be traced.

---

## 41.4 ERROR CONTROL

Although it is true that R and V systems have the potential for causing serious patient mistreatments when incorrect data are entered and not subsequently checked (Muller-Runkel and Watkins 1991; Barthelemy-Brichant et al. 1999), studies have shown that the rate of malfunctions is a fraction of the rate of mistakes prevented, and as systems are continuously improved, this fraction will decrease (Podmaniczky et al. 1985; Fraass et al. 1998). In a study of errors aggravated by the R and V system, Patton et al. (2003) identified 0.04% of treatment errors to be in this category. In order to keep these to a minimum, vigilance is required.

### 41.4.1 TYPES OF ERROR AND MEASURES TO AVOID THEM

Patton et al. (2003) identify four error types:

1. *Incorrect Patient.* Incorrect identification of the patient is surprisingly common. This may be because of two patients with the same name or because a patient is expecting their name to be called and responds to that of another patient. It is common practice for one member of staff to be interacting with the computer system while another prepares the patient for treatment. Asking the patient for their name and date of birth, each day, is a useful precaution, as is requiring the person who set up the patient to check the identity of the patient selected on the R and V system.
2. *Incorrect Data.* Incorrect data can arise in a number of different ways. A bug in the data-transfer software may result in data being incorrectly transferred. Problems may also be associated with human error. Incorrect data may also result from the use of the copy-settings facility referred to in [Section 41.2.2](#).

3. *Incorrect Site.* It is common practice to use a reference point and to then carry out a move relative to this point. It is possible to forget to carry out the move, and if wide tolerances are set, the R and V system may not identify this as an error (Fontenla et al. 1996). The chances of this leading to an error are reduced if tolerances are kept as tight as possible (see [Section 41.3.2](#)).
4. *Incorrect Beam Modifier.* Beam modifiers such as bolus, lead blocks or compensators, are often not identified by the R and V system. This type of error is perhaps not directly related to the use of the R and V system, but where different coding is provided it should be used. It is also useful to put a reminder into the system that appears on the screen during treatment.

#### 41.4.2 TRAINING REQUIREMENTS

Staff training is extremely important for the acceptance and efficient use of any new system, particularly as the R and V system is often part of a much larger package of new technology. It is important that staff who will be using the system on a daily basis have time and training to become familiar with all aspects of the system and have access to a trainer or the system manager for an immediate response to software and hardware problems. When data are to be entered by hand, it is important that the input information is in a standard format, to assist accuracy and speed. It is useful to have the same user interface for all linacs in a department, even when the linacs are from different manufacturers.

Commercial systems are often manufacturer-specific, and never exactly conform to the requirements of a particular department. Acceptability is dependent on the software design and the reliability of the computer hardware. The whole system should be both user-friendly and robust enough to cope with many operators. It is sensible to run the system initially with minimum functionality, and then to add to it once the system has become familiar. Initially, when an R and V system is introduced, patient throughput decreases until staff become familiar with the system. However, this is temporary, and patient throughput will soon rise, particularly if assisted setup is used.

#### 41.4.3 USE OF OVERRIDE FACILITIES

There will be times when the settings for a field are modified at the time of treatment; for example, a change in daily dose or a reduced field size. In this case, an override facility allows the user to change parameters. Because the check system is disabled, the use of the override facility is a significant cause of errors. It is important that there is a human check of the overridden data. It is also important that the software makes clear which items are being overridden; overriding everything when half way through an assisted setup can lead to some items being overridden unintentionally. Provided that passwords are correctly used at all times, the system can provide a useful audit trail.

The R and V override facility may also be used when the machine control system is exhibiting a fault, but only with *extreme care*. It is not advisable to use it to speed up treatment when a change has been made.

---

### 41.5 QUALITY ASSURANCE

A quality assurance program should ensure that failures, such as corrupt data, power failures, etc. are kept to a minimum and do not significantly affect patient treatments. Individual QA programs will depend on the system in use. [Table 41.4](#) gives a suggested list of checks that might be performed by trained personnel while the system is relatively new to the department. The frequency of some of the QA checks can be reduced as confidence in and familiarity with

**TABLE 41.4**

## Quality Assurance Program

**Daily checks:****1. Before treatments commence**

Treat a *test* patient, using the assisted setup (this has the advantage of familiarising the operator with the system), print out the daily record and check that the following are as prescribed:

- The parameters obtained using the assisted setup
- The Monitor Units delivered (look at screen and printout)
- The number of fractions
- The cumulative dose
- The date on the printout

**2. After every treatment**

- Look at the screen and daily printout (if done) and check it before going on to next field and signing it
- Check next field before treating
- Be especially careful with overridden parameters

**3. At the end of the day**

- Check the record of that day's treatments either using printout or by examination of the data on screen
- Backup and check patient database

**Weekly checks:**

- Backup and verify system files
- Check machine performance statistics from machine record printout

**Monthly checks:**

- Archive or delete patient prescriptions from database one month after completion
- Backup and verify customisation programs (such as tolerance table consistency)
- Test and time the assisted setup of machine parameters
- Test uploading of simulator parameters into the prescription

**Checks at the end of a course of treatment:**

- Check that the number of fractions and the cumulative dose are as prescribed
- Check that the R&V record is the same as the treatment sheet, if used

the system grows (Carson et al. 1992). The daily check (which can be carried out as part of the run-up process) and backup of the system are the most important. IPEM Report 93 (2006) provides further recommendations.

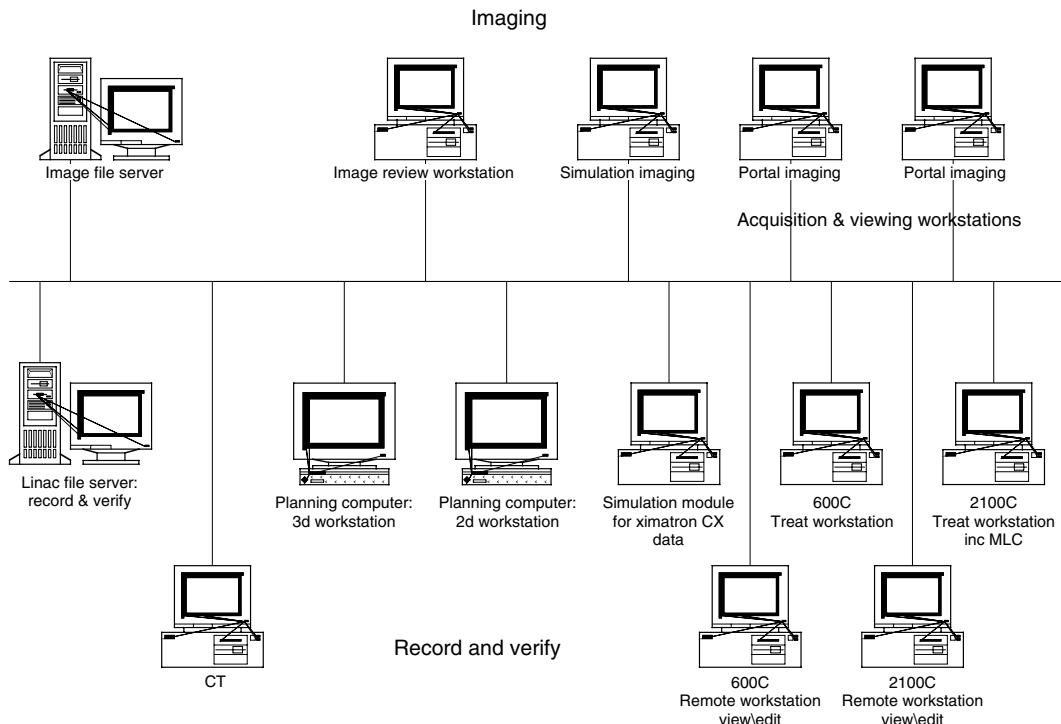

---

## 41.6 THE NETWORKED DEPARTMENT

To use the R and V system efficiently, networking is essential between simulator, treatment machines, and treatment planning systems. If the treatment machines are networked, it is then possible to switch patients from one machine to another without having to re-enter the data. If the planning system and the simulator are linked to the network, the need for typing in field parameters is removed, and patients are treated with the same data that has been simulated and planned.

There are different views on the best method of networking. Some systems have a master database on each unit, the data of which may be accessed by other units but not transferred to them. This ensures that a patient's data cannot exist on two units simultaneously. Others have a central master database of all patients stored, as well as separate databases on each of the units of the patients currently on treatment. A warning is displayed when treating a patient, if the two databases are not identical. The general trend is toward a single relational database accessible from anywhere. This puts a high demand on reliability and safety features. For a single database, record locking should ensure that it is not possible to access the data on two units simultaneously. A typical medium-sized radiotherapy network is shown in [Figure 41.1](#).

For patient data transfer alone (i.e. mainly text files), a typical network in a small department would have a hub and star configuration, using 10-base-T twisted pair cabling. Image

**FIGURE 41.1**

A typical radiotherapy network.

handling and transfer requires a much larger capacity cable and a storage system (fileserver) of much higher capacity. At present, 100-base-T cabling is essential for image transfer in reasonable time. Any network cabling over distances greater than 98 metres requires the use of fibre-optic cables.

A contentious issue is whether the network should be isolated from the main hospital network. Virus infections on a radiotherapy network can be disastrous and strict discipline needs to be exercised to prevent attacks as some system suppliers are reluctant to authorise the use of antivirus software on their equipment because of the problem of testing, and undesirable effects on real-time control systems. It is best practice to use a firewall or VLAN to isolate the R and V system from the hospital network. Some manufacturers now also firewall the treatment workstations from the radiotherapy network.

#### 41.6.1 INTEGRATION WITH HOSPITAL INFORMATION SYSTEM

The next step is to have an integrated radiotherapy system where a central database contains all the patient data, including clinic appointments, test results etc, which is linked to all the treatment units, simulators and treatment planning computers and can handle images from these systems (Saunders 1990). This can be a costly setup, because not only does it need to have a powerful database and linked workstations situated at treatment units, in offices, and clinic rooms, but also a sophisticated backup system so that treatments can continue in the event of computer failure. It is important to have sufficiently powerful uninterruptible power supplies (UPSs) installed to maintain the system long enough to keep the full integrity of the data. For a completely integrated system, the computing power should be sufficient to handle image files, such as CT, MRI, portal images, simulator images, Beam's-Eye Views (BEVs) and Digitally Reconstructed Radiographs (DRRs), and connections to other hospital sites are extremely useful.

As these systems are introduced, staff instruction will need to include an emphasis on the interrelationship between all sections of staff. For example, secretaries may enter the general information about a new patient and simulator staff use the system to book simulation, mould room work, and treatment. Complete integration of the databases may not be possible, but it should be possible to ensure automatic transfer of data. Duplication of data entry should be avoided because it may lead to two different versions of the data. The simulator or treatment planning staff should be responsible for the entry of the treatment setup parameters. After treatment, follow-up data is added by different staff from those producing statistics, and it is important for the latter to make known to the former which are the vital data to ensure maximum usefulness of the system.

## 42.1 INTRODUCTION

Unless all the equipment being used in a department is from a single software supplier, it is a requirement that image and other data should be transferable between different computing systems in such a way that it can be interpreted by different software. The Digital Imaging and Communications in Medicine (DICOM) standard aims to provide a standard format and has now reached general acceptance as the standard for such data transfer. In this chapter, the radiotherapy requirements for data transfer are considered in the context of the DICOM standard.

The DICOM standard began in 1985 as the American College of Radiologists and National Electrical Manufacturers Association (ACR–NEMA) standard for the transfer of CT images. As digital imaging progressed the need for a broader standard was identified and the ACR–NEMA standard was expanded in scope to become the DICOM standard we have today. The standard itself can be found in digital form on the NEMA web site (<http://medical.nema.org>), but it is written in quite technical language, and less-technical web sites such as <http://www.rsna.org/Technology/DICOM> or <http://www.dclunie.com> may be more helpful. The lecture notes for a course run by the Swiss Society of Radiobiology and Medical Physics are available at <http://www.sgsmp.ch/dicom>. Published articles on DICOM (Bidgood et al. 1997; ECRI 2001; Mildenberger et al. 2002) are also a useful source of information.

This chapter is intended to give an introduction to some of the concepts that need to be understood by the radiotherapy physicist to support the use of the standard for radiotherapy communication. It begins with a description of the building blocks of the standard and then considers the application to radiotherapy.

## 42.2 ELEMENTS OF THE STANDARD

The DICOM standard has three main components: a data format, a definition of actions to be taken on the data and a protocol for the communication of the data\*. The standard applies the concepts of object-oriented programming languages, defining a series of data objects and operations that may be done to them.

### 42.2.1 THE DATA FORMAT

As with any database, each real-world object can be described by an information object. Part 3 of the standard contains a series of information object definitions (IODs) which specify the structure of all DICOM objects. Part 10 of the standard describes a disk file format.

---

\* This began primarily as a data transfer protocol in the same way as HTTP, but it is increasingly common for the data to be stored on disk in DICOM format.

A truly object-oriented data structure would contain within the object only those items of information that are related to that object. For example, the *information* about the patient—such as name and date of birth—would be contained in a *patient* object, and information about an image—such as the pixel size and image location—would be contained in a separate *image* object. Some of the simpler object types, such as print jobs or system messages, follow these principles, but items such as images are defined as composite objects. This means that the image format includes within its header, details of all objects that are relevant to the image, such as the patient details and the clinician's name, as well as details (or *attributes*) of the image, such as the pixel size and the location of the image. Because each object is sent in a separate transaction, or stored in a separate file, the use of composite objects is faster.

Each item or data element in a DICOM file consists of a tag indicating what sort of data it is, an indication of the length of the data and finally the data itself in the form:

Tag 1	Tag 2	VR	Value Length	Data
16 bit	16 bit	16 bit	16 bit	Variable

The *tag* consists of two 16-bit integers. For example, the tag (0010,0020) represents a patient identification number. The first of these numbers indicates the data group—group 0010 contains all tags relating to the patient\*. A list of all the tags defined is contained in the data dictionary (Part 6 of the standard) and their application to a particular data object is contained in the IODs (Part 3). The next two integers provide a definition of the data representation that follows. In the original ACR–NEMA version of the standard, the type of data or *value representation* (VR) was looked up in the data dictionary and the *value length*, was a 32-bit integer. This method of data type definition is called *Implicit VR*. In the newer versions of the standard, a method called *Explicit VR* is preferred. In this, the first 16 bits define the data type, or VR and the second indicates the length. VRs use a two-letter code indicating the type of data. For example, the patient name is type PN and an integer is type IS. Provisions are also made for variable lengths. The DICOM standard aims to provide backwards compatibility, so both methods are permitted. The DICOM data dictionary defines three types of data. *Type-1 data* are required to be present and a blank value is not acceptable. *Type-2 data* elements are also required, but it is permitted for their value to be empty. *Type-3 data* are optional. Both type-1 and type-2 data can be conditional (as in *type 1C*), indicating that their presence is required only if some condition is met.

Different computer systems use different ways of storing data that are larger than 8 bits (1 byte). Some computers, such as Windows™ based PCs, represent a two-byte number with the least significant byte being stored (or transmitted) first. This is referred to as the *little endian*<sup>†</sup> storage format. The other method, still used in many UNIX workstations, was to reverse the two bytes; this is called the *big endian* storage format. DICOM provides for both methods of representation, but little endian is the default.

To examine DICOM data, one must first get the data as a file in the part-10 format, which is not always easy; two systems may transfer data via DICOM but not use DICOM files internally. Many radiotherapy systems have an intermediate step where the data are stored as files until a user explicitly imports them. Otherwise, it is possible to set up a DICOM service on a PC

\* The standard only specifies even-number groups. All odd-number groups are provided for companies to use for proprietary data not included in the DICOM object definitions. All such private groups are registered with the aim of ensuring that there is no misinterpretation of data between manufacturers. If the object is an image, the last tag (7fe0,0010) is the pixel data as a continuous stream. The information required to read the image data (image size, bit depth, etc.) is contained in group 0028 of the DICOM header.

<sup>†</sup> The term originates in *Gulliver's Travels*, where it referred to the issue of whether to open a soft-boiled egg at the big end or the little end.

which will receive DICOM data and store it as a file\*. The text fields in the header of a DICOM file can, to some extent, be understood using a standard text editor, but a DICOM dump program (available from the ERL or OFFIS) will be needed for any thorough analysis.

#### 42.2.2 DATA ORGANISATION

DICOM data structures are fundamentally based on a hierarchical data structure. At the top level is the patient. The patient's data are broken down into examinations, or "studies", that are further divided into "series". Thus, an MR study may consist of a T1 weighted series and a T2 weighted series. Because each slice of a multi-slice image is a separate composite object in DICOM, all of these related objects are grouped in the single series. As shall be seen later ([Figure 42.2](#)), DICOM RT objects, such as DICOM RT Plan, are stored at the series level.

#### 42.2.3 DICOM ACTIONS (SERVICE CLASSES)

For two systems to communicate, a number of transactions must be defined. For composite information objects, such as images, the allowed transactions are STORE, GET, MOVE, FIND and ECHO. These elemental services are called *DICOM message service elements*, or DIMSEs. Any practical task may involve a sequence of these transactions, which is called a *service class*. A service class such as *Query/Retrieve* is made up of three elemental services: FIND, GET, and MOVE. Services are carried out on data objects, and the manner in which the service is performed is dependent on the data object on which it is performed. Thus, the service and the object form a *service-object pair class*, or SOP class. An example of an SOP class is CT image storage.

#### 42.2.4 DICOM IDENTIFIERS (UNIQUE IDENTIFIERS)

The DICOM standard includes a system to enable objects to be identified in such a way that each system that generates data can create an identifier for the data that is guaranteed to be unique. This is called the unique identifier (UID). The UID can be used as a pointer that allows objects to be linked together. Each manufacturer registers a UID root unique to that manufacturer. It is then the responsibility of the manufacturer to ensure that the remainder of the numbers making up the full UID are also unique. Each SOP instance has its own UID stored in data element (0008,0018). If one object has been used as the basis to create a new object—for example, a structure set based on a CT image—then the structure set will reference the CT image UID within the DICOM header. There are also study and series UIDs through which a database can determine exactly which objects belong together. With the aid of UIDs, it is possible for related data objects to be sent by separate routes to an archive system, and the linkages can be restored on arrival.

#### 42.2.5 DATA COMMUNICATION

The DICOM standard is built on the International Standards Organisation Open Systems Interconnection (ISO-OSI) seven-layer model in which data are passed through various layers from the application down to the physical transport layer. DICOM deals with the application layer, and some of its terminology, such as *application entity title (AE Title)*, is derived from this. For practical application, the standard is based on TCP/IP networking.

---

\* Such software is available in the form of the Central Test Node (CTN) software which is available from the Electronic Radiology Laboratory of Mallinckrodt Institute of Radiology (<http://wuerlim.wustl.edu>) or from OFFIS (<http://dicom.offis.de/dcmtk.php.en>).

Each system has a fixed IP address, and service class providers (SCP) (see Section 42.2.5.1) will listen for DICOM associations on a specified TCP port. The standard port for DICOM communication is port 104, but provided that the port selected is not one dedicated to other network services, such as ping, ftp and telnet, any port can be chosen. A system may have different DICOM services operating simultaneously on different TCP ports.

#### 42.2.5.1 *Users and Providers*

DICOM communication is always between two computers, one of which is the user (or client) and the other being the provider (or server) for the particular transaction. These are termed *Service Class User* (SCU) and *Service Class Provider* (SCP). Thus, a CT scanner wishing to transmit data is defined as the SCU, and the PACS\* archive or treatment planning system is the SCP. A given computer may be both an SCP and an SCU. For example, the planning system may additionally be able to query the CT scanner database and retrieve images. For that transaction, the CT scanner is the Query/Retrieve SCP, and the planning system is the Query/Retrieve SCU.

A list is maintained in each system of all other systems with which it will associate. This list has three required fields: the IP address, the TCP port and the AE Title of the DICOM service. The AE Title is set within the software for each DICOM application. It can be anything, but it is wise to make sure each system has a different and representative AE Title. Some systems sort the list internally by AE Title, so multiple entries with identical AE Titles can cause serious problems.

#### 42.2.5.2 *DICOM Data Transfer*

Transfer of data using DICOM consists of three stages. The first stage is a *handshaking* operation between the two computers, which is referred to as establishing an *association*. Each SCU and SCP has a defined AE title. The SCP listens on a defined port on the computer, so the SCU must know the SCP AE title, the port number and the IP address which identifies the computer. The SCU first requests an association with the SCP providing information on its own AE title and IP address. Depending on the degree of protection incorporated in the SCP, this association may be rejected if either the AE title or the SCU host IP address are not recognised, but the SCP may be set up to accept any association. The next step is to negotiate the action (SOP class) required and the transfer syntax (e.g. VR little endian) of the data. Communication may also be rejected at this stage of the negotiation.

Once it has been established that the data are potentially compatible, the data are transmitted. The SCP will now try to carry out the requested SOP class. It may be that this proves impossible because some data element is missing, in which case an error message may be returned. However, an error message is not necessarily an indication of failure of the data transfer, as it may refer to something that is not a requirement. Equally, an allegedly successful data transfer may not actually have succeeded because of some problem with the data. An example of this is that different systems use different methods to determine whether two images are different. If the recipient uses an optional DICOM element (see Section 42.2.1 and Section 42.2.6) for this purpose which is not transmitted by the sending system, succeeding images may overwrite each other.

#### 42.2.6 THE DICOM CONFORMANCE STATEMENT

In view of the wide applicability of the DICOM standard, software that interacts with DICOM data is unlikely to support all the data types that are defined in the standard. For a

---

\* PACS=Picture Archiving and Communication Systems.

given data object, certain mandatory parameters are defined which must be included if the data object is to be supported at all, but additional optional items can also be included. For this reason, each software supplier is required to produce a *DICOM conformance statement* in which the objects that are supported and the optional items that are used are defined. The conformance statement also lists actions that are taken and any specific requirements that have to be met. From the DICOM conformance statements of two pieces of software, it should be possible to determine whether the software systems will communicate with each other and the degree of interoperability that can be expected. In the example given in [Section 42.2.5.2](#), images can be communicated between the systems, but interoperability is not achieved because the images are not stored properly. Another example of a failure of interoperability is where data about image magnification are not transmitted in the form used by the recipient system. By comparing two conformance statements, it is relatively easy to determine whether communication will be possible. However, because of the many optional items within DICOM and because of frequent misinterpretation of the standard, interoperability can only be confirmed reliably by a live data transfer test coupled with careful assessment of the transferred data.

## 42.2.7 DATA TRANSLATION AND QUALITY ASSURANCE

It is frequently thought that electronic data transfer is bound to be error-free, provided that an appropriate check (such as a checksum) is carried out by the system to ensure data integrity. This is not the case, because the process of data transfer is likely to involve translation of the data from one standard to another\* (see, for example, [Section 42.4.2](#)). It is, therefore, essential that each DICOM interface be carefully tested to ensure that the transferred data are as expected.

---

## 42.3 DICOM APPLIED TO DIAGNOSTIC IMAGE DATA

Image data from a number of different sources are used in radiotherapy treatment planning. Data sources include CT, MR, PET, SPECT, ultrasound and planar x-ray images. The most mature part of the DICOM standard is that relating to CT data. As indicated above ([Section 42.2.1](#)), the DICOM image format consists of a header section, much of which is in ASCII format, which defines such things as the patient name, image identification, and details about the type and format of the image. Each slice of a CT data set is stored as a separate file, usually with the file extension *dcm* or *img*. In addition to transverse slice data, DICOM defines a secondary capture data type referred to as DICOM SC. This allows almost any 2D image type to be stored as a DICOM file. Some images will only be available as bitmap image format files, such as TIFF or BMP, and a means of translating such images into the DICOM SC format and attaching an appropriate header is useful. Viewers for DICOM image files are widely available, many of them at no cost (Escott and Rubinstein 2003).

### 42.3.1 DICOM PRINT FUNCTION

DICOM defines a standard for printing images which can be used to obtain hardcopy images on any printer that supports the standard, but which is particularly useful for a laser imager. Any software system that has a DICOM print output can then produce high quality images on the imager. This can be a useful feature for producing digitally reconstructed radiographs (DRRs) on x-ray film.

---

\* There is an increasing trend towards using the DICOM standard for internal data storage. This will tend to reduce the requirement for data translation and thus improve security.

### 42.3.2 DICOM WORKLIST

The DICOM worklist provides a methodology to streamline the work of a diagnostic department and enables workloads for CT scanners or other image acquisition systems (*modalities*) to be more easily managed with close integration to a PACS or radiology information system (RIS). Where different modalities receive identical demographic information from the RIS via DICOM worklist, this eliminates problems of subsequently associating, in an archive, studies from the same patient which have accidental typing discrepancies in demographic data (see also [Section 42.5](#)). The *performed procedure step* allows the imaging system to record the start and completion of the requested imaging operation. A format also exists for the definition of an imaging report (Hussein et al., 2004). A later addition to the standard is the ability to request a storage commitment. This is useful when sending an image to an archive. The CT scanner sends a *storage commitment request* and the archive responds with confirmation that the data are satisfactorily committed to storage. The CT scanner can then safely delete the image.

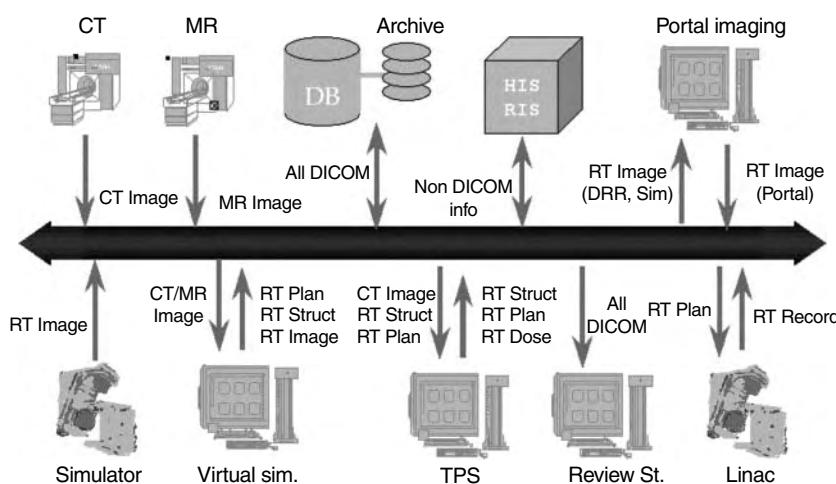

### 42.3.3 MEDIA STORAGE

The standard includes definition of how images and other data are stored on various removable media, such as DVDs and CD-Rs. This enables data to be archived in a relatively future-proof manner in the absence of a PACS, to be easily transported to a different treatment centre and to peripheral clinics, or given to the patient.

---

## 42.4 RADIOTHERAPY DATA OBJECTS

Although the image itself is what is of principal interest in diagnostic radiology, in radiotherapy, the magnitude of the pixel data elements is also important. In addition, overlays indicating regions of interest need to be available as separate data objects so that they can be used in the design of treatment fields. For this reason, in 1997, the DICOM committee decided to add a set of radiotherapy objects to the standard (Neumann 2002). Figure 42.1 shows the flow of data in a radiotherapy department and the relevant DICOM objects that are transferred.

**FIGURE 42.1**

Diagram showing the transfer of DICOM data at different stages of the treatment planning and delivery process. A DICOM printer could also be added. Data transfer between devices implies that a connection has been specifically established between them. Alternatively, interfaces may be set up between each device and the archive, which can then provide a link between devices (although care must be taken to ensure that treatment plans are not made available to the linac until they are fully approved).

#### 42.4.1 DICOM RT STRUCTURE SET

To carry out radiotherapy treatment planning, the target tissue and organs at risk are defined. This process of segmentation of the tomographic images leads to a set of structures, which are defined by the DICOM RT structure set object. The data structure allows for different contour types, including the body or *external* contour and the target as PTV, CTV or GTV. Structures can also be defined as *avoidance* structures. These structures have special meanings that must be maintained across the different computing systems. A Structure Set is linked to an image (see [Figure 42.2 in Section 42.4.7](#)). In addition to contours, the standard allows the definition of markers and isocentres, although interpretation of these may not be the same.

#### 42.4.2 DICOM RT PLAN

The treatment planning process leads to a series of treatment beam definitions as defined by the DICOM RT plan object. This includes an indication of the position of the treatment isocentre, as well as the field sizes and beam orientations, and there is provision for definition of tolerance tables. The number of monitor units is defined, as well as methods of describing doses to the target and organs at risk and the planned fractionation. Couch movements can be relative or absolute. The DICOM standard requires that all beam definitions follow the IEC 1217 standard (IEC 1996, and see [Section 11.5.4](#)) apart from the definition of the coordinate system. In DICOM, the positive Z direction is along the couch towards the gantry, whereas in IEC1217, this is the Y direction. In IEC1217, the positive Z direction is anterior (for a supine patient), whereas in DICOM, the positive Y direction is posterior. The X direction is unchanged. This issue can lead to confusion.

Transmission of an RT plan may require a number of data translations. These may include the name of the treatment unit, the name of the wedge and of any electron applicators. It is, therefore, especially important to verify such data transfers with extreme care when the link is set up and to apply appropriate caution subsequently. For multi-segment treatments, such as IMRT beams and automatic wedge treatments, it may be necessary to change the number of segments. For example, the treatment planning system may consider a step-and-shoot IMRT treatment as consisting of four radiation segments, while the linear accelerator may treat this as a sequence with eight control points, one at the beginning and end of each segment, because the accelerator requires three extra *move-only* segments. DICOM itself uses the accelerator convention.

Provision is made for plan approval status, but it is not mandatory that this be implemented. Definitions also exist to define brachytherapy treatments, although these are not yet widely used.

#### 42.4.3 DICOM RT DOSE

Treatment planning systems calculate the radiation dose distribution as a matrix of points with associated doses. These dose grid files are provided for in the DICOM RT dose object. Definitions also exist in the DICOM RT dose specification to store relationships between dose and structures through dose volume histograms and dose region of interest (ROI) statistics. Isodose curves may also be defined. This functionality is slowly being implemented.

#### 42.4.4 DICOM RT IMAGE

In radiotherapy, planar x-ray images are closely associated with the geometric settings of the related treatment beam. The RT image is an extension of the planar x-ray format to give additional information about the exact geometry of the image, such as the distance to the source, and also to combine the image with the field definition modules of the DICOM RT plan object relating to that particular beam. In this way, the anatomical image may be overlaid by the shape of the treatment field with which that anatomy is to be treated, as well as any

anatomical structures which are outlined. It is also possible to represent the field as a curve object, but this is less useful.

Such images may be generated in a number of ways. The treatment planning system will generate DRRs, which show the image that would be obtained from a radiotherapy treatment beam in a plane perpendicular to the beam beyond the patient. Additional sources of such images are the radiotherapy treatment simulator and the radiotherapy treatment set electronic portal imaging device. Associated with these images, but not currently covered by a DICOM object, are the associated field placement errors, which are calculated by comparison with the planning RT Images.

To provide backwards compatibility, many systems allow the overlay to be incorporated into the image pixel data and store the image in the DICOM SC format. The image may then be viewed on systems which do not interpret the RT Image elements. This is not a satisfactory solution, as image data are lost and the beam information is only retained in a visual form.

#### 42.4.5 DICOM RT TREATMENT RECORD

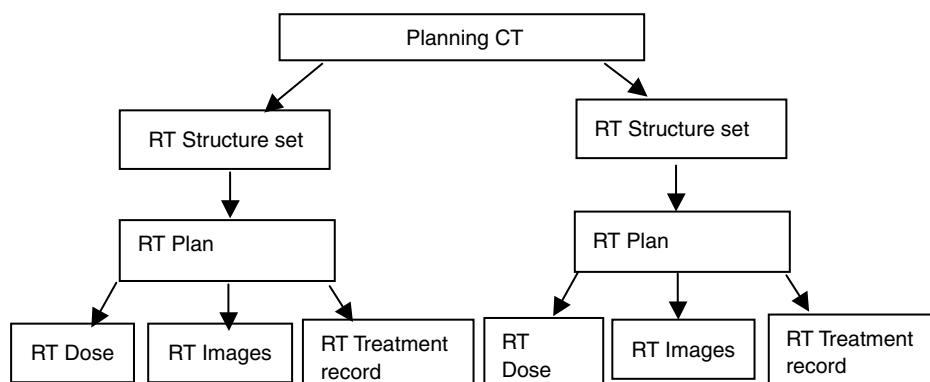

Although not in widespread use, the DICOM RT treatment record object completes the list of available data objects under DICOM RT. Included are brachytherapy treatment records and treatment summaries. It is provided for completeness and for the purposes of future compatibility. It is more usual for this type of information to be interfaced directly with the electronic patient record.

#### 42.4.6 OTHER DATA FORMATS

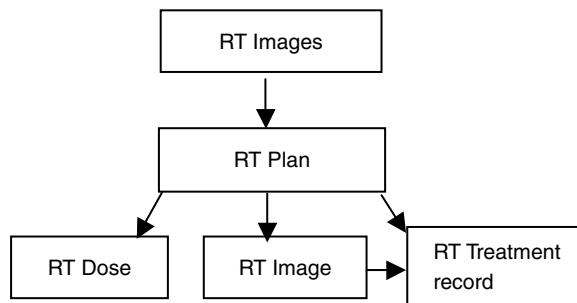

Although each treatment planning manufacturer has their own internal proprietary data format and many can read and write data into the various DICOM objects, there is another data format that is widely used particularly in systems originating in the U.S.A. This is the RTOG format, which was designed for the purpose of transferring radiotherapy data to the Radiotherapy and Oncology Group data centre so that quality assurance of clinical trials could be performed. This data set provides access to all the data required for radiotherapy planning and is widely supported.

#### 42.4.7 DICOM RT DEPENDENCIES

In the radiotherapy process, a number of DICOM objects are created. There is a system of dependencies in which each DICOM RT object contains references to the DICOM objects which preceded it. These are illustrated in Figure 42.2 and [Figure 42.3](#).

**FIGURE 42.2**  
Example 1: CT Plan with two phases.

**FIGURE 42.3**  
Example 2: Simulator plan.

## 42.5 DATA VISUALISATION IN THE RADIOTHERAPY PROCESS

While the requirements for viewing data in the diagnostic field are well-established, the viewing of radiotherapy data other than by using the proprietary software that generated the data is in its infancy. However, the standardisation provided by DICOM RT provides the opportunity for visualisation of radiotherapy data using generic visualisation tools that conform to the standard. In this section the way in which such facilities would be used is described.

Where visualisation of particular objects is not supported, it is essential that the storage system should accept all the objects without modification and be able to transmit them, unmodified, to other computer systems as required. Because some computer systems are unable to accept particular objects, the objects transmitted by the storage system must be selectable (i.e. it must be possible to transmit any combination of objects to the chosen recipient). It is also important that patient identifiers stored in different objects should be consistent. Recipient systems often require the ability to identify different DICOM objects as belonging to the same patient data set. Thus, it is essential that the specifications applied to issues such as the spaces between names and at the end of fields are identical for all the objects.

### 42.5.1 TARGET VOLUMES

Radiotherapy consultants often see patients in peripheral clinics away from the treatment planning computers. They want to be able to review and alter the volumes defined and to discuss them with colleagues in multidisciplinary teams. This requires the display of DICOM RT Structure Set overlays together with the possibility of editing them.

### 42.5.2 PLANNING RT IMAGE VIEWING

For simulator-planned patients, the radiation oncologist will need to view the RT Images acquired at simulation to establish that the plan is satisfactory. They will need to view the image with the associated beam overlay and be able to edit the collimator positions and any shielding structures. For CT-planned-patient viewing, the DRRs will form part of the review of the completed plan.

### 42.5.3 DOSE PLANNING

The availability of all the DICOM objects is essential for dose planning. To be able to use the defined contours, the structure sets are required to be available in the appropriate DICOM format.

The standardisation provided by DICOM RT allows interchange of data between planning systems and facilitates the independent verification of dose calculations (Spezi et al. 2002).

#### 42.5.4 DOSE PLAN VIEWING

The dose plan will be generated by a specialist dose calculation computer. This dose plan will need to be viewed by the radiotherapy consultant and accepted (or otherwise) as suitable for treatment. It will also be desirable for these dose displays to be available for review whenever the patient is seen subsequently. A 3D view of the dose display and its relationship to the defined target and organ at risk volumes is required, as well as a 2D display superimposed on transverse images and on reformatted coronal and sagittal images.

#### 42.5.5 PORTAL IMAGE VIEWING

Portal images are taken to be compared with simulator images or DRRs. Portal imaging software usually includes facilities for such image comparisons and for measuring the differences between the images or *field placement errors*. This is done by the use of overlays of the field shape and of patient anatomy. In order for medical staff to be able to review these registrations, it should be possible to display the images together with the overlays side-by-side. Ideally, it should be possible for the consultant to use the sort of facilities available on the imaging workstations to confirm or edit the registrations and to record approval or otherwise of the images. The values of the field placement errors need to be stored along with the images. One approach to this would be for the matched template images to be stored as DICOM-SC objects so that the consultant can see the end result of the matching process.

#### 42.5.6 RECORDING APPROVAL

One of the main aims of RT object visualisation is for the clinical oncologist to review plans, dose and images, and give their approval to the plan that has been produced. Once treatment has started, the clinical oncologist may view the portal images in conjunction with planning reference images and give their approval for treatment to continue. The approval status of radiotherapy objects is very important and is included within the DICOM standard. It should be possible for clinicians to approve objects with an electronic signature and for this approval status to be clearly indicated.

---

## 42.6 SUMMARY

The DICOM standard provides a method to enhance interoperability between computer systems in radiotherapy. However, although image transfer is usually a seamless operation, the complexity of the radiotherapy extensions to the standard means that individual testing of each data link is essential. Advice on such testing can be found in IPEM Report 93 (IPEM 2006). Electronic transfer of data is more reliable than human data transfer by typing at a keyboard, but because of the many translations that occur during data transfer, accuracy cannot be guaranteed. Considered protocols must be in place to ensure that appropriate checks are carried out. Electronic methods of data verification that are independent of DICOM need to be developed. The DICOM standard is not yet fully mature and in the future we should expect that new standardised methods of viewing the data will facilitate wider availability of the electronic data. However, because of the potential for serious harm in radiotherapy treatment, caution should be applied before implementing a completely paperless system.

---

## INTRODUCTION

In this Part we cover all those external-beam radiotherapy techniques that, for a variety of reasons, do not easily fit into conventional treatment planning ([Part G](#)). Today Conformal Therapy (CFRT)\* is no longer considered to be a special technique, but it is used here as a foundation for introducing Intensity-Modulated Radiotherapy (IMRT) which is a particular form of CFRT ([Chapter 43](#)). The deceptively simple idea of introducing another degree of freedom in treatment planning, namely to create deliberate variations or modulations in the intensity across the beam, has spawned an unprecedented period of development in treatment machine technology (e.g. dynamically controlled multileaf collimators (MLC)), in treatment planning systems capable of so-called *inverse planning*, and also in the search for truly meaningful criteria by which to judge the merit of a treatment plan (see Part G, [Chapter 36](#)). A separate chapter is devoted to the *clinical implementation* of IMRT ([Chapter 44](#)).

Stereotactic techniques ([Chapter 45](#)) have come a long way since the initial idea of putting a small circular collimator on a linear accelerator as an alternative to the multisource cobalt-60 machine known as the Gamma Knife®. Superb dose distributions to treat small quasi-spherical lesions in the head can be achieved with these small circular collimators, but currently there are multileaf collimators with especially narrow leaves (miniMLCs) that can adjust to the projected shape of the tumour as the gantry rotates, enabling highly conformal dose distributions to be delivered also to irregularly shaped tumours. Additionally, stereotactic *body* radiotherapy, also known as *extracranial* stereotactic radiotherapy, is now a very active field of development (SBRT 2006).

Proton beams ([Chapter 46](#)) are the ultimate modality with which to do Conformal and Intensity Modulated Therapy, possessing far superior depth-dose characteristics than either megavoltage photon or electron beams; today, only the high initial capital cost of the accelerator (cyclotron or synchrotron), and more especially, the proton gantry, is hindering the widespread construction of proton therapy facilities.

In complete contrast to conformal techniques of increasing sophistication, there are situations where the aim is to treat the whole body with very large fields. The two principal techniques of this nature are described here: total body irradiation with photon beams ([Chapter 47](#)) and total skin irradiation with electrons ([Chapter 48](#)).

All the modalities mentioned thus far have one thing in common—they are *low-LET*<sup>†</sup> radiation, i.e. the ionisation density along the charged particle tracks is relatively low; this is the case even for protons except at the very end of their tracks. [Chapter 49](#) deals with two, so-called high-LET modalities in clinical use, neutron beams, which have unfavourable depth-dose characteristics, and so-called *light-ion* beams such as carbon ions, which have depth-dose characteristics similar to those of proton beams. The important difference between high-LET and low-LET radiations is in their *radiobiological* properties (see [Part B](#)), and efforts are underway to exploit these differences to further improve the clinical efficacy of radiation treatment.

As indicated above, the pace of change in radiotherapy is considerable, and new techniques are constantly being developed. These techniques are evolving rapidly, and it is through the scientific (research) literature rather than textbooks that readers can keep up-to-date with such developments. The common thread in these new developments is to take advantage of the progress in tumour imaging to improve the accuracy of treatment delivery; the weak points in the current practice of radiotherapy are the uncertainties in patient set-up and in internal movements (Goitein 2004; Purdy 2004) as well as the uncertainty in delineating the tumour itself. For example PET imaging has become an essential part of tumour delineation

---

\* The abbreviation CFRT is used here rather than 3DCRT which is commonly used in the U.S.A.

† For a further discussion of LET (linear energy transfer) see [Section 7.14](#).

in non-small cell lung cancer (Nestle et al. 2006). These advances in tumour imaging allow margins to be reduced that, in turn, enable the prescription dose to be escalated where appropriate with the intention of increasing the probability of local tumour control (TCP) while maintaining an acceptably low probability of normal tissue complications (NTCP). It is even possible, in some cases, with the use of PET/CT and MR spectroscopy to identify particular parts of the tumour where a higher dose is required (Coleman 2002; De Santis et al. 2002; Perez et al. 2002; Bentzen 2005; Malinen et al. 2006); this leads to the concept of the *Biological Target Volume* (Ling et al. 2000; Grégoire et al. 2006). PET imaging is now a recommended part of planning for non-small cell lung cancer (Nestle et al. 2006).

One way to improve the accuracy of treatment delivery is to use advanced imaging methods throughout the process. To describe this, the term *Image Guided Radiotherapy* (IGRT) has been coined (Mackie et al. 2003; Bortfeld et al. 2006). However, IGRT is not a precise concept; indeed, most radical radiotherapy carried out in recent years could be described as *image guided*. IGRT as presently used implies that a 3D imaging system is provided on the treatment machine, allowing accurate assessment of the beam setup in relation to the tumour before each individual fraction. This follows the experience acquired in proton therapy where this approach has been carried out for many years, using fixed kilovoltage x-ray tubes mounted in the treatment room (see [Section 46.2.2](#) and [Figure 46.10](#)). Elekta (see [Figure 40.11](#)) and Varian are both marketing accelerators with a conventional kilovoltage x-ray tube, orthogonally mounted to the megavoltage beam, which is capable of both standard x-ray and so-called *cone-beam* CT imaging. Siemens offers a CT scanner installed in the same room as the accelerator with a common couch that supports the patient both for treatment and for CT scanning. A group in Utrecht (Raaymakers et al. 2004; Raaijmakers et al. 2005) is investigating the use of MR imaging to provide image guidance in the treatment room, and this concept is being taken up by Elekta.

Tomotherapy (see [Section 43.3.4](#)) fully integrates imaging with treatment delivery (Fenwick et al. 2006). This solution, described originally by Mackie et al. (1993), consists of rotating a 5 MV linac around the patient, similarly to what is done with a kilovoltage x-ray tube on a CT scanner. Complemented with appropriate beam shutters and detectors and combined with longitudinal motion of the table, *helical* intensity modulated treatment as well as megavoltage CT imaging are carried out (using a 3.5 MV beam—Forrest et al. 2004).

The availability of on-line image data presents a challenge to the treatment staff who are required to make instant interpretations of these data in order to decide whether to correct the patient position before proceeding to treat the patient or not. As computer speed increases, it may become possible to carry out instant recalculations of treatment plans based on these images (Court et al. 2005; Mohan et al. 2005; Scherrer et al. 2005); techniques such as *target of the day* and *adaptive radiotherapy* (Yan et al. 1997; Hugo et al. 2007) are currently being evaluated. The use of implanted markers (King et al. 2003; Shirato et al. 2004) enables the position of the soft-tissue target volumes to be detected by planar kilovoltage x-ray imaging.

In contrast with the more conventional use of orthogonal portal images, 3D reconstruction (possibly aided by implanted markers) enables, in principle, the patient position to be corrected to ensure perfect consistency with the treatment plan provided that the six degrees of freedom can be used. Current systems for correcting the patient position are based on orthogonal movements of the couch and couch rotation, which do not allow accurate correction for couch tilt or *roll*. Therefore, efforts are being made to develop systems, often derived from industrial robotic techniques, that allow more flexibility in 3D patient positioning (Hornick et al. 1998). The use of an accelerator mounted on a robotic arm (Webb 1999) as achieved, for instance, with the Cyberknife (Schweikard et al. 2000; King et al. 2003; and [Section 43.3.9](#)), is another solution to correct for 3D misalignment of the beam with respect to the patient.

As an additional aid to patient positioning, video-based systems that record the external surface of the patient can be used (Johnson et al. 1999; Yan et al. 2002; Meeks et al. 2005; Djajaputra and Li 2005). A reference surface is either obtained from external contours derived from CT images or acquired during a reference session (i.e. combined with portal images),

and this is used to ensure patient position reproducibility, either inter- or intra-fraction. Such a system may also be used to record the variation of the surface with the patient's respiratory movement.

This movement of the tumour because of respiration (or possibly the cardiac cycle) presents another opportunity for the reduction of treatment margins. This has become known as breathing-adapted radiotherapy (BART). The general principle of BART is that breathing is monitored or controlled, and treatment is suspended when the tumour moves out of the field. However, this process relies on reproducible motion of the tumour in synchrony with breathing, and this condition may not be satisfied in some patients. Different methods of monitoring respiration and controlling the beam are being developed (Kubo et al. 2000; Giraud et al. 2003; Dawson and Balter 2004; Mageras and Yorke 2004; Jiang 2006; Keall et al. 2006).

A first solution resides in asking patients to hold their breath at a fixed level of respiration while the beam is on (Rosenzweig et al. 2000). This is achieved with the help of a spirometric system connected to a patient mouthpiece that provides a real-time signal of the respiration displayed on a monitor or on video glasses and made visible to the patient. *Beam-on* is allowed only when the signal is within a preset range corresponding generally to medium inspiration with a tolerance around  $\pm 0.1$  L. In the Active Breathing Control (ABC) system, a valve blocks the respiratory flow when the preset level is reached (Wong et al. 1999). In the voluntary breath hold system, the patient keeps full control of the respiration, but the beam is stopped if the signal drifts out of the preset range (Garcia et al. 2002; Zhang et al. 2003). In both cases, patient training and coaching are necessary (Kini et al. 2003).

With synchronisation methods, the patient breathes normally and regularly. One of the most commonly used systems is the Real-Time Position Manager (RPM) system developed by Varian where a small cube equipped with reflecting circular spots is placed on the patient's chest and its movement followed by a fixed infra-red camera. The movement of the cube seen from the camera is converted into a signal that is used to switch the beam on and off (i.e. to gate the beam) in such a way that the radiation delivery occurs within a preset range of respiratory movement (Mageras et al. 2001; Ford et al. 2002; Hugo et al. 2002). This method requires some patient cooperation, training, and coaching to achieve a reproducible breathing cycle, but not as much as with spirometric techniques. An even more sophisticated approach is to move the MLC blades in synchrony with breathing (Neicu 2003; Murphy 2004) or to robotically track the tumour as in the Cyberknife (Schweikard et al. 2002 and [Section 43.3.9](#)).

Whichever BART approach is used, the CT images used for planning must be representative of the patient anatomy during delivery. Therefore, breathing monitoring, similar to that used for treatment, is required during CT acquisition. For the RPM, two solutions have been implemented: either *prospective* CT gating where images are acquired only in the gating window or *retrospectively* gated CT where a full series of images are acquired covering a full respiratory cycle with sufficient redundancy to allow reconstruction at any desired phase of the cycle. This latter solution, sometimes referred to as 4D CT, necessitates sorting of the slices according to each phase of the recorded respiratory cycle and subsequent selection of one or more series to serve as the reference for planning (Ford et al. 2003; Underberg et al. 2004; Giraud et al. 2005).

The benefit of BART is still to be fully assessed (Starkschall et al. 2004; Rosenzweig et al. 2005). When comparing breath-hold and gating techniques, there are two issues to be considered: margin reduction where both techniques may yield similar results, and improvement of the dose distribution with respect to planning target volume coverage and organ-at-risk protection where normal breathing is probably not as beneficial as forced breathing. However, the difficulties of reproducibility may limit the number of patients for whom BART is applicable. Fortunately, Bortfeld et al. (2004) have shown that the effect of movement on the accuracy of the dose distribution is not as great as it might at first appear, and therefore it may not be essential to eliminate movement. Whatever solution is adopted, the incorporation of internal organ movements and, ideally, of setup uncertainties into treatment

planning is one of the most important developments taking place in precise conformal radiotherapy.

Whereas these solutions are perhaps more versatile than tomotherapy, they currently lack the systems integration that is offered by the tomotherapy machine. Dose distributions produced with the tomotherapy device present a considerable challenge to the linear accelerator manufacturers; it remains to be seen if techniques such as Intensity Modulated Arc Therapy (IMAT) (Yu et al. 2002), which is similar to tomotherapy but can be carried out on a conventional linac, can match these dose distributions. There is also some debate as to whether the *dose bath* (i.e. large volumes of normal tissue receiving relatively low dose) associated with tomotherapy and IMAT will result in more second cancers (see [Section 61.5.2](#)). This is also an issue in connection with cone-beam CT. The dose must always be limited to that which is strictly necessary for the purpose rather than seeking the highest quality images for their own sake.

All these new approaches require the physicist to have a good understanding of patient positioning techniques as well as of the imaging and image registration techniques used by the treatment staff. In addition, new algorithms are called for to allow computers to assist as much as possible in the process. A reappraisal is also required of the degree to which the equipment can be relied on and the degree to which manual checking is required. Without greater acceptance of the capabilities of the technology, it will be difficult to make further progress and thus to deliver the potential benefits of these more advanced techniques.

## 43.1 GENERAL OVERVIEW

The rationale for conformal radiotherapy (CFRT) is straightforward to state. The goal is to achieve a tumoricidal high-dose volume which conforms to (i.e. wraps closely around) the planning target volume (PTV) whilst simultaneously the organs-at-risk (OARs) (which might lie tightly adjacent to the PTV) receive a dose sufficiently low as not to cause any complications. The concept behind this rationale is that if the difference between the relative dose received by the PTV and the OARs can be made as large as possible, then the dose to the PTV can be *escalated* with consequent expectation of a higher tumour control probability (TCP) without causing unwanted radiation damage to normal-tissues (i.e. a low normal-tissue complication probability (NTCP)). Today the words *conformal radiotherapy* have replaced the somewhat older term *conformation radiotherapy* coined by Takahashi (1965) over 35 years ago.

So what is new? Has this not always been the goal of radiotherapy? Of course it has (Mould 1993, 1995; Thomas et al. 1995). In that case, why is CFRT viewed as a modern development? The answer is simple. Radiation oncologists have always known that they wanted to *concentrate* the radiation at the target (Kieffer 1938) but because photons have to pass through normal tissues to arrive at the target and also scatter *en route* to deposit dose at unwanted locations, the goal has been thwarted. Additionally, before the advent of modern 3D imaging techniques (the first being x-ray computed tomography (CT) in 1972; see Webb 1990) radiation oncologists were unsure of the exact location of disease (Webb 1988). Also radiotherapy equipment for delivering photons generally formed a rectangular field, maybe with simple wedges or blocking, limiting the possible shape of the high-dose volume. Moreover, the patient geometry is known to change between fractions and factoring this in limits the precision of the delivery. In the very early days, the lack of high-energy beams with sufficient penetration was itself a limitation. Techniques to verify the patient position at the time of treatment were limited to the use of film and there were no methods of automatically correlating the at-treatment position with the at-simulation position. Finally, knowledge of radiobiology had to grow co-temporally with the development of radiotherapy techniques and therefore normal-tissue tolerances and dose-(tumour) response data had to be collected. Hence it may be observed that whilst radiation oncologists wanted to perform CFRT (they would not have used that term of course) from about 1896 onwards, they simply lacked the tools to do so.

It may be said that the reason CFRT is possible today is that there has been a simultaneous development in all the required elements of the *chain of radiotherapy*, i.e. one may observe that the CFRT process is like a chain having many links, all of which must be strong and reliable if CFRT is to succeed (Figure 43.1). An exemplary radiotherapy department is one in which there is emphasis given to the physical (and biological) basis of all links of the chain. CFRT has

**FIGURE 43.1**

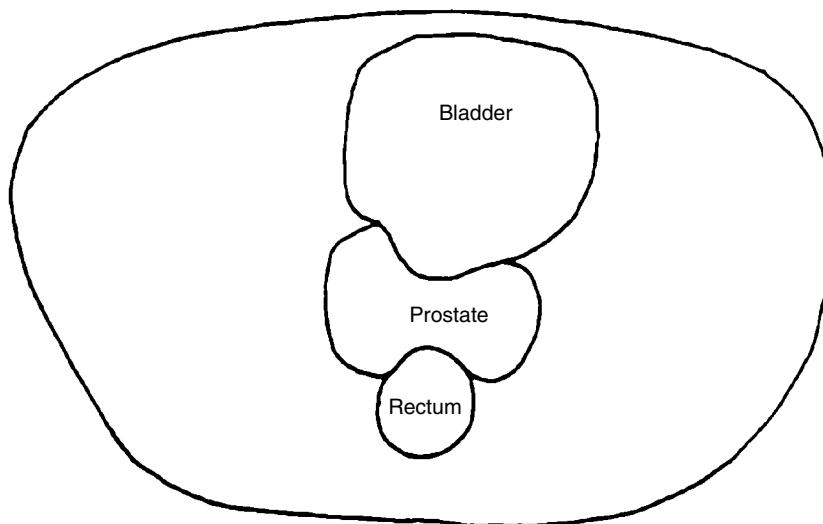

The chain of processes leading to conformal radiotherapy and illustrating that the physical basis of radiotherapy depends on good performance at each stage.

become a major specialty and has already been the subject of several substantial reviews (Webb 1993, 1997a, 1998a, 2000a, 2000b, 2003a, 2003b, 2004b; Smith 1995; Meyer and Purdy 1996; Sternick 1997; Van Dyk 1999; Schlegel and Mahr 2001; Palta and Mackie 2003; Bortfeld 2006; Ahnesjö et al. 2006). Techniques to shape beams, including the multileaf collimator, are covered in [Section 22.5](#). Although beam-shaping is an essential aspect of conformal therapy, it can no longer be considered as a *special technique*. The emphasis in this chapter is on more advanced CFRT, principally intensity-modulated radiotherapy (IMRT).

The *chain of CFRT* comprises the following links:

- High-quality three-dimensional medical imaging to localise both the extent of disease and the anatomy of neighbouring normal tissue ([Chapter 30](#) and [Chapter 31](#)). Ideally this imaging should comprise use of x-ray CT, magnetic resonance imaging (MRI), single-photon-emission-computed tomography (SPECT) and positron emission tomography (PET). All 3D imaging modalities should be networked to each other and to the planning workstation. Tools should exist to determine the PTV and the OARs automatically with the possibility of manual editing.
- The planning workstation should allow all tasks to be performed in 3D. It should include tools to optimise the beam directions and geometrical shapes, tools to optimise the beamweights, tools to optimise the fluence of radiation on a fine spatial scale (for IMRT) and tools to export the determined fields to the treatment-delivery device.
- The planning workstation should also be able to compute dose via accurate algorithms. These should ideally include both modern convolution algorithms and Monte Carlo dose calculation (see [Part F](#)).
- The planning workstation should include tools to evaluate the treatment plan and in particular competing treatment plans based on different human choices. These should include the computation and display of dose-volume histograms, of shaded colour dose planes, of isodose plots, of 3D surface dose distributions, of volumetric dose data and the prediction of biological outcome (TCP and NTCP) through suitable, albeit quasi-empirical, models (see [Chapter 35](#) and [Chapter 36](#)).
- The patient position at the time of treatment should be verifiable via electronic portal imaging (EPI). Tools should exist to quantify discrepancies between treatment position and planned position and to evaluate consequences and make corrections ([Section 40.1](#)).

When is CFRT required? Ideally, the answer is *always*. There is clearly no point in irradiating normal tissues. However, the circumstances absolutely requiring CFRT are those tumour sites for which the cure rate would very probably be increased by increasing the prescription dose (i.e. the dose to the target volume), but where presently this dose increase is not possible due, for example, to OARs closely abutting the PTV and more specifically for those circumstances in which the PTV has a concave surface and an OAR lies in the concavity. Hence there has been a great deal of interest in CFRT of the prostate since this organ is concave and the adjacent rectum limits dose escalation (Dearnaley et al. 1999) ([Figure 43.2](#)). A second CFRT indication is for tumours where the cure rate is satisfactory but treatment-related morbidity, while not life-threatening, is highly unpleasant, e.g. xerostomia (or dryness of the mouth) from irradiation of the parotid gland. Head-and-neck tumours present a challenge to CFRT because many such tumours are in the vicinity of the parotid gland and the spinal cord, both of which require functional preservation. Some brain tumours have concave shapes with potential danger for irradiating the orbits, optic nerves, chiasm and normal brain. The breast requires CFRT to spare heart, lungs and brachial plexus. CFRT of the lung may spare other normal lung function and also the heart. There have been hundreds of papers on the physics of CFRT of these targets. Prostate in particular has been subject to numerous theoretical studies on improving treatment by CFRT including IMRT. However at the time of writing it should be emphasised that clinical trials to establish and quantify the clinical benefit of either *conventional* CFRT or advanced CFRT, i.e. IMRT, have been few. Amongst reasons for the slow introduction of CFRT and IMRT in many countries, the following may be identified:

**FIGURE 43.2**

Why CFRT and IMRT are needed for the prostate. The concave prostate is shown abutting the rectum and the bladder.

- The argument that *proof of benefit* should precede change
- The requirement to quality-assure new techniques (particularly challenging for IMRT)
- The lack of the *complete chain* in every clinic

A U.K. study (Dobbs et al. 2002) has emphasised how essential it is that CFRT and IMRT become routinely established and the author's observation is that the year 2002 marked the change from IMRT being viewed as a research specialty to its acceptance as a practical clinical tool. In the U.S.A. IMRT is now well documented as a clinical practice (IMRTCWG 2001; Ezzel et al. 2003; Ten Haken and Lawrence 2006)

What are the physical means for achieving CFRT? The techniques divide into two broad classes:

1. Those involving only geometrical field shaping, sometimes known as *conventional* CFRT
2. IMRT techniques

Radiation delivered by the first method can only yield a convex 3D dose distribution whereas a concave 3D dose distribution can result from the latter. The main achievement of the techniques with only geometrical shaping is the shaping of the radiation field to the beam's-eye-view of the target. Although for decades this has been possible with cast metal blocks, the multileaf colimator (see [Section 11.4.3](#) and [Section 22.5.4](#)) provides fast automatic verifiable beam shaping. IMRT may be delivered by many methods, some involving MLC-generated field-shaping combined with modulating the radiation fluence. This is appropriate for the estimated 30% of tumours which have concave surfaces. IMRT is a rapidly expanding subspecialty of CFRT. The various methods of IMRT delivery will be discussed in [Section 43.3](#).

The necessary infrastructure for the development of CFRT is apparent from the above comments. Both conventional CFRT and IMRT are the product of synergistic development in computer technology, in electromedical equipment manufacture and in computer modelling. CFRT stands on the firm rock of clinical 3D medical imaging. Against this background, some heroic historical attempts at CFRT can be identified.

Takahashi in Japan developed rotation therapy with variable field shaping and blocking in the 1960s (Takahashi 1965). Also in the 1960s Proimos and colleagues in Boston developed

rotational techniques with both variable field shaping and synchronous shielding (Proimos 1960). Jennings and colleagues in the 1960s at London's Royal Free Hospital developed the *tracking cobalt unit* which continuously varied the field shape to conform to the beam's-eye-view of the target (Jennings 1985). Note that all these developments took place before the invention of CT and before computerised control of equipment was possible. They also pre-dated any form of 3D treatment planning. Heroic indeed and holding a worthy place in history but never widely developed or copied and ultimately failing to be established clinically at other centres. The modern development of CFRT including IMRT is really the story of development in the late 1980s and the 1990s (Marinker and Peckham 1998; Webb 2003c; Webb and Evans 2006).

---

## 43.2 OPTIMISATION AND INVERSE PLANNING

### 43.2.1 WHY OPTIMISATION?

In the very early days of radiotherapy there were no methods of treatment planning. Radiation Oncologists flew by 'the seat of their pants'. They applied beams to the tumours until crude indices such as skin reddening showed that some particular dose had been delivered. There was no method of combining dose from different beam directions. By the 1940s the dose-deposition properties of single beams were beginning to be understood. Depth-dose distributions could be measured. They were transferred to acetate sheets. Then the combined dose distribution from several beams emanating from different directions could be *computed* by overlaying several sheets and adding up the doses to each point by hand. This became known as *hand planning* and even in the 1970s treatment planners were still using this method to learn their trade, and in many centres to plan real cases. Physicists designed devices to perform similar manual additions when the beams were not coplanar.

By the late 1960s, a number of pioneering groups were developing computer-based treatment planning. A computer was used to do the dose additions. The planning was two-dimensional. Perhaps the best known early system in the U.K. was the RAD8 designed by Roy Bentley and Jo Milan at the Royal Marsden Hospital and now something of a legend (Bentley and Milan 1971). By the mid 1980s, 3D treatment planning was well-established in research centres and commercial equipment was becoming available. Today, 3D treatment planning is regarded as a state-of-the art necessity for a strong link in the chain of radiotherapy. The planning stands on a firm bedrock of knowledge of the patient anatomy, of the dose-deposition characteristics of photon beams of different energy, size and shape, of the relationship between the position of the beams and that of the patient (Webb 1993, 1997a, 2000a).

Yet even in the early years of the new millennium, most treatment planning is what, in the jargon of the trade, has become known as *forward planning*, i.e. the treatment planner knows what dose distribution they would like to achieve in consultation with the radiation oncologist, making use of prior experience of similar cases, and then the task is to try out the positioning, shaping and weighting of a number of beams until the goal is reached. This is still the everyday technique of routine treatment planning. It relies on the expectation that patients are largely similar in geometry and so what works well for one patient will probably work well for another after some fine tuning. For many relatively simple situations it works satisfactorily.

### 43.2.2 PHILOSOPHY OF OPTIMISATION AND INVERSE PLANNING

The main objection to *forward planning* is that there is no way of knowing if the plan thus produced is the best which could be obtained. There is just not enough time for the human planner to explore all the options. The Holy Grail of planning is what has come to be called

*optimisation* although, for the reasons to be discussed, the term *customisation* might be preferable. A second major objection to forward planning is that it simply cannot be done for complex IMRT. The number of variables in the planning problem is just too large. When several beam directions each with 2D intensity modulation are combined there is a requirement to determine hundreds of beam-weights. Hence from the earliest days of IMRT (and long before it was called by that name) *inverse planning* was developed (Lax and Brahme 1982; Brahme 1988). The 3D dose distribution was specified and the computer was programmed to arrive at the *optimum plan*, the set of beam element (bixel) beam-weights, which would deliver a 3D dose distribution as close to the prescription as the physics of photon-tissue interactions would allow. Inverse planning has become a cottage industry, a major specialty of radiotherapy physics, and today there are dozens of techniques, many variants on each other, and thousands of papers on the subject. Lengthy reviews have appeared (Webb 1993, 1997b, 2000a, 2003a; Ten Haken and Lawrence 2006). The principle is simple. The differences between the methods lie in the details.

Whilst inverse planning has grown up to serve IMRT, it need not be restricted to this. There is an equally large number of papers reporting the application of inverse planning to the determination of the beam-weights for a few open or wedged fields and for determining beam orientations. Inverse planning is rapidly being implemented into commercial treatment-planning system, thus moving out of the research-tool arena and into everyday clinical practice.

Before reviewing some key techniques, a fundamental question should be addressed: does *inverse planning* as currently practised really produce the optimum treatment plan? The answer is *no* (Rowbottom et al. 1999). To arrive at an *optimum plan* the computer would have to examine an infinite range of beam orientations, an infinite number of beams, a wide range of beam energies, the combinations of beams with different energies, beams of different particles (photons, electrons, protons, heavy ions), an infinite flexibility on numbers of bixels and fluence quanta in IMRT. It does not do this. Instead all inverse planning techniques *fix* certain parameters and then seek to optimise the remaining free parameters, e.g. usually the beam energy is chosen a priori. A fixed number of beams is selected (whether for IMRT or non-IMRT), a set of predetermined orientations are chosen. No particle-modality combining is done. Then the computer is asked to *optimise* the beam-weights. The result is called the *optimum plan*. Yet if the initial assumptions were to be changed, a new and possibly better *optimum plan* might result. The same is true for the result of changing the cost-function being minimised by inverse planning. This would lead to statements of the kind that one of the two contenders was *more optimum* than the other, an English language violation. Yet the planners would know what they meant. It is proposed that the term for the plan resulting from inverse planning be called the *customised plan* and the term for the process be called *customisation* because this would overcome the difficulty. There can certainly be a *better customised plan*. The term *optimum plan* would refer to that in which the TCP were unity and the NTCP were zero, something probably unobtainable. However, it must reluctantly be recognised that the term *optimisation* has entered the language such that it is unlikely to be reversed. Hence, the terms *optimisation* and *customised plan* will be used here with the above caveats.

### 43.2.3 PRINCIPLES OF MODERN INVERSE PLANNING

The 3D dose distribution,  $D$ , is related to the set of beam-weights,  $w_i$ , through a matrix,  $\mathbf{M}$ , via the operation

$$D = \mathbf{M}w_i \quad (43.1)$$

where  $\mathbf{M}$  is a matrix containing all the information linking beam-space to dose-space and there are  $i$  beams. When  $i$  is a small number, forward planning adjusts the beamweights,  $w_i$ , until the distribution,  $D$ , is *acceptable*. The process is one of informed trial and error. Inverse planning does the reverse and is particularly useful when  $i$  is large for IMRT and the weights  $w_i$  refer to

small bixels (Webb 1995). The computer explores a range of options for  $w_i$ , deduces the delivered  $D$  and accepts or rejects options depending on whether some cost function decreases or increases with respect to that for other choices. The methods divide conveniently into those which are stochastically iterative and those which are deterministically iterative. The methods are characterised by the choice of cost function. Incidentally this also provides another reason to criticise the term *optimisation* because a change of cost function using the same technique would yield a different outcome.

The easiest way to understand cost functions is to consider the widely used quadratic cost function of dose:

$$C = \sum_i^N I_i (D_i - D_i^P)^2 \quad (43.2)$$

where  $D_i$  is the dose delivered to the  $i$ th dose voxel (at some stage in the optimisation) and  $D_i^P$  is the prescription dose to the  $i$ th voxel and there are  $N$  voxels.  $I_i$  is the importance factor for the  $i$ th voxel. Clearly this has the desirable property that minimising the cost function minimises the difference between the dose distribution obtained at some stage of the iteration and the prescribed dose distribution (in a least-squares sense). The presence of the *importance factor* (a simple dimensionless number) allows the user to assign more importance to certain regions of space rather than others. For example, given that photons deposit dose by the laws of physics, one cannot obtain arbitrarily high dose to a PTV and negligibly small dose to an adjoining OAR. The importance factor allows the planner to choose between the importance of obtaining the dose as close as possible to the prescription in the PTV whilst possibly compromising the OAR, or conversely, the clear protection of the OAR whilst possibly compromising the dose distribution in the PTV (conformal avoidance). Part of the art of inverse planning becomes that of selecting these importance factors; in turn, it is seen that this, yet again, gives an added flexibility to the solution which mitigates against calling the result the optimum plan. Critics of optimisation claim this human activity has simply replaced that of selecting beamweights by experience. To counter this, the generally adopted scheme is to determine *recommended importance factors* from test cases which are then applied to future inverse planning. Papers have appeared indicating ways to avoid presetting importance factors and these are reviewed in [Chapter 5](#) of Webb (2000a).

Of course, although it is intuitive and possibly the first cost function used, the quadratic dose-based cost is only a *physical* cost function. It makes no distinction between under and overdosing. It takes no account of the location of dose discrepancies. For organs at risk it seems to require specification of a *required dose*, whereas critics would argue that this should be zero. Consequently, *dose-volume-based* cost functions have been investigated (Bortfeld et al. 1997). In these the volume of normal tissue to be raised to a certain dose is specified for a number of points on the dose-volume histogram—in principle, for all such points. Optimisation then attempts to force the OAR DVH within the constraints and makes no further improvements provided these can be met. It is claimed that such cost functions more closely model the way clinicians think.

A further option is to use biologically-based cost functions (see [Chapter 36](#)), e.g. if TCP ( $D_i$ ) is the tumour control probability corresponding to the 3D dose distribution  $D_i$  at some stage of the inverse planning and NTCP ( $D_i$ ) is the normal tissue complication probability at the same stage, then one could do any of the following (Webb 1997b):

- Maximise TCP subject to some maximally allowed NTCP
- Minimise NTCP subject to some minimally allowed TCP
- Maximise  $P_+ = \text{TCP}(1 - \text{NTCP})$ , the so-called probability of uncomplicated tumour control

These approaches each have their champions. They require, of course, a model for TCP and NTCP together with data to support the model. Herein lies the basis of much criticism of

these approaches. It can be argued that the models and certainly the data on which they rely are somewhat arbitrary and insubstantial (see [Chapter 36](#)). It can also be argued that clinicians have a century of experience to guide them regarding requirements on dose and are less experienced in *biological modelling* and its predictions. There is also a halfway-house position in which the optimisation is conducted using dose-based cost functions but the results are reported also in terms of TCP and NTCP—the best of both worlds?

In its simplest form optimisation can be viewed as a computer recipe. The process states: make some change; observe the effect on the cost, either accept or reject the change and carry on until the cost converges to a minimum. Whatever the *state of the choices* is at this endpoint becomes *the solution*. Methods can be classified in terms of the instruction base which determines the directions of change. Stochastic instructions are slow but particularly easy to understand and very flexible. Deterministic instructions are generally faster but not always allowable. Hoffmann et al. (2006) have presented a particularly interesting analysis of this important area.

#### 43.2.4 WHAT CAN BE OPTIMISED?

The following parameters have all been subject to optimisation schemes:

- Beamweights for open fields
- Beam directions for *few-field* irradiation
- Wedge angles for *few-field* irradiation
- Bixel weights in IMRT

For the first and last, an obvious constraint is that the weights must remain positive. This can be easily built into stochastic iterative optimisation. For some other schemes which generate negative beam-weights these have to be set to zero *a posteriori*, arguably damaging the *optimum* status of the solution. There have been several very detailed papers explaining how perfect dose distributions could be obtained with negative beam-weights but these papers are of academic interest only.

In summary, optimisation is entirely necessary for IMRT which can produce concave dose distributions such as those discussed in [Section 43.1](#). It is also feasible for non-IMRT problems aiming to achieve convex dose distributions and particularly relevant to the optimisation of the number of beams, the beam directions and wedge angles.

There have been so many proposed variants on the optimisation scheme that they cannot be comprehensively reviewed in a short section such as this; readers requiring more details can consult Webb (1993, 1997b, 2000a, 2003a). In the next subsections a couple of specific methods are presented to give a flavour for what is done, how it is done and to provide some typical results.

#### 43.2.5 OPTIMISATION BY SIMULATED ANNEALING

This technique was introduced into radiotherapy at the end of the 1980s (Webb 1989, 1991). At the time it was developed to minimise the quadratic-dose cost function. The methodology was based on that described by Barrett et al. (1984) for reconstructing nuclear medicine images. Since that time, it has become apparent that the convex cost function has only one global minimum (for beam-weight optimisation) and so the complexities of simulated annealing are *not* required. However the methodology is still sound (if slow) and it certainly *is* needed for optimising beam directions and for optimising problems using certain biologically-based cost functions where local minima are expected. It also has an intrinsic comprehensibility. It is easy

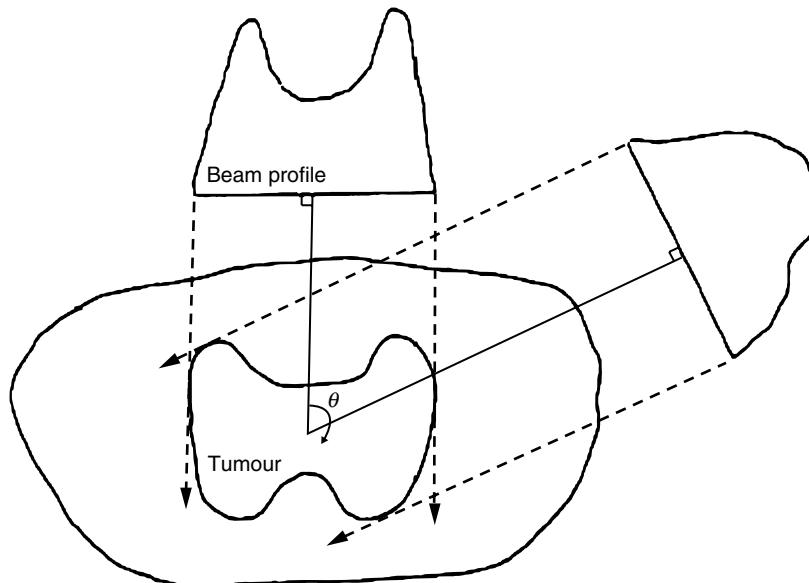

to describe and to see exactly what is happening. Its variant, least-squares optimisation, is similarly transparent.

The method works as follows. It will be described as it applies to determining the 1D intensity-modulated beams (IMBs) for IMRT of a 2D dose slice. First, certain choices are fixed: the number of 1D IMBs and their orientation, the number of bixels per 1D IMB, the modality and beam energy, the deposition vector linking each bixel to each dose pixel, etc. For total transparency, imagine, for instance, 9 1D IMBs spaced at  $40^\circ$  azimuthal orientations with 20 bixels per 1D IMB, using photons from a spectrum of peak potential 6 MV as would be delivered by the NOMOS MIMiC operating at a fixed gantry orientation (see [Section 43.3.4](#)). The problem becomes that of determining the  $20 \times 9 = 180$  bixel beam-weights (Figure 43.3).

Let  $C(D_i)$  be the cost associated with the dose distribution  $D_i$  at the  $i$ th iteration. It is expected that the form of this cost function is such that it has several local minima. The goal is to arrive at the distribution of beam weights which yields the global minimum and avoids any trapping in local minima.

The process starts with, for example, empty bixels, i.e. zero applied fluence. A *grain* of fluence is offered to a randomly selected bixel (the selection is simply controlled by using the random number generator in the computer). The grain is very small in relation to the expected final *settled* distribution of bixel intensities, say 1% of the expected maximum. The 3D dose distribution is computed throughout the irradiated slice using Equation 43.1 and the corresponding cost is deduced from whatever function is represented by  $C$ . It could be Equation 43.2, although, as already stated, this strictly does not need simulated annealing.

Provided the cost function *decreases* as a result of the grain addition, the addition is accepted. One might imagine the converse to then be invoked, i.e. that an *increase* in the cost function would lead to the decision to reject the change. However, this is not so. Let  $\Delta C_i$  be the change in the cost function at the  $i$ th iteration. When  $\Delta C_i$  is negative the change is accepted. If  $\Delta C_i$  is positive the change is accepted with a probability  $\exp -(\Delta C_i)/kT$ , where  $kT$

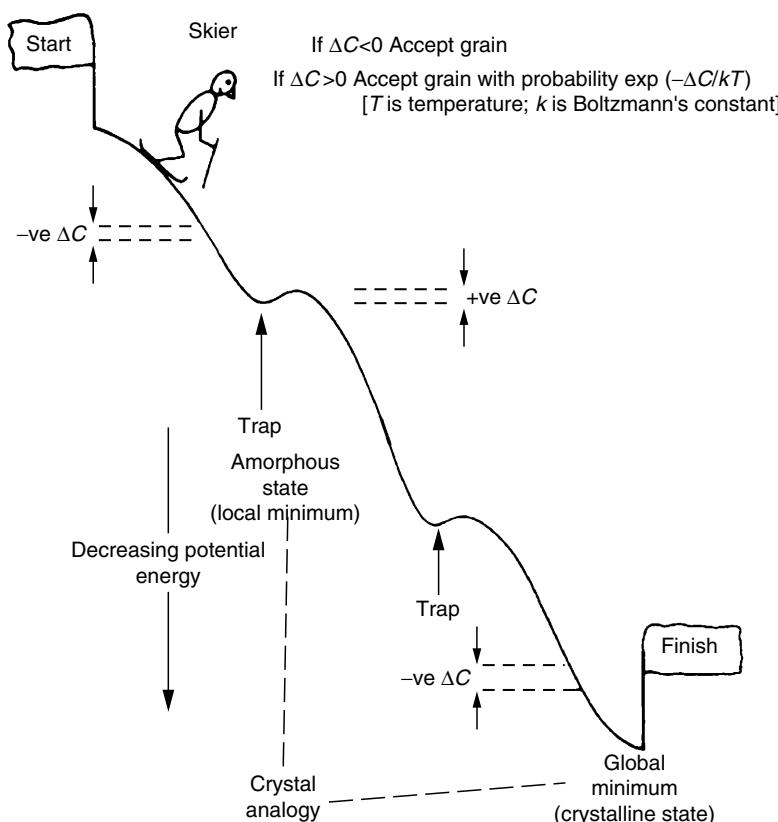

**FIGURE 43.3**

The concept of intensity-modulated beams. Two (of a large set of such beams with 1D intensity-modulation) are shown irradiating a 2D slice. The beams combine to create a high dose treatment volume spanning the PTV which has a concave outline in which OARs might lie. Such uniform high-dose treatment volumes cannot be achieved using beams without intensity modulation. Planning such treatments relies on tools such as simulated annealing (for cost functions with local minima) and projection-reprojection.

is a controlling parameter with the same dimensions as  $\Delta C_i$ .  $T$  may be thought of as a temperature and  $k$  is Boltzmann's constant. At the start of iteration the temperature is set high so many *wrong-way* (or *uphill*) changes are accepted. The temperature is gradually reduced during the iteration such that at the end of the process it is so low that no matter how small is  $\Delta C_i$  the change is rejected. The process is subject to *cooling* and it can be shown that provided the cooling is slower than the reciprocal of the logarithm of the iteration number then the global minimum will be reached. This is known as the Metropolis condition after the discoverer of the process. The technique mimics the slow annealing of a metal or crystal, the crystalline state representing a global minimum potential whereas the higher local minimum potentials correspond to amorphous states. Thus the local minima are avoided and the iteration always reaches the global minimum.

Both positive and negative grains require to be added so that structure created early in the iteration can be removed if required. A random number randomly selects positive and negative grains. The positivity constraint on pixel beam-weights can easily be applied as the iteration progresses. The grain size can be reduced during the iteration so that the late changes are very small.

An analogy which is sometimes considered useful is to imagine that the progress of the iteration towards a minimum cost function is like a skier descending a hill. The starting line at the summit represents the cost associated with the initial conditions (e.g. empty beams). As the IMBs are constructed so the cost decreases, corresponding to the skier descending the *cost slope*. The goal is for the skier to arrive at the foot of the hill (the point of global minimum cost).

**FIGURE 43.4**

The analogy between minimising a cost function by simulated annealing and the technique of a skier descending a slope (see text for details).

However en-route there are small snow bumps creating local minima. If skiers only ever agree to go downhill (reducing cost), then they will be trapped behind such bumps, knowing that they are at a local, not global, minimum, but unable to *escape*. The acceptance of *wrong-way* moves is the mechanism by which the skier escapes, i.e. has to occasionally ski uphill which is counter-intuitive in a minimisation problem but absolutely essential to reaching the global minimum. This is illustrated in [Figure 43.4](#).

The technique described is the so-called *classical simulated annealing mechanism*. An alternative is *fast simulated annealing*. In this, the temperature is reduced much faster but the grains are selected from a Cauchy distribution whose width is initially large and decreases as iteration progresses. This has the effect of allowing the system to jump out of a local minimum by *tunneling*.

Simulated annealing has been widely used together with its variant, least-squares minimisation (when  $T=0$  is set and there is only one minimum in the cost function). It is intuitive, easy to control, capable of much adaptation (e.g. the application of smoothing constraints), always gives positive IMBs but is computationally slow. This is one reason why faster semi-analytic optimisation techniques have been developed. The technique due to Bortfeld and colleagues will be described as an example. There are many variants of this too. The simulated annealing technique forms the basis of the inverse planning which is provided by PEACOCKPLAN or the CORVUS inverse-planning system marketed by the NOMOS Corporation (Sternick 1997).

### 43.2.6 FASTER OPTIMISATION BY PROJECTION-BACKPROJECTION

The projection-backprojection method was developed by Bortfeld and colleagues (1994a). The 3D solution creates a first estimate of the 2D fluence profile  $\varphi_\theta^{(0)}(x_s, y_s)$  in the direction  $\theta$  ( $x_s$  and  $y_s$  indicate coordinates in the plane normal to the central axis of the beam through the isocentre;  $x_s$  is in the transverse plane). This is done by *projecting* the 3D dose prescription  $D^P(r)$  along fan lines but weighting it by a factor which applies a higher weight to rays that pass though regions of the target with a larger average distance from the source and vice-versa. The projections were filtered by a 1D function  $h(x_s)$  and finally a positivity constraint  $C^+$  was applied. Formally,

$$\varphi_\theta^{(0)}(x_s, y_s) = C^+ [ \{ P_\theta[D^P(r)] / P_\theta^\Delta[D^P(r)] \} (P_\theta[D^P(r)] \otimes h(x_s)) ] \quad (43.3)$$

Here, there are two projection operators. The first,  $P_\theta$ , simply projects all the dose values at  $r$  along each ray line. The second,  $P_\theta^\Delta$ , projects the same values but each weighted by a function  $\Delta$  that is the product of the tissue-maximum-ratio and the inverse-square-law factor. It may be seen that Equation 43.3 contains a ratio that applies a higher weight to rays that pass through regions of the target with a larger average distance from the source.

In turn, this leads to a first estimate of the 3D dose distribution by *backprojecting* the fluence weighted by photon attenuation and the inverse-square-law and summing over all the beams, i.e.

$$D^{(k)}(r) = \sum_\theta \varphi_\theta^{(k)}(x_s, y_s) \Delta \quad (43.4)$$

The parameter  $k$  labels the iteration number; for the first time,  $k=0$ .

This first estimate of the 2D fluence profile was then iteratively refined using the projection of the difference between the 3D dose prescription  $D^P(r)$  and the first estimate of the delivered 3D dose  $D^{(k)}(r)$  at  $k=0$ , weighted by a function  $f_s$  that controlled the relative importance of constraints in the PTV and OAR. The resulting new fluence profile became the next estimate and the process cycled to convergence. Formally,

$$\varphi_\theta^{(k+1)}(x_s, y_s) = C^+ [ \varphi_\theta^{(k)}(x_s, y_s) - P_\theta^\Delta[D^{(k)}(r) - D^P(r)] f_s ] \quad (43.5)$$

The parameter  $f_s$  was unity in the PTV and a value between 1 and 10 in the OAR if, and only if, the dose was above a preset constraint limit and zero elsewhere.

As the delivered dose distribution finally approaches the prescription the cyclic operation of Equation 43.4 and Equation 43.5 will have diminishing effect. Whilst the authors have made ongoing modifications to this technique, the above represents the fundamental steps and is the basis of the inverse planning applied in the KONRAD treatment planning system (Bortfeld et al. 1997, see Section 43.2.8). There are many variants on this theme. The main observation is that this technique is much more rapid than simulated annealing. It is still based on minimising the difference between prescription dose and delivered dose at each iteration. Later variants have considered dose-volume constraints.

### 43.2.7 EXAMPLE OF IMRT-DELIVERED DOSE DISTRIBUTIONS COMPUTED BY INVERSE-PLANNING OPTIMISATION

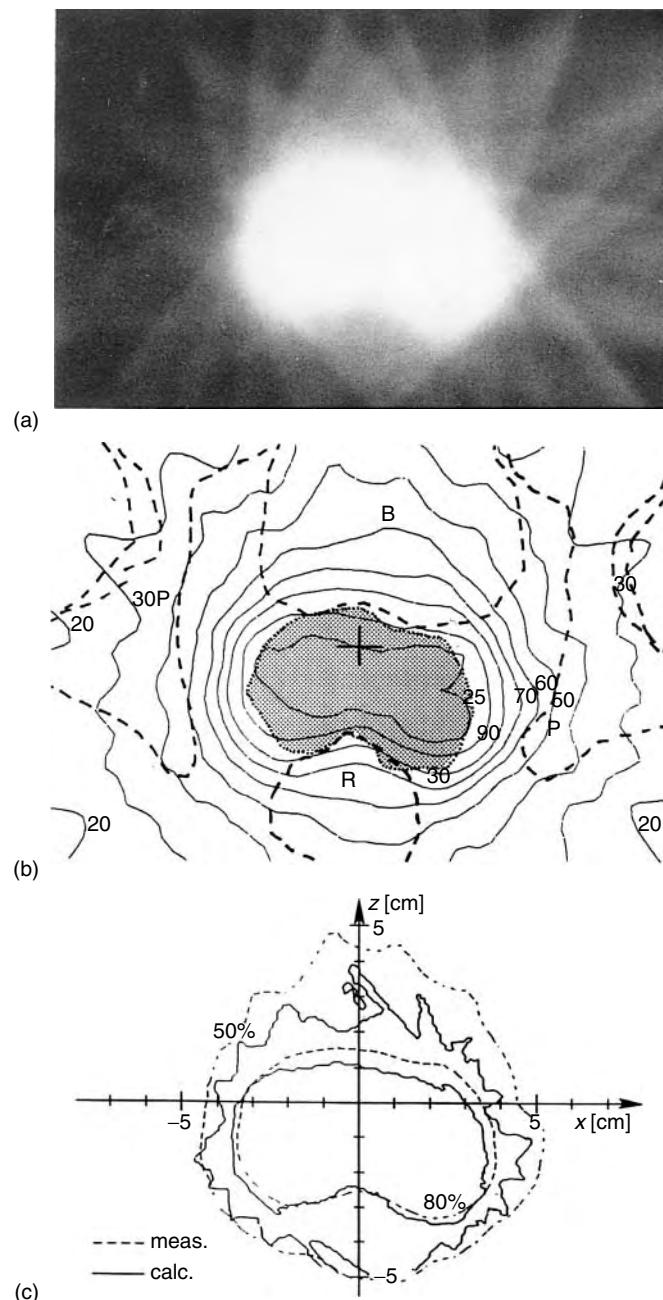

Some results from the application of the above two methods of inverse-treatment planning are now presented. Bortfeld and colleagues (1994a) constructed a model problem in which the prostate, rectum and bladder were represented on a series of 2D contiguous slices. Inverse planning was performed for each slice using the method described in Section 43.2.6 and then the IMBs so determined were actually delivered to a phantom using the method known as multiple-static-field MLC delivery (see Section 43.3.2). Nine fixed fields were used spaced at 40° intervals. The spacing in the projection grid was 2.21 mm × 10 mm and the spacing in the calculation grid was 1 mm × 4.87 mm × 1 mm. The tolerance dose of the bladder was 85% of the maximum PTV dose and that of the rectum was 60% of the maximum PTV dose. The penalty value  $f_s = 3$ . Eleven iterations were performed. Figure 43.5 shows, for one such slice, the comparison between the computed isodose distribution and the measured one. The concave nature of the high-dose region is readily apparent and the 80% isodose contour was deemed to match well. The subject of the actual delivery will be discussed in Section 43.3. Here, the intention is just to show the planning outcome. This somewhat old reference is quoted because it was the first to make measurements in so-called MSF mode.

One slice of the same problem was planned using the simulated annealing technique (Webb 1994) described in Section 43.2.5. Figure 43.6 shows the results from this approach for two different arrangements of the number of beams (either 9 or 120) which represent different methods of delivering IMRT (see Section 43.3). Once again, the concave dose distribution so determined is readily apparent.

### 43.2.8 OPTIMISATION IN COMMERCIAL TREATMENT-PLANNING SYSTEMS

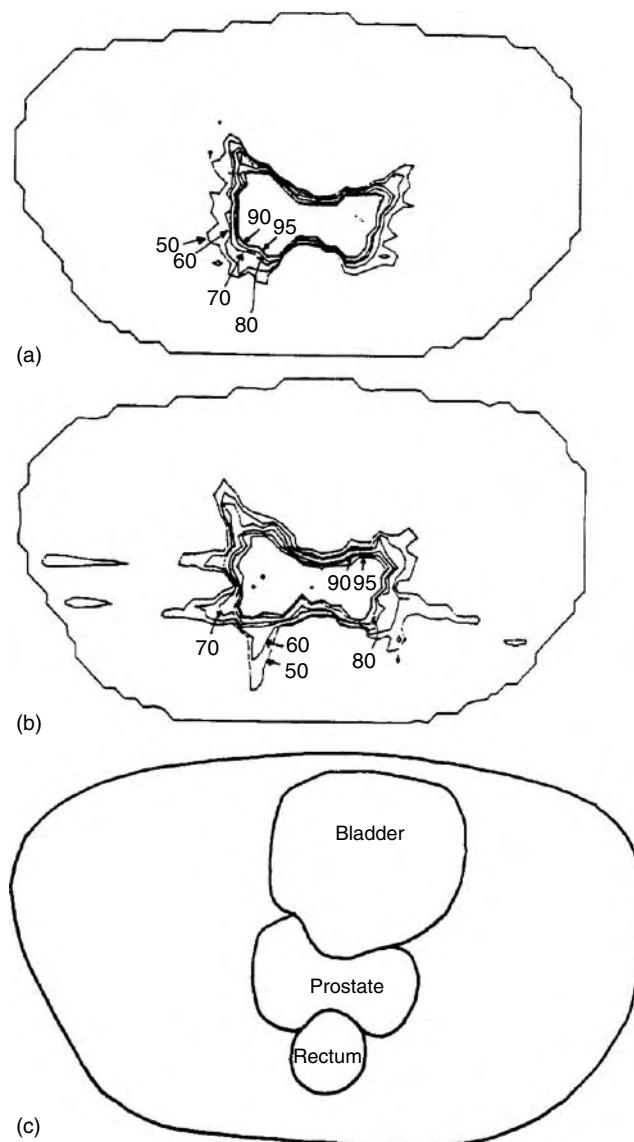

The serious growth phase of optimisation and inverse planning commenced in the late 1980s at a time when commercial treatment-planning systems were dedicated to *forward planning*. Twenty years later, the situation has changed radically; most commercial treatment-planning systems now have an inverse planning module. The first inverse-planning system was PEACOCKPLAN from the NOMOS Corporation, announced in 1992, which gradually evolved into the present system known as CORVUS. This made use of a simulated annealing algorithm based on the concepts expressed in Webb (1989, 1991). An example from this system is shown in Figure 43.7.

The second such system was KONRAD which emerged from DKFZ, Heidelberg, and was based on the projection-reprojection method. This was commercialised by MRC (now part of Siemens) and was subsequently incorporated into other commercial treatment-planning systems e.g. PLATO (Nucletron) to combine the advantages of forward and inverse planning in one treatment-planning system. Other manufacturers (e.g. Varian (Eclipse), Philips

**FIGURE 43.5**

Representations of the dose distribution in the central slice of a model planning problem posed by Bortfeld. (a) Copy of the exposed and developed film (negative display). (b) Superposition of the measured isodose distribution on the anatomy; R, rectum; B, bladder; P, pelvis. Isodose values are in percent of the maximum global dose. (c) Comparison of measured and calculated isodose lines. (From Bortfeld, T. et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 30, 899–908, 1994. With permission.)

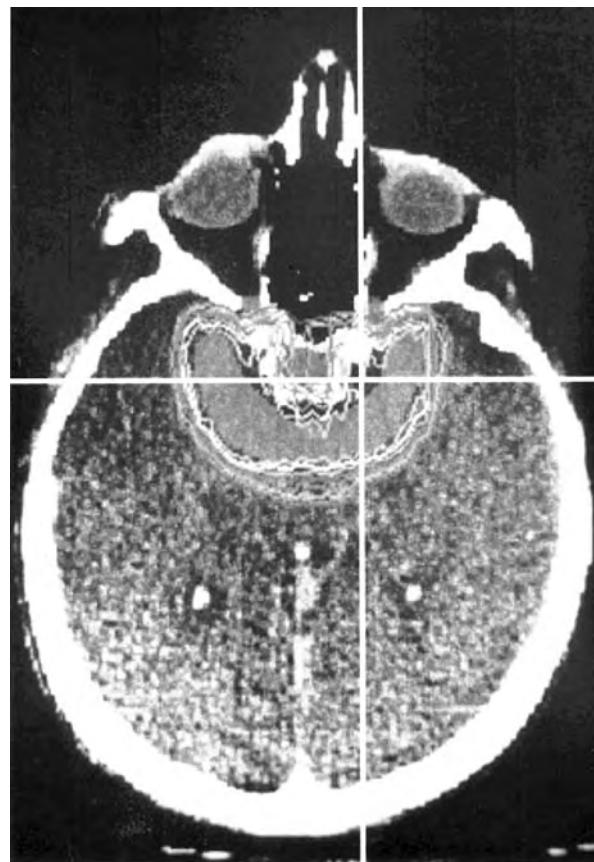

(Pinnacle), CMS (Focus), Nucletron (Oncontra/Masterplan) have since incorporated inverse IMRT planning into their systems. Potential purchasers of treatment-planning systems are advised to ask manufacturers what optimisation tools are provided since commercial systems are continually evolving.

**FIGURE 43.6**

The isodose plot for the plan created according to two separate conditions: (a) 120 beams; (b) 9 beams. The cost function had importance parameters  $I_{PTV}=200$  and  $I_{OAR}=10$ . The isodose distribution is tightly conformal in both cases. In case (a), corresponding to delivery by tomotherapy (see [Section 43.3.4](#)) the isodose lines are a little tighter than in case (b) that is nevertheless still an acceptable distribution. The isodose lines shown are 95%, 90%, 80%, 70%, 60%, and 50%. The ROIs are shown in (c). The bean-shaped ROI is the prostate; the anterior ROI is the bladder and the posterior ROI is the rectum.

In summary, optimisation has been the subject of enormous interest, particularly since the late 1980s, and the literature on it is vast. The papers selected here for reference are just a few examples of what one might cite. Optimisation could be said to be desirable for conventional radiotherapy but it is *essential* for IMRT planning. Inverse planning is the way forward; see [Chapter 36](#) for a discussion on incorporating biological functions into the inverse-planning objective function. Virtually all manufacturers now have inverse-planning capabilities in their products.

Having established the methods by which optimised IMRT may be planned, the next section will describe how intensity-modulated radiotherapy can be delivered.

**FIGURE 43.7**

An example of the highly concave treatment volume which may be obtained from the NOMOS inverse-planning system for IMRT. The horseshoe-shaped tumour wraps around the sensitive structure in the brain which is correspondingly shielded.

### 43.3 INTENSITY-MODULATED BEAM DELIVERY

#### 43.3.1 CLASSES OF IMRT DELIVERY TECHNIQUE AND HISTORY

IMRT offers the potential for a substantial leap in TCP at fixed normal-tissue complication probability in view of its ability to *sculpt* the high-dose treatment volume around the possibly concave target volume, and in other circumstances (e.g. breast radiotherapy) it can be used to create highly uniform coverage of target volumes. The planning of IMRT has been dealt with in the previous section. This section deals with the different ways to deliver and verify IMRT.

Before the early 1990s, there were virtually no practical methods to deliver IMRT. The methods available at present are (Webb 1993, 1997b, 1998a, 2000a, 2000b, 2003b; Williams 2003; Webb and Evans 2006):

- The metal compensator
- The MSF or *step & shoot* technique
- The dynamic multileaf collimator (DMLC) technique
- Tomotherapy
- Swept pencil beams

- The scanning attenuating bar method
- Intensity-modulated arc therapy (IMAT)
- The robotic cyberknife

Some of these techniques are still at the research and development phase. Others are being introduced clinically with varying levels of support, and still others have been found to be impractical. They each have advantages and disadvantages, champions and critics (Sternick 1997, Webb 1998a, 2000a, 2000b, 2003b; Williams 2003).

Historically the compensator is the oldest method of creating an IMB and has been available for much longer than any of the other techniques by a factor of at least 3 in time. Simply a piece of metal whose thickness in the direction of the beam varies with position in the beam, it creates an intensity-modulated beam (IMB) with the minimum of technological inventiveness. If a fluence  $I(x,y)$  is required and the unattenuated fluence is  $I_0$ , then the thickness,  $x$ , is given by  $x = (1/\mu) \ln [I_0/I(x,y)]$  where  $\mu$  is the x-ray effective linear attenuation coefficient appropriate to the spectrum of the beam and the compensator thickness\*. This equation clearly specifies only the primary fluence on the exit side of the compensator. The total fluence will be a complex mixture of primary and scatter and this could be determined by modelling the radiation transport using Monte Carlo simulation (see [Chapter 5](#) and [Chapter 28](#)). There are many ways to make a compensator. These include:

- Pouring liquid metal into a mould of the appropriate shape
- Building a pixellated compensator using blocks of a finite size and different heights (like a LEGO<sup>TM</sup> construction) (Ellis et al. 1959)
- Cutting thin (e.g. 0.5 mm) sheets of lead and sticking them together on a baseplate to make the required variable thickness ([Figure 43.8](#))

The advantages of the compensator are:

- It is a physical device that is placed in the shadow tray on the linac. One can see it and easily check that the correct one is in place and that it is in the correct orientation.
- It has no moving parts, unlike many other methods.
- There are no constraints due to the linac collimation.
- There is no need for complex portal verification.
- There is no *tongue-and-groove* interleaf leakage (as there could be for MLC-based methods), etc.

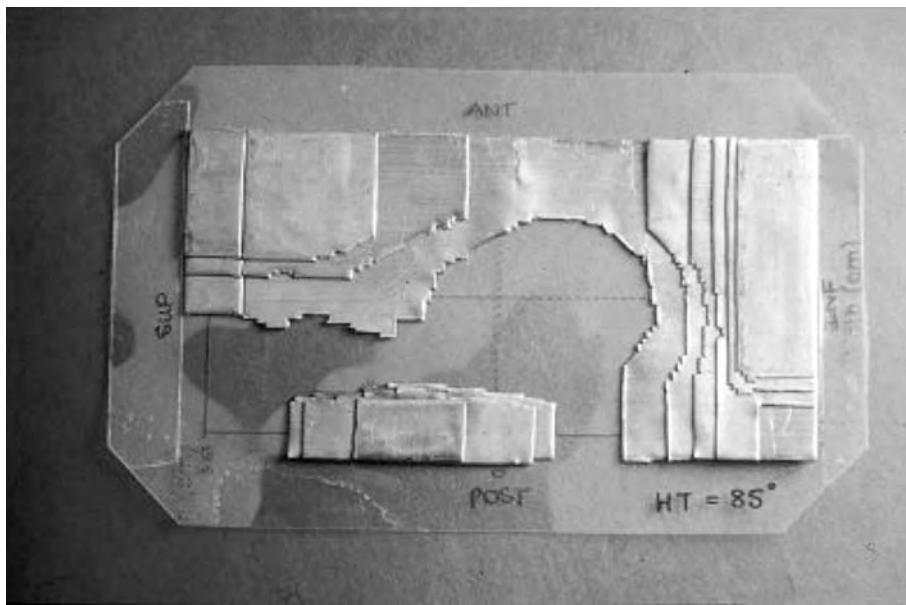

The advocates of the technique are quick to point these out (Sherouse 1997). However there are disadvantages:

- The compensator has to be fabricated manually for every required field. Therefore, it is impractical for those methods requiring a large number of fields.
- It is cast at the beginning of the treatment and so the IMBs cannot be altered during the treatment (to account for changes in the target volume) without some difficulty.
- Its construction is a time-consuming process and somehow anachronistic today when one is able to control fieldshapes by computer.

It must be recognised that, in a field in which safety is paramount, there is a lot to be said for using tried-and-trusted methods, whatever their disadvantages. Consequently, given that the other methods also require more sophisticated technology, the compensator will not vanish

---

\* The attenuation is not strictly exponential because there is a spectrum of photon energies; hence, the effective  $\mu$  varies with thickness.

**FIGURE 43.8**

A photograph of a metal compensator created by cutting thin sheets of lead and gluing them together. (Courtesy of Dr P. Evans and the Breast Dosimetry Group, Royal Marsden NHS Foundation Trust.)

until the other methods have developed an equal following and the necessary quality assurance is achieved, and possibly not even then.

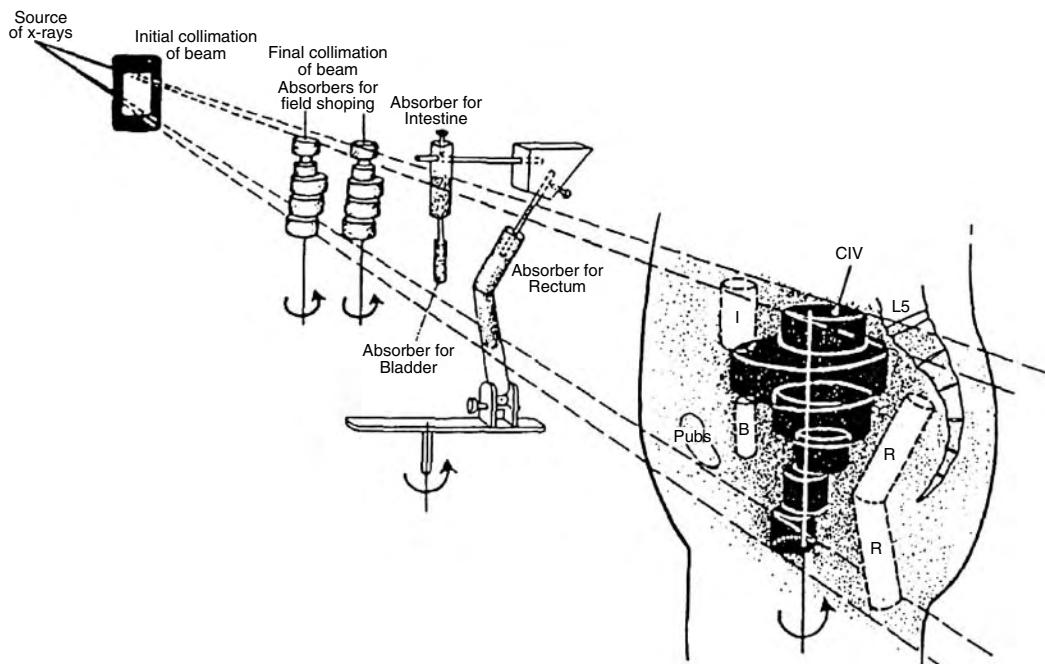

There have also been a few other heroic attempts at IMRT in the distant past (Webb 2003c). Of these the most-remembered is the synchronous field-shaping and organ shielding method developed by Basil Proimos and colleagues 40 years ago (Proimos 1960). The method is simple in principle. Radiotherapy is delivered by a rotation technique in which the beam sweeps a full circle around the patient. As it does so, the collimation is adjusted so the beam continuously adopts the beam's-eye-view of the target. This is achieved by fabricating special rotating collimators (Figure 43.9). At the same time the OARs are kept in the shadow of absorbers which rotate synchronously. There were many implementations of the method which was continually developed throughout the 1960s and Figure 43.9 shows one of them in which the upright patient, collimation and protection synchronously rotate in a stationary beam. There were other implementations in which the patient was horizontal and the collimation and protection was rotated by gravity with respect to the reoriented beam.

This method of delivering radiation is intensity-modulated in a very crude sense—the primary radiation is binary *on* or *off*. The method did not gain wide acceptability because:

- It was complicated (all the equipment had to be individually fabricated for each patient).
- The delivered dose was not uniform because the modulation was not constructed through an inverse-planning process.
- This was pre-CT and so there was opposition from those who did not believe the targets and normal structures were well enough localised.

However, the method has resurfaced (Danciu and Proimos 1999) from its original protagonist.

There now follows a brief review of modern techniques to deliver IMRT. The six methods outlined in the next sections were all developed co-temporally, largely in the 1990s (maybe

**FIGURE 43.9**

How synchronous absorbers for field shaping and synchronous protection can be arranged to provide a high-dose volume in the continuously irradiated volume (CIV) and protect the intestine (I), bladder (B), and rectum (R). (From Ilfield, D. N., Wright, K. A., and Salzman, F. A., *Am. J. Roentgenol.*, 112, 792–796, 1971. With permission.)

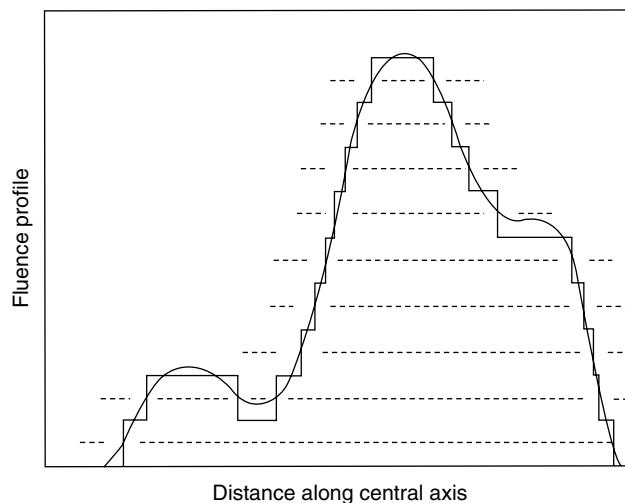

with a little activity at the end of the 1980s). There has, of course, been some rivalry and intercomparisons.

### 43.3.2 THE MULTIPLE-STATIC-FIELD (MSF) TECHNIQUE

The MSF technique relies on the observation that any 2D IMB can be created by a superposition of open fields with different fieldshapes. The fieldshapes are conveniently defined by a multileaf collimator (MLC). The principle is illustrated in Figure 43.10 for a 1-D IMB and even better by the many excellent computer simulations (as .mpg files) in Schlegel and Mahr (2001).

A 1-D IMB may be created by sequentially delivering open fields of different widths, each created by one leaf-pair of the MLC. Given that this may be done independently for any number of leaf pairs at the same time, the 2D IMB is built up from a series of 2D open field shapes. Figure 43.11 and Figure 43.12 show two possible configurations which yield the required primary fluence shown in Figure 43.10.

Thomas Bortfeld and Art Boyer (Bortfeld et al. 1994a, 1994b) were the originators of this method. An intuitive advantage is that the method is primarily a geometrical addition and so one can be easily convinced that the required 2D IMB is formed. The leaf-pairs can initially be considered to act independently and so the 3D dose-delivery problem requiring 2D IMBs breaks down into a set of 2D dose-delivery problems requiring 1D IMBs. Therefore, the delivery can be worked up from a series of 2D inverse-planning problems. This was how the method was initially conceived. However, very soon the connectivity between the 2D problems was recognised and genuine 3D inverse-planning was performed. The forward-dose calculations also took account of the 2D MLC shapes. Once conceived, the method was tested experimentally (Bortfeld et al. 1994a, 1994b) by laboriously delivering 2D IMBs

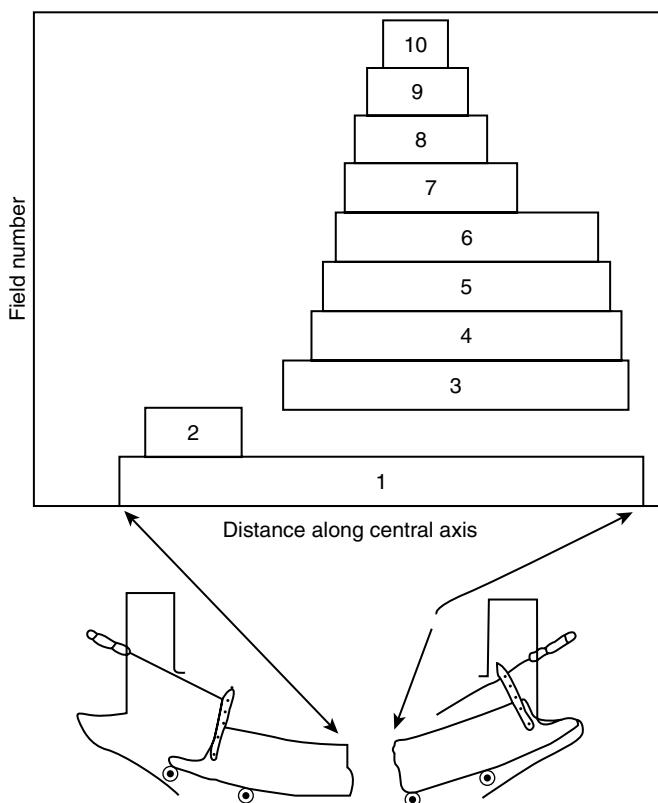

**FIGURE 43.10**

Shows how a 1D intensity modulation may be created for a radiotherapy beam profile. The horizontal axis is the distance along the direction of travel of the leaf, measured at the isocentre of the beam (called a central axis in the transaxial cross-section of the patient). The vertical axis is x-ray fluence. The solid line is the intensity modulation expressed as a continuous function of distance, interpolated from the discrete modulation resulting from some method of inverse planning. The horizontal dotted lines are the discrete intervals of fluence. Vertical lines are created where the dotted lines intersect the continuous profile thus giving a set of discrete distances at which discrete fluence increments or decrements take place. These are realised by setting the left and right leaves of a MLC leaf-pair at these distances in either the *close-in* or *leaf-sweep* technique. Note that all left leaf settings occur at positions where the fluence is increasing and all right leaf settings occur at positions where the fluence is decreasing.

at 9 gantry orientations each with between 21 and 30 subfields. At that time there was a significant time-penalty attached to resetting the leaf positions because the beam had to be switched off between each segment and then stabilise itself again at switch-on for new segments. Hence the experiment took many hours. However it is now regarded as a pioneering demonstration of the power of the MSF IMRT delivery technique.

One difficulty with the MSF technique is that the MLC imposes specific constraints on the leaf placements, these constraints varying between MLCs from different manufacturers. For example, the 10 mm Elekta MLC does not allow any leaf pair to close completely, nor does it allow a left leaf to come closer than a specified distance to its adjacent right leaf. Interdigititation, in which a left leaf travels to the right of an adjacent right leaf, is certainly disallowed (Figure 43.13). On the other hand, the Siemens MLC allows leaves to touch and the Varian MLC does allow interdigititation. The Elekta Beam Modulator MLC also allows interdigititation.

There are limitations on the allowed 2D configurations for MLCs not allowing interdigititation. It implies that one cannot simply solve the 1D leaf-placement problems independently and then put the solutions together. Another issue is that, when fields are shaped by an MLC, partial-depth leaf sides jut into the field components (Figure 43.13). Hence, unless the issue is specifically addressed, so-called *tongue-and-groove* underdoses can occur along the thin lines between leaves. Help is at hand because of the enormous number of ways in which 1D leaf segments can be put together to make any 2D IMB. This problem has been studied in detail and the number of configuration options established, whatever the number of local maxima and minima in the 1D IMB (Webb 1998b). One can then pose a formal optimisation problem of requesting the set of 2D field-shapes which, when added together, yield the required 2D IMB, without violating any of the MLC leaf-placement constraints, and minimising, preferably zeroing, the tongue-and-groove underdose. It has been shown that this formal optimisation problem cannot be solved due to the enormous computational effort required. However, it has also been shown that certain well-posed 2D

**FIGURE 43.11**

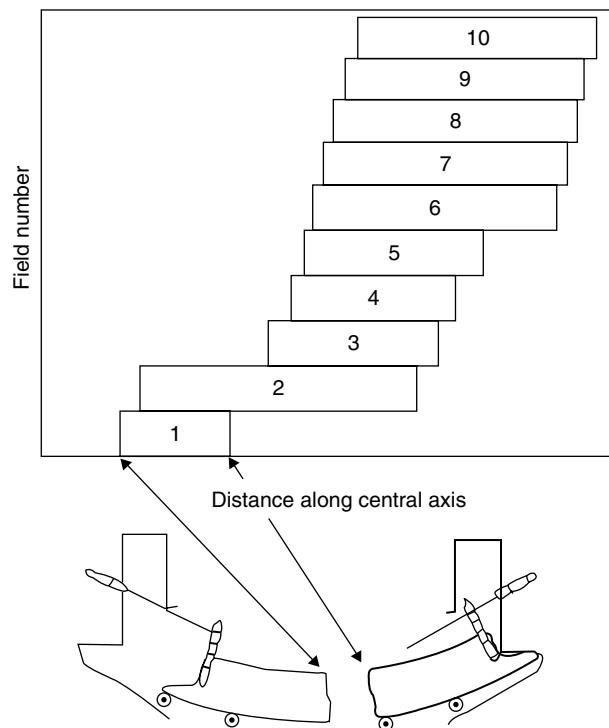

Shows the ten separate fields which when combined would give the distribution of fluence shown in Figure 43.10. Each rectangle represents a field and the left vertical edge is the position of the left leaf and the right vertical edge is the position of the right leaf. This method of setting the leaves is known as the *close-in* technique. A schematic of a pair of MLC leaves is shown in the lower part of the figure with arrows indicating the correspondence with the field edges.

IMBs (Figure 43.14) can be delivered without violating MLC constraints and with zero tongue-and-groove underdose (Webb 1998c).

It may be observed that the MSF method is less efficient than the delivery of the corresponding IMRT using a compensator when the 2D IMB has multiple extrema. There is also the concern (above) over the *deadtime* between field resettings and field restabilisation. Manufacturers are continually working to reduce this intersegment deadtime; for example, the fast tuning magnetron of Elekta has reduced the *deadtime* from about 5 s previously to 1 s. However, apart from Varian, manufacturers have taken the view that step-and-shoot IMRT is a simpler option and shown reluctance to implement dynamic leaf movement.

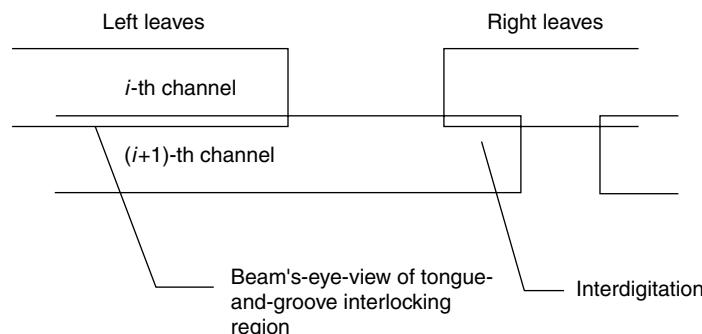

IMRT may also be delivered via the dynamic MLC (DMLC) method (see next section) in which leaves sweep across the field and take up many positions. When this is executed with the radiation off during leaf movement, the method reduces to the MSF IMRT technique albeit with a huge number of segments.

Finally a word about nomenclature. The MSF method does not have to be inverse planned. The IMRT required for breast radiotherapy may be delivered via metal compensators, or using a few static IMRT fields (Evans et al. 1997). Several other centres, notably the University of Michigan, the University of Ghent and The Netherlands Cancer Institute, are also delivering what they call *segmented-field* therapy which is another form of the MSF method. In some cases the 2D fields are very simply segmented into a couple of components, one with the beam's-eye-view of the target only and the other with the beam's-eye-view of the target and organs at risk.

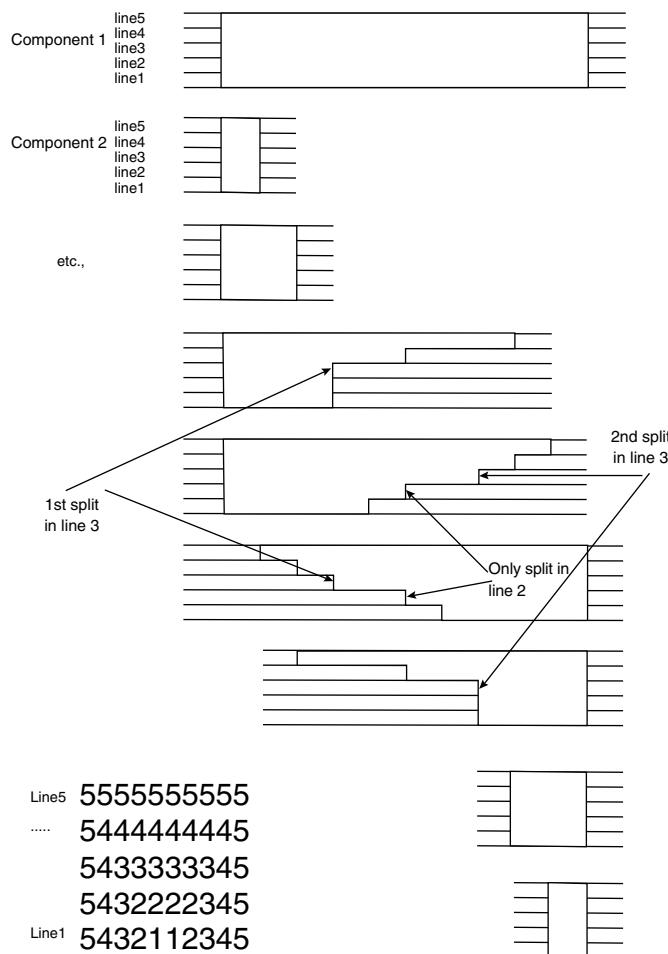

**FIGURE 43.12**

Shows the ten separate fields which when combined would give the distribution of fluence shown in Figure 43.10. Each rectangle represents a field and the left vertical edge is the position of the left leaf and the right vertical edge is the position of the right leaf. This method of setting the leaves is known as the *leaf-sweep* technique. A schematic of a pair of MLC leaves is shown in the lower part of the figure with arrows indicating the correspondence with the field edges.

The subfields are separately weighted (usually by an inverse-planning optimisation technique) and then separately delivered via MLC collimation. It may be appropriate to restrict the terminology *MSF method* to imply the (possibly not automated) delivery of a relatively small number of subfields at each gantry orientation and to use *step-and-shoot* IMRT to describe inverse-planned MSF IMRT.

**FIGURE 43.13**

Two leaf-pairs of an MLC are shown, the  $i$ -th and the  $(i+1)$ -th channels. The leaves are shown interdigitating, an arrangement forbidden on the original 10 mm leaf-width Elekta MLC. The beam's-eye-view of the tongue-and-groove interlocking region is also illustrated and one might seek to minimise the underdose in this region by a judicious choice of 2D field components.

**FIGURE 43.14**

This shows the nine field components required to give the inverted half-pyramid 2D IMB fluence distribution shown in the lower left. Line 1 contains exactly 9 rising fluence increments and hence 9 subfields are required. However given that the largest fluence is 5 units the efficiency of delivery is only 5/9 for this problem. This optimum solution, found by an intelligent search is a symmetrical set of fields in which the first is entirely open and so may be verified by portal imaging. There is no leaf collision and no interdigititation and also zero tongue-and-groove underdose. This cannot be determined by simply looking at the components here but can easily be established by writing code to determine the fluence both in the line-of-sight of leaves and leaf intersections. (From Webb, S., *Phys. Med. Biol.*, 43, 1481–1495, 1998. With permission.)

### 43.3.3 THE DYNAMIC MULTILEAF COLLIMATOR (DMLC) TECHNIQUE

A related but technically quite different method to deliver IMRT is the DMLC technique. This, as its name suggests, also makes use of the multileaf collimator. Imagine the radiation switched on with all the leaves closed and at the far left of a field. The right leaves then start moving to the right exposing the field to radiation, followed at some later time by the commencement of movement of the left leaves. The right and left leaves move, changing their speeds from time to time until both sets come to rest in a closed position at the right of the field. To a first approximation the primary intensity, or fluence, delivered to some point in the field will be given by the difference between the time at which that point is uncovered by the leading leaf and the time at which it is once again covered by the trailing leaf, provided the fluence is delivered at a uniform rate. Therefore, any arbitrary 2D IMB can be generated by

varying the velocity profile of each leaf pair. The principle is delightfully simple. Needless to say there are many practical complexities.

First, it is worth stating the laws which govern the leaf movement in an ideal situation. Imagine that the 2D IMB is created by a set of 1D IMBs each created by a leaf-pair. Then concentrate on that leaf-pair.

$$I(x) = t_1(x) - t_2(x) \quad (43.6)$$

where  $t_1(x)$  is the time of arrival at  $x$  of the trailing leaf and  $t_2(x)$  is the time of arrival at  $x$  of the leading leaf. Intensity and time are measured in the same units. To generate an arbitrary 1D IMB, the leaf velocities are chosen such that

$$\begin{aligned} v_2(x) &= v_{\max} \\ v_1(x) &= v_{\max}/[1 + v_{\max}(dI/dx)] \quad \text{if } dI/dx > 0 \end{aligned}$$

and

$$\begin{aligned} v_1(x) &= v_{\max} \\ v_2(x) &= v_{\max}/[1 - v_{\max}(dI/dx)] \quad \text{if } dI/dx < 0 \end{aligned} \quad (43.7)$$

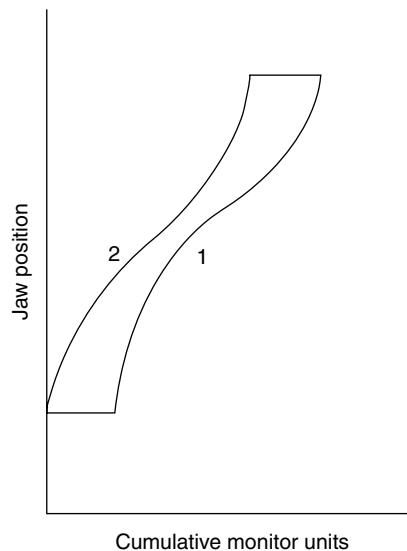

where  $v_{\max}$  is the maximum leaf speed. This means that when the fluence profile is increasing the leading leaf moves at maximum speed and the trailing leaf provides the modulation. However, when the fluence profile is decreasing the trailing leaf moves at maximum speed and the leading leaf provides the modulation. This algorithm was simultaneously discovered and published by three groups in different countries (Stein et al. 1994; Svensson et al. 1994; Spirou and Chui 1994). It has been shown that this gives the most efficient delivery and it is possible to calculate the total delivery time as the sum of the time taken for the leaf-pairs to sweep the whole field plus the sum of the rising fluence parts (Stein et al. 1994). The trajectory diagrams then characterise the radiation delivery (Figure 43.15 and Figure 43.16). A particularly graphic demonstration of these equations (due to Art Boyer) is in Chapter 3 of Webb (2000a).

In practice there are a lot of instrumental limitations to consider e.g. the equations imply that leaves will make sudden large accelerations. The experimentally possible accelerations may thus be exceeded but there are methods to cope with this. Versions of these equations exist which also take account of an upstream modulation in radiation primary fluence.

More importantly, the equations only express the movements required to obtain a required *primary* fluence. In practice there will also be a contribution to delivered fluence through leaf leakage and also through the head scatter and phantom scatter generated. Methods to cope with all of these exist and rely on an iterative process whereby the leaf movements are first generated for a required primary fluence. Then the actual delivered fluence is computed through some model. Then the primary fluence is modified so that after a second run of the equations the actual fluence more closely matches the required fluence and so on iteratively until convergence of actual to required fluence.

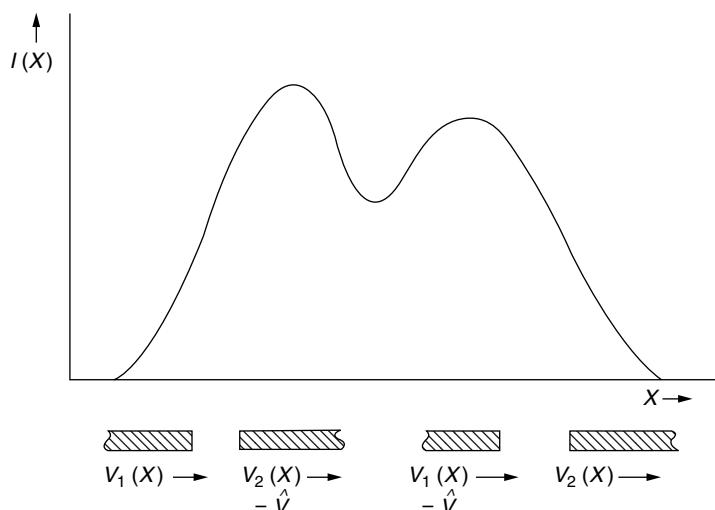

The above operations are sometimes called an *interpreter* because the mathematics interprets the IMB into a leaf pattern. However, as previously discussed in Section 43.3.2, it is not enough to interpret each 1-D IMB independently of its neighbours because when the separate interpreted leaf patterns are merged, this may lead to violations of the equipment limitations on interdigitation. It also can lead to a phenomenon known as the *tongue-and-groove effect* in which the beam's-eye-view of the interlocking leaf sides is underdosed with respect to the dose delivered to adjacent channels.

Several workers have shown that the tongue-and-groove problem is entirely soluble by a process known as leaf synchronisation (Van Santvoort and Heijmen 1996; Webb et al. 1997) which sets the underdose to exactly zero. Also, more intelligent interpreters have been developed which make use of both leaves and jaws and can thus create an island of zero

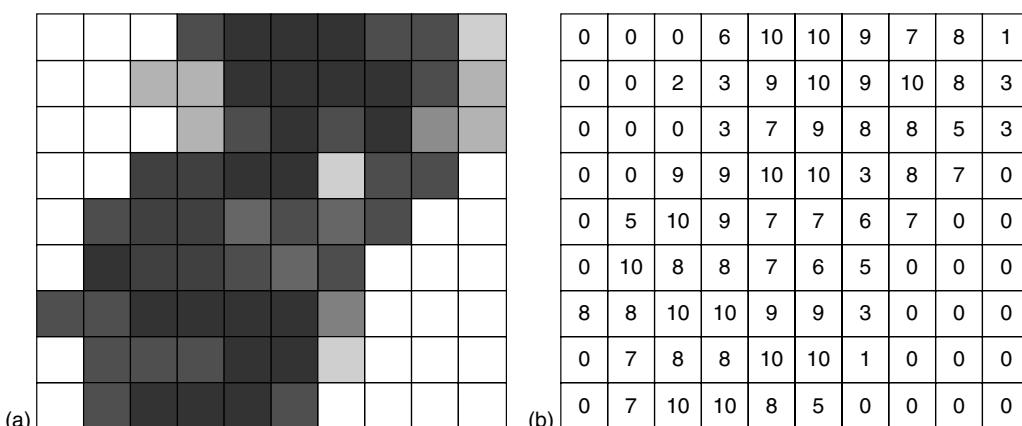

**FIGURE 43.15**

Showing the jaw or leaf positions as a function of cumulative monitor units for two jaws or leaves (the trailing jaw or leaf is number 1) in dynamic therapy. The horizontal axis is a measure of cumulative MUs representing time  $t$ . The vertical axis is a measure of position  $x$ . At any position  $x$ , the horizontal width between the two curves gives the intensity of the IMB in MU.

primary fluence (leakage ignored) in a field (Convery and Webb 1998). This can also arrange for zero tongue-and-groove underdose and can also avoid the interdigititation excluded by some (e.g. the standard Elekta) MLCs. The only price paid is a moderately complex algorithm and a slightly increased treatment delivery time. An example of one such component field is shown in Figure 43.17.

**FIGURE 43.16**

When the gradient  $dI/dx$  of the intensity profile,  $I(x)$ , is positive, the leading leaf (2) should move at the maximum velocity; conversely when the gradient  $dI/dx$  of the intensity profile  $I(x)$  is negative the trailing leaf (1) should move at the maximum velocity. Equation 43.7 is illustrated by showing a schematic of the pair of leaves in two separate locations delivering the IMB profile shown in the upper part of the figure.

**FIGURE 43.17**

An example of a discrete IMB shown as (a) greyscale and (b) the matrix of relative intensities. The intensity distribution is for a posterior oblique field of an eight-field prostate plan with 10% intensity stratification and 10 mm by 10 mm beam elements at the isocentric plane planned with the CORVUS planning system. (From Convery, D. and Webb, S., *Phys. Med. Biol.*, 43, 2521–2538, 1998. With permission.)

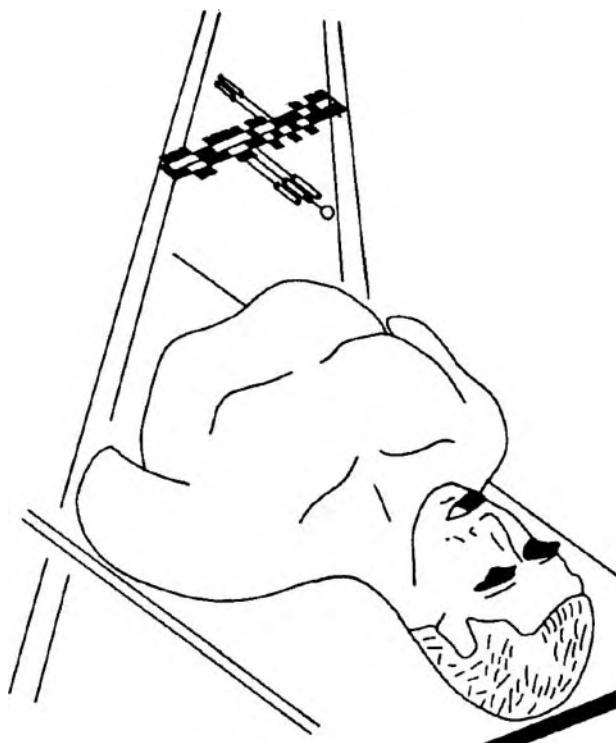

Many different groups have generated different interpreters, all with slightly different aims. The reader is referred to the wider literature. IMRT by the DMLC technique has been promoted by the accelerator manufacturer Varian. The technique has been clinically implemented in many centres.

#### 43.3.4 TOMOTHERAPY

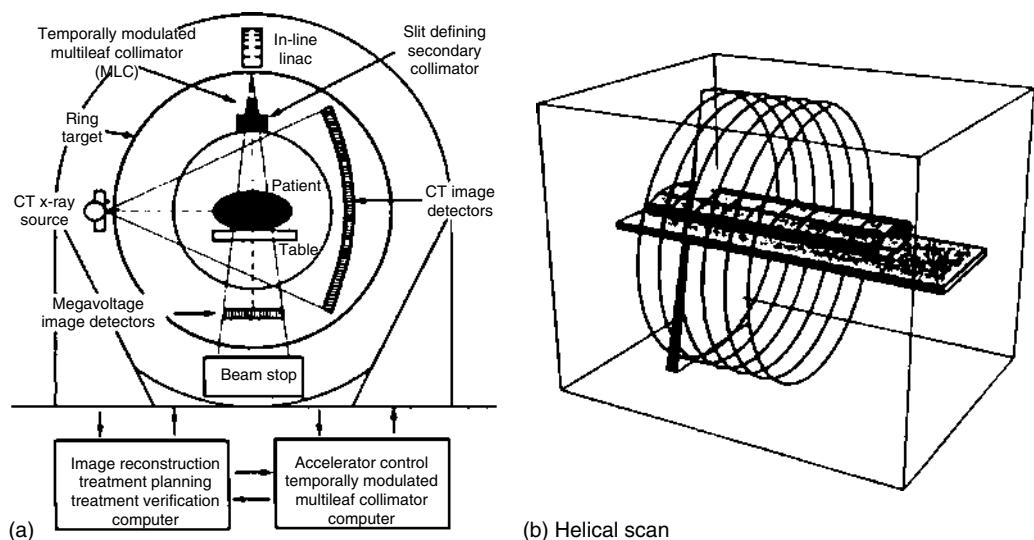

The concept of tomotherapy represents a totally different technique for delivering IMRT. It does not make use of the conventional multileaf collimator. Instead the radiation is collimated to a narrow fan and the fan-beam rotates isocentrally around the patient. As it does so the 1-D IMB is created and continually modified by shooting, vanes, of attenuating tungsten into the aperture at right angles to the direction of the slit. There are two methods which, whilst related through this concept, have distinctive features. In the first the patient lies on a stationary table. Therefore, IMRT is performed for a small slice of the patient and to complete IMRT of the other slices the patient table must be incremented sequentially. In the other implementation, the patient table translates slowly through the rotating beam which then executes a helical motion relative to the patient considered stationary. The first method was proposed and developed by Mark Carol and the NOMOS Corporation\* and the second by Rock Mackie and colleagues at the University of Wisconsin (Mackie et al. 1993). The first technique is illustrated in [Figure 43.18](#) and the second in [Figure 43.19](#).

Common to both realisations is the multivane slit collimator. The collimator was invented and patented by Swerdluff et al. (1994) in Wisconsin but was first constructed by the NOMOS Corporation who christened it the MIMiC (multivane intensity modulating collimator). The MIMiC comprises two banks of 20 vanes of tungsten which can be fired into and out of the (half) slit under electro-pneumatic control. Air pressure to the back of the vanes keeps them closed until a higher air pressure to their front opens them. They can be switched from open to closed state in 20 ms. The IMB is constructed from the varying dwell-times of the vanes in the aperture. The vanes are focused to the source axially, are 5 mm wide on the source side, 6 mm

\* This was first presented at the American Society of Radiotherapy and Oncology meeting in 1992.

**FIGURE 43.18**

Shows the location of the MIMiC stubby-vane collimator in relation to the patient with some of the vanes closed and others open. The two back-to-back slit apertures each comprise 20 vanes.

**FIGURE 43.19**

A schematic diagram of Mackie's original proposal for tomotherapy. (a) An in-line linac with a temporally modulated MLC is mounted on a gantry along with other components which will perform megavoltage CT and diagnostic CT. The equipment rotates continually as the patient is translated slowly through the beam, hence (b) the motion is helical with respect to the patient. In the commercial implementation the separate diagnostic CT scanning source has been omitted with CT images being created using the linear accelerator run at a lower energy. (Figure (b) from Mackie, T. R. et al., *Med. Phys.*, 20, 1709–1719, 1993.)

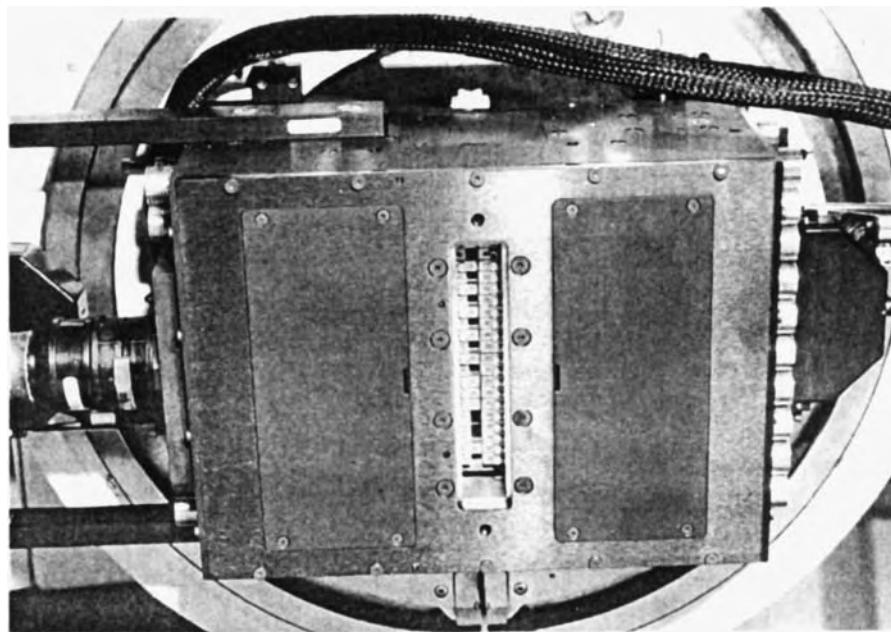

wide on the patient side, 8 cm deep and the *throw* can be adjusted to be 1 cm or 2 cm at the isocentre. The MIMiC creates two IMRT slices simultaneously (Figure 43.20). The MIMiC changes its 1-D IMB (per bank) every 5° of arc and generally rotates through 270° avoiding irradiation through the couch. The 1-D IMBs are computed via the inverse-planning process on PEACOCKPLAN (CORVUS) (see [Section 43.2.8](#)) and the plan is transferred on disk to an onboard computer. The apparatus looks a little cumbersome but has been designed to fit any accelerator and is used in many clinics, particularly in the U.S.A.

An issue of concern with the MIMiC technique is that of ensuring the matchline is accurate. There have been several studies which show that the couch increment must be made to 0.1 mm accuracy and NOMOS have provided the CRANE to achieve this, a device that permits accurate increments without backlash and with full stability. There is also a quite complex commissioning and quality-assurance procedure to follow before clinical use.

The NOMOS MIMiC IMRT technique has been a practical reality since 1992. The University of Wisconsin prototype tomotherapy apparatus whilst conceptualised in 1993, underwent a much longer period of development, and was first made commercially available by Tomotherapy, Inc. in 2002. This is partly because the scheme is more ambitious, intending to create a *radiotherapy system in a box*, doing away with almost all existing techniques. The group have also made an enormous number of careful studies of the concept including building a full laboratory mockup to study the process. Fuller details of these and indeed the other IMRT techniques are given in Webb (1997b, 2000a). Up-to-date reviews of commercial clinical spiral tomotherapy can be found in Palta and Mackie (2003) and in Fenwick et al. (2006). [Figure 43.21](#) and [Figure 43.22](#) show the modern Tomotherapy equipment. Quality control of tomotherapy is discussed briefly in Section 38.

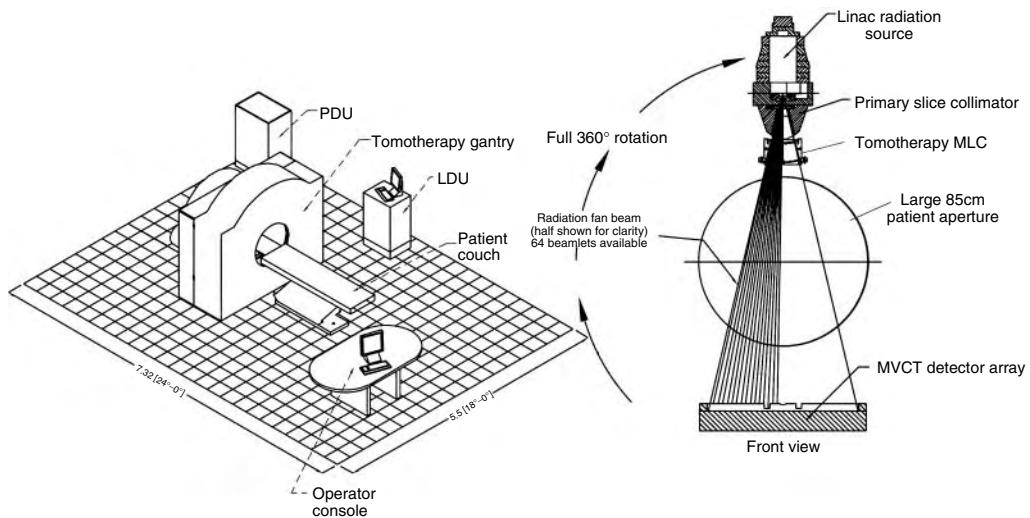

### 43.3.5 SWEPT PENCIL BEAMS

The concept of *sweeping* a *pencil beam* of radiation is attractive, giving maybe the ultimate control over beam delivery. The idea was proposed some time ago using the Racetrack

**FIGURE 43.20**

A view of the NOMOS MIMiC collimator attached to an Elektac accelerator at the Royal Marsden NHS Foundation Trust, showing a leaf pattern. (Loan—courtesy of the NOMOS Corporation.)

**FIGURE 43.21**

The tomotherapy system. (Courtesy of Prof. Rock Mackie.)

Microtron (Lind and Brahme 1995). However at that time the photon beam, far from being a *pencil*, was more like a *broom* with a FWHM of many centimetres and so the idea did not seriously rival the other IMRT methods. Recently it has been shown theoretically that a narrower beam can be generated using an optimised bremsstrahlung source and a short isocentric distance (Svensson et al. 1999).

**FIGURE 43.22**

### 43.3.6 THE MOVING BAR TECHNIQUE

A 1-D IMB can be created by sweeping an attenuating bar through the field. By varying the dwell-time of the bar at different locations the 1D profile receives an intensity modulation. In its simplest form the algorithm requires the bar to dwell at location  $x_i$  for time  $t_i$ , where

$$t_i = T(1 - I(x_i)/I_u) \quad (43.8)$$

$I_u$  is the unattenuated fluence, and  $I(x_i)$  is the fluence at location  $x_i$  and  $T$  is the total irradiation time. It may be appreciated that because of the condition:

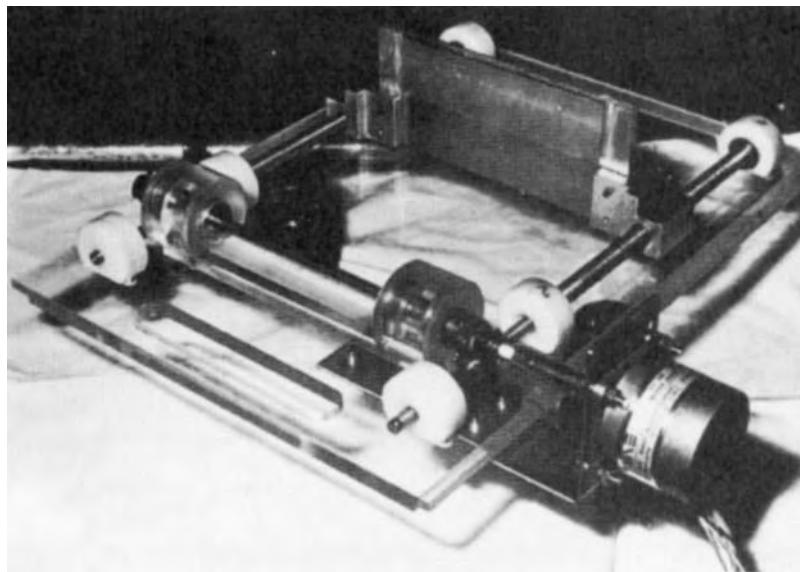

$$\sum_i^N t_i \leq T \quad (43.9)$$

not all modulations are achievable; the sum of the dwell times must clearly not come to more than the total irradiation time. It is clear that the method works best for shallow modulations, the exact opposite of the ideal conditions for the DMLC technique where shallow modulations would demand high leaf velocities. The moving bar technique involves many considerations. The spatial scale of the modulation is determined by the width of the bar in the direction of scanning. Therefore, there is a compromise between the accuracy of the IMB and the ability to actually provide the modulation at all. Detailed equations (see Webb 1997b) explain these concerns.

The technique has received attention because it has actually been engineered (Fiorino et al. 1992) and used, for example, to modulate the intensity to provide a missing-tissue compensator for head-and-neck treatments (Figure 43.23). In principle one could imagine creating a 2D collimator with this approach but then the complexity would rival that of the DMLC method. Hence this development is not expected.

### 43.3.7 INTENSITY-MODULATED ARC THERAPY (IMAT)

IMAT is a technique invented by Yu et al. (1995). It capitalises on the observation that any 1-D IMB can be created by a set of MLC-shaped fields in an enormous number of ways (Webb

**FIGURE 43.23**

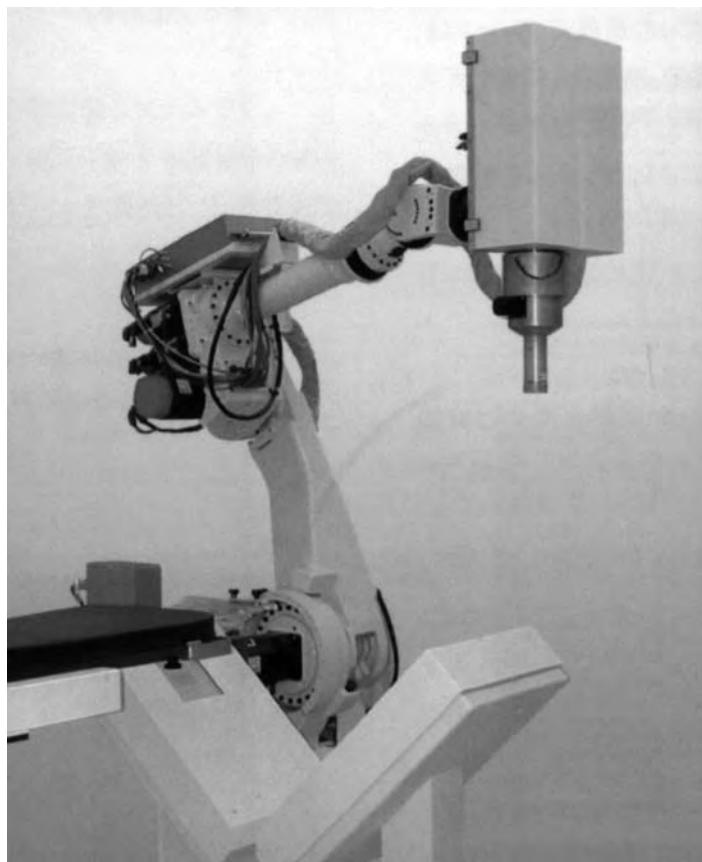

The moving bar technique. The bar is translated across the radiation field spending a variable time shielding each part. In this way some (but not all) 1D IMBs can be constructed. The apparatus is motor controlled and resides in the blocking tray of the linear accelerator.

1998b, 1998c). Consider just one 2D slice irradiated by a set of 1-D IMBs arranged to be delivered by gantry rotation. The basis of the method is to decompose the 1-D IMBs into components and deliver the components by multiple gantry rotations. For each rotation the difference in field size between one orientation and another is minimised leading to an optimal delivery method. The method was implemented successfully in a prototype IMRT delivery and is now in use clinically.

### 43.3.8 VERIFICATION OF IMRT

The delivery of IMRT is a major change from the delivery of radiation with geometrical shaping alone. Many of the methods require collimating apparatus to be moving either whilst the radiation is on or between successive bursts of radiation. When clinical IMRT was first started (about 1994) there was consequently natural concern about its safety. Physicists have risen to the challenge of demonstrating that delivered fields match those planned within acceptable tolerances; this is known as IMRT verification. The years since 1994 have seen the steady growth of a variety of verification tools and now there is more confidence. It is a big subject, extensively reviewed by Webb (2000a) (see references therein), and here some of the available techniques for assuring quality are simply listed:

- Film may be strapped to the accelerator head and record the integrated fluence as leaves move in the DMLC technique. These films may then be compared with the corresponding maps from inverse-planning computers. By inspecting films taken on successive occasions the stability of leaf movement may be studied. Some groups have also used electronic pixelated detectors in the blocking tray with the same purpose.
- Electronic portal imaging devices can record the integrated fluence from the sequence of irradiations which make up the intensity-modulated beam in either the DMLC technique or the step-and-shoot technique. The detector developed at the Royal Marsden NHS Foundation Trust has the special property of recording the dose from each pulse of radiation. The positions of the leaf ends can also be extracted from EPID data and correlated with the expected positions. Movies of these motions are particularly instructive; e.g. sticky leaves can be identified. Other groups have developed *a posteriori* methods of correlating image frames from EPIDs to the planned geometrical patterns.
- Intensity-modulated beams may be replanned on to simple geometric or anthropomorphic phantoms to give a new plan. These beams are then delivered to such phantoms loaded with TLD chips and/or with film sandwiched between slices. The doses measured by TLD and film are then compared with the plans. It is usual to quote the dose error in regions of low-dose gradient and the distance error for selected isodoses in regions of high-dose gradient (see also [Section 39.3.4.3](#)).
- Polyacrylamide (BANG) gel dosimetry is growing in popularity as it is an integrating 3D dosimeter (see [Chapter 17](#)). There is a linear relationship between the  $1/T_2$  image intensity of BANG gel and dose (Maryanski et al. 1996). Therefore, one can irradiate a phantom containing gel, read out the dose using MR and correlate with the plan. The gels may also be imaged optically.
- Megavoltage CT (MVCT) has been used to reconstruct the patient position during therapy to compare with the planned position. The University of Wisconsin tomotherapy device ([Section 43.3.4](#)) can actually make MVCT images with either *flashed on* open fields or even the leakage radiation from the modulated beams created by the collimator.
- NOMOS MIMIC IMRT ([Section 43.3.4](#)) has been verified through the use of a special box of films to which the modulated irradiations are applied followed by comparing measurements with computed predictions.
- Quality assurance programmes for DMLC have been designed based around the deliberate starting and stopping of leaves to create expected patterns which are then compared with measured patterns of dose.

**FIGURE 43.24**  
(See colour insert following page 590.) The Accuray Cyberknife.

### 43.3.9 THE FUTURE OF IMRT

IMRT is here to stay. It represents the future of improving the physical basis of radiotherapy. Its study has generated an enormous literature. Seven methods have been proposed and demonstrated at least in principle. From the literature the reader may draw their own conclusions about which are likely to succeed clinically; a technique which scores well for one clinical application may not be so good in others.

A radical new proposal has been put forward, namely that the ultimate IMRT may be delivered by a robotically controlled short-length linac (Webb 1999, 2000c), such as the Accuray Cyberknife (Figure 43.24). The inverse-planning technique has been completely worked out; it has been shown that complex 3D dose distributions can be delivered, albeit with very poor efficiency. Conversely, several radically new concepts for IMRT have been proposed but not yet experimentally realized (Webb 2001), e.g.:

- The shuttling MLC (Webb 2000d, 2001)
- *Jaws plus mask* IMRT (Webb 2002a, 2002b)
- The variable aperture collimator (Webb et al. 2003, 2004a)

The technical development of IMRT shows every sign of continuing (Webb 2004c; Bortfeld et al. 2006).

## 44.1 INTRODUCTION

Clinical implementation of intensity-modulated radiotherapy (IMRT) needs all the work required to implement 3D conformal radiotherapy (CFRT) and more (see Chapter 39 and Chapter 40). Consideration must be given to important issues such as equipment and space requirements, time and personnel requirements, additional dosimetry verification and treatment quality assurance (QA), staff training and patient education and changes in treatment scheduling. It is essential for a clinic to designate an implementation team to think through the implications in advance, and to periodically update procedures as lessons are learned. Bringing the modality to the clinic is only the first step. Much effort is needed to keep it running smoothly and to keep pace with upgrades and future developments in IMRT technology. To achieve the full benefit from IMRT, various resources must be in place, and all persons involved in IMRT, not only physicists but also physicians and other personnel such as radiographers, service engineers and administrators, must be properly trained. Furthermore, IMRT is an integrated system. Every single technical/physical component and treatment step must be considered carefully. In this chapter, a brief description is provided, which details the requirements for clinical implementation and guidelines on IMRT treatments.

---

## 44.2 REQUIREMENTS FOR CLINICAL IMPLEMENTATION

### 44.2.1 EQUIPMENT, SPACE AND SHIELDING

It may be necessary to upgrade existing equipment to provide IMRT functionality. MLC-based IMRT may involve adding an MLC, upgrading an existing MLC to dynamic capability, or purchasing special add-on collimators. For compensator-based IMRT, special equipment, such as a computer-controlled milling machine, may be required. Similarly, special software for IMRT treatment planning must be acquired, which may include add-on modules for an existing treatment planning system, or a dedicated treatment optimisation system. Existing record and verification systems may need to be upgraded to accommodate IMRT treatments. Computer networks may need to be enlarged or improved in order to permit the necessary file transfers. Additional dosimetry equipment may be needed for the commissioning and ongoing QA of IMRT (e.g. it is important to have an efficient film-scanning system to accomplish these tasks). Additional phantoms may also be needed.

Extra space may be required for additional computer workstations, especially if IMRT planning is to be done on a dedicated system. Space may also be needed for additional equipment, such as add-on collimators or dosimetry devices. IMRT treatments require more beam-on time than conventional treatments, so room shielding should be re-evaluated. The increase in monitor units (MU) is 1 to 3 times for MLC-based IMRT treatments and up to 9 times for sequential tomotherapy delivery (see Section 44.3.4), depending on the number of gantry rotations involved. Compensator-based IMRT generally requires only a small fractional increase in MU. However, it is usually the secondary barriers, not the primary barriers, that may be affected (Motic et al. 2001; Stathakis et al. 2005). The changes in neutron dose due to beam-intensity modulation basically scale with the increase of MU, but have limited clinical effect (Followill et al. 1997; Price et al. 2003a). However, these authors suggest that 18 MV should only be used for IMRT when treating older patients.

### 44.2.2 TIME AND PERSONNEL

Sufficient time and resources should be allocated to complete all the tasks involved in clinical implementation. Radiation oncologists and treatment planners (physicists or

radiographers) will need to learn a very different approach to planning. Physicists must complete comprehensive measurements to assure that the treatment planning and treatment delivery systems are accurate. The implementation team should set up and test the processes used for individual patient treatments. QA procedures must be implemented. Special training should be arranged for personnel involved in the IMRT process. These tasks will probably require an initial investment of several person-months of work on the part of the physics staff and other members of the implementation team.

#### 44.2.3 TREATMENT SCHEDULING

Due to the changes in patient immobilisation, target localisation, beam delivery and dosimetry verification, some IMRT treatments will take at least 50% longer than conventional treatments\*. Only some of the treatment machines may be equipped for IMRT. New imaging studies and immobilisation devices may be required. Staff responsible for scheduling will need to be advised of these new requirements. They should be consulted early in the implementation process so that consequences of those changes can be anticipated, and adjustments made. Changes in charting procedures should also be considered, including documentation of daily treatment with many complex fields, documentation of QA procedures and records of dose summaries that adequately describe dose-volume goals and results.

#### 44.2.4 STAFF TRAINING

IMRT is an integrated process which is much more complex than CFRT. Therefore, staff training and education should be an essential part of the clinical implementation of IMRT. Experience gained by the staff in 3D treatment planning and delivery (see Chapter 39) is helpful but not sufficient for IMRT. There are significant differences between the two that necessitate additional specialised training. Each member of the IMRT team should understand the whole process in order to be able to use this technology safely and effectively. IMRT differs from traditional radiation therapy enough that it should be considered as a special procedure, which necessitates the didactic training of key members before the new modality is implemented in a clinic. The training curriculum for each IMRT team member must include all of the critical steps in the IMRT process.

##### 44.2.4.1 *Radiation Oncologists*

IMRT represents a significant departure from current radiotherapy practice. Treatment planning for IMRT is complex and non-intuitive. The optimisation process is generally completely computer-controlled (see Section 44.3.4), and its success in achieving the clinical goals is very much dependent on the set of parameters used as input to the computer algorithm. It is therefore difficult for the oncologist and planner to identify an optimal solution without having a complete understanding of the optimisation process and its limitations. Learning how to adjust the parameters to steer the results in the desired direction is essential to avoid treating a patient with a sub-optimal IMRT treatment plan.

A basic use of IMRT is to treat tumours that are in close proximity to critical, normal structures. This requires the oncologist to delineate between the target and the critical structures precisely and accurately, and to choose appropriate planning margins judiciously. This, in turn, requires training in image-guided treatment planning and a good understanding of treatment-planning and delivery uncertainties. IMRT often results in the gross tumour and regions of sub-clinical disease being given different doses per fraction concomitantly.

\* The treatment time can also be reduced if replacing a complex non-IMRT treatment.

In addition, the dose distribution in the target volume is often much more inhomogeneous than is the case with (non-IMRT) conformal therapy. It is important that the radiation oncologists critically evaluate differential dose-fractionation schedules for IMRT in light of their clinical experience with conventional radiation therapy. This requires an understanding of the concept of biologically equivalent doses and tissue-tolerance doses (see Part B). Radiation oncologists whose residency training did not include IMRT should consider attending special training courses or workshops. Short-term clinical training at academic institutions that have active clinical IMRT programs can also be considered.

#### *44.2.4.2 Physicists and Dosimetrists*

Physicists play a much more significant and direct role in IMRT planning and delivery than in conventional radiation therapy. It is therefore essential that they (and dosimetrists) have a good understanding of the mathematical principles of dose optimisation (Section 43.2), computer-controlled delivery systems and dosimetry issues related to small and complex shaped radiation fields. They also need to have a better understanding of treatment setup, planning and delivery uncertainties and their impact on patients treated with IMRT. The QA procedures for IMRT are much more complex than for conventional radiation therapy (see Part H). Physicists are responsible for the design and testing of the QA procedures, and thus they should actively participate in the QA process. It is imperative that each physicist involved with IMRT has special training in the whole process of IMRT.

#### *44.2.4.3 Treatment Radiographers*

Implementing IMRT requires the active involvement of the radiographers. They should be involved in the design and testing of treatment procedures. If the IMRT delivery involves specialized equipment (e.g. an add-on collimating device or compensators), there will be the need to train the radiographers in its use and storage. They may also have responsibilities for basic maintenance and QA. Radiographers will need to be trained to use any new immobilisation or localisation systems, as implemented in the new procedures. Carrying out mock procedures with phantoms ought to be part of the process of testing the new procedures. Delivery details that escape the physicist's notice may be important to the radiographers. For example, the initial field shape for an IMRT treatment may obscure the light field or the crosshair, requiring that the patient be positioned before the MLC is programmed. Radiographers must be provided with the means of knowing that the treatment they are about to deliver is correct. Given the complexity of IMRT treatments, it is essential for the treatment delivery to be fully monitored by a record and verify system. Radiographers must nevertheless be trained to verify that the record and verify system is running correctly and this training must include how to respond to unplanned events. They need to know how to interrupt and restart a treatment, how to recover from a partial treatment that requires the console to be reprogrammed and how to recognise and act on new error messages and interlocks. Radiographers will need to be trained in any new procedures related to portal imaging as well as in daily QA tests. As with any QA procedure, clear instructions and action levels must be provided.

#### *44.2.4.4 Service Engineers*

Service engineers must have a good knowledge of all aspects of the IMRT beam delivery process and the equipment required. Compared to standard treatment techniques, it is much more difficult to recover cleanly from an interruption in dose delivery after an intensity-modulated treatment has started. Therefore, accelerators with a poor history of reliability are not suitable for this type of treatment, and expanded preventive maintenance programs are

extremely important. Intensity modulated dose delivery can place demands on the MLC that far exceed the criteria used for the design of these systems. For example, some implementations can require several hundred MLC fields per patient, or many thousands of fields per treatment day, which may result in more frequent component failure. The accuracy of calibration of MLC leaves is more critical than for CFRT, and for ‘step and shoot’ IMRT (see Section 43.3.2), beam startup characteristics are more important because of the small doses for individual beam segments. Special QA procedures should be established to ensure proper calibration of leaf position and to avoid treatment interruptions. With the co-operation of the physicist, preventive maintenance programs should be implemented to meet the special needs of IMRT.

#### 44.2.5 PATIENT EDUCATION

Patients treated with IMRT should be informed of several issues. These include the goal of the treatment, potential side effects, realistic estimates of the time required for each treatment, the immobilisation method to be used and the beam delivery process. IMRT can potentially improve local control and quality of life through dose escalation and normal-tissue sparing. This will be site- and protocol-specific. If IMRT is used to improve local control by escalating doses, then the potential for acute or chronic sequelae may increase. Parotid-sparing protocols may decrease the incidence of xerostomia, but increase acute mucositis, especially if target doses are more inhomogeneous than with conventional treatments. It is reasonable to expect that compared to CFRT, normal-tissue complications will be reduced by IMRT for the same target dose. For example, it is possible to achieve identical prostate dose coverage with a reduction in the dose delivered to the nearby critical structures such as rectum, bladder and femoral heads. It is necessary to discuss patients’ expectations of IMRT. Some patients may desire to be treated with this new, highly advertised modality, whether or not it is advantageous or appropriate for their condition.

---

## 44.3 GUIDELINES ON IMRT TREATMENTS

### 44.3.1 GENERAL CONSIDERATIONS

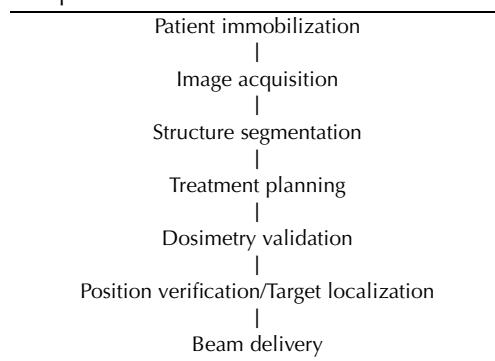

Intensity modulation increases significantly the level of sophistication and complexity of the treatment planning and dose delivery process. Table 44.1 shows the key components of a general IMRT treatment process. Detailed discussions are given below on these key components.

### 44.3.2 IMAGE ACQUISITION

There is growing interest in image-guided radiation therapy (see Introduction to PART I), especially with the widespread use of IMRT. Image guidance is playing an increasingly important role in structure segmentation, target (treatment volume) determination, inter- and intra-fraction target localisation and/or target redefinition (Mah et al. 2002; Chapman et al. 2003; Grégoire et al. 2006). IMRT requires more precise information about the target and normal tissue structures for treatment planning. Hence, there will be increasing use of contrast agents for CT scans, as well as increasing registration of images from other modalities, such as MRI or PET scans, which both provide additional anatomical as well as functional information. This information can, in principle, make it possible to plan heterogeneous dose distributions within the target which account for variations in tumor cell density and oxygenation conditions

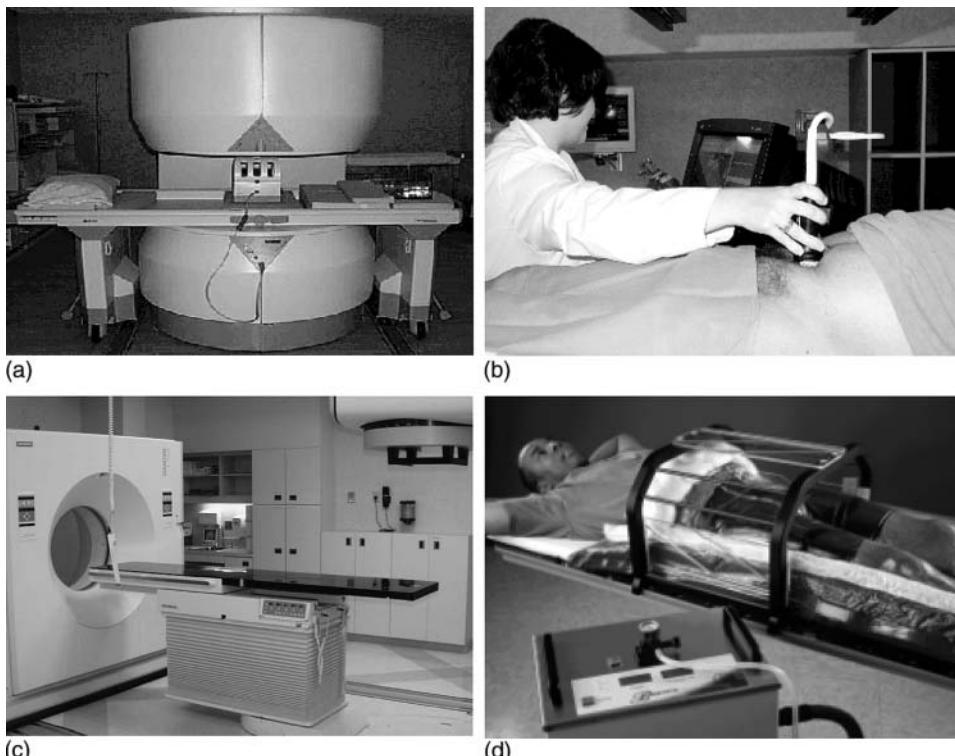

**TABLE 44.1**

## Components of an IMRT Treatment Process

e.g. IMRT can be used for *dose painting* or *sculpting* (Ling et al. 2000; Webb 2003d; Bentzen 2005).

CT scanning for treatment planning will be performed with the patient in the treatment position in the immobilisation device. Chen et al. (2004) show that an MRI may also be used for treatment planning of abdominal and pelvic sites ([Figure 44.1a](#)). IMRT treatment planning needs 3D image data with more slices at a finer spacing than has previously been the norm,

**FIGURE 44.1**

(See colour insert following page 590.) Imaging, immobilization, patient positioning and target localization devices used for IMRT at Fox Chase Cancer Center, Philadelphia, Pennsylvania; (a) a low-field open MRI scanner for structure segmentation; (b) a BAT ultrasound system for soft-tissue target localization; (c) a CT scanner in the treatment room for target localization; (d) a body localizer with vacuum fixation for patient immobilization and repositioning.

depending on the MLC leaf width. For example, a slice spacing of no more than 5 mm should be used for an MLC with 10 mm leaves, and finer spacing may be needed to generate digitally reconstructed radiographs of sufficient quality. It may be necessary to extend the range of slice acquisition for planning non-coplanar beam arrangements.

#### 44.3.3 STRUCTURE SEGMENTATION AND TARGET DEFINITION

It is labour-intensive to delineate targets, critical organs and other reference structures for IMRT treatment planning. One important feature of inverse planning is that the high-dose region will be limited to the exact target volume defined, and only those normal-tissue structures specifically identified will be avoided. This requires the physicians and the planners to define structures in more detail. For example, implementing an IMRT protocol for breast patients would require the breast target volume together with the lung and the heart (and perhaps the contralateral breast) to be defined on each axial slice, with due consideration for margins. This can be more difficult than defining conventional tangential photon fields on simulator films. Other reference structures may be added to assist the optimisation process in improving target dose conformity (Price et al. 2003b). This also requires more effort from the physicians and the planners.

#### 44.3.4 IMRT TREATMENT PLANNING

Treatment planning and plan optimisation for IMRT require a change of approach compared to conventional planning. In terms of clinical implementation, a key point is to allow time for the physicians and planners to develop their skills in using the system. Physicians have to prescribe dose-volume limits that define an acceptable plan, and planners need to learn how to control the dose distribution by modifying unfamiliar input parameters. There is a change from planning beams to give a uniform dose to a volume, to designing volumes for the target and organs at risk that will support the appropriate objectives to achieve the desired dose distribution. Tissue not specifically included in the target volume will probably get a low dose and sensitive normal tissues that are not specified as such may well receive a higher dose than is desirable. Clinics will need to develop tools to aid these tasks. New forms may be needed for radiation oncologists to communicate complex planning goals to the planners, for planners to keep track of the parameters that have been tried and for planners to report the final plan results. Since an IMRT plan is only *optimal* (or customised) in terms of the predefined beam directions and plan parameters, its dose distribution may not necessarily be superior to an alternative CFRT plan. IMRT is useful for those unusual cases where there are particular challenges, but in order to develop an understanding of the way in which the constraints available with a particular planning system affect the dose distribution, it is useful to begin with a common tumour site, such as prostate. In the initial implementation phase, plan comparisons between IMRT and conventional CFRT should be performed for each specific site and treatment protocol in order to maximise the benefit from the new technology. This information may be obtained from published results and the experiences of other institutions, but it is important to realise that the way in which IMRT objectives affect the outcome of optimisation is planning-system dependent. As a guide for such plan comparisons, calculation of relative TCP, NTCP and/or EUD (see Chapter 36) may be useful. Templates with favourable beam arrangements and optimisation parameters, called *class solutions*, can be established for common treatment sites (such as prostate), to facilitate routine IMRT treatment planning.

The most obvious parameters available to the planner are the *maximum* and *minimum dose* to *target* tissues and the *maximum dose* to *organs at risk*. In addition there is the possibility of defining *dose volume objectives* so that a particular percentage of an organ-at-risk volume can be set to receive no more than a certain dose. The latter is usually called a dose-volume histogram (DVH) objective (see Section 35.3.1). Another useful option is a *uniformity* objective.

The perfect plan, with the prescribed dose delivered uniformly to the target volume and no dose outside the target, is unachievable and the optimisation algorithm has to balance the various objectives in order to achieve an approximation to the desired result. In order to guide the algorithm each objective can be assigned an *importance factor* or *weight*. If all the objectives were achievable there would be no need of weighting factors. Although experience shows that setting achievable objectives is more successful than setting unattainable goals, it is useful to be able to indicate which objectives are more important. Another concept is that of a particular goal that *has* to be met even if all other objectives are not achieved—this can be distinguished from other types of objective by describing it as a *constraint*, although this term is often used interchangeably with *objective*. IMRT optimisation essentially involves *moving* dose from one sensitive part of the patient to another part that is less sensitive. If no dose limit is specified for a particular volume of tissue it is possible that the dose will be *dumped* into that volume. To avoid this, the definition of dummy volumes can be useful. For example a shell around the target volume can be defined to help to ensure that the dose falls away sharply outside the target volume (Price et al. 2003b). Balancing all these tools is a new skill and indiscriminate application of them can result in an excessively complex plan that is difficult to deliver accurately. It is therefore advisable that, wherever possible, class solutions be developed including a table of acceptable dose volume limits.

In principle it would be possible to specify objectives directly in terms of tumour control probability and normal tissue complication probability (see Chapter 36). There has been much controversy about whether this is the right way to go, with those opposed to this saying that the biological parameters are not adequately known.

On the other hand the ranking of plans does not require such a high level of accuracy in terms of the absolute value of tumour control and several treatment planning system vendors are now offering the possibility of biological objectives; it is likely the use of these will grow (Grigorov et al. 2006). However, it is important to remember that if the complication probability for a particular organ is not specified in the plan design, the computer has no means of assessing the risk of that complication. This is especially important when doses are raised above the limits of normal experience.

When an IMRT plan has been satisfactorily computed and approved by the physician, the treatment control files can be generated. For MLC systems, these include leaf-sequence files for each gantry angle. Because IMRT involves complex beam shapes and control files, digital capability for plan transfer is essential to avoid possible mistakes during manual transfer. Depending on the individual clinic's information system, the files can be transferred by floppy disk or, preferably, directly transferred to the *record and verify* server through data-exchange software. If the department has a record and verify system that fully supports IMRT treatments, then many of these problems are reduced (and replaced by the need to verify the initial programming of the record and verification system).

#### 44.3.5 PLAN VALIDATION AND QUALITY ASSURANCE

The implementation team should also design and implement an appropriate QA programme (see also Section 43.3.8). A number of useful papers are available to provide guidance on the QA programme (e.g. Losasso et al. 2001; Low 2002; Ezzell et al. 2003). The QA of IMRT consists of three parts: (1) commissioning and testing of the treatment planning and delivery systems, (2) routine QA of the delivery system and (3) patient specific dosimetry verification. The first part is to ensure the accuracy and performance of the inverse planning and IMRT delivery system. The second part is to ensure the normal operation of the dynamic or 'step & shoot' delivery system, and will involve additions to the daily, monthly and annual QA protocols (for example, the daily checks may be augmented to include a test of a dynamic treatment, including an output measurement that checks the stability of a

**TABLE 44.2**

Items to Be Tested before an IMRT Treatment

Item to be Verified	Method
Monitor units (absolute dose at a point)	Measurements in a phantom
MLC leaf sequences or fluence maps	Measurement with film or a digital imaging device
Dose distribution	Measurement with film or a dosimeter array (TLDs, ion chambers) in a phantom
Collision avoidance	A <i>dry run</i> before treatment

programmed MLC gap width). The third part is to ensure the accurate and safe treatment of the patient.

While IMRT produces conformal doses, the level of sophistication has been increased considerably. The goal of dosimetry validation is to verify that the planned dose distribution will be delivered to the patient (Wang et al. 1996; Low et al. 1998; Boyer et al. 1999). This ensures that the plan has been computed correctly and that the leaf sequence files and treatment parameters charted or stored in the record and verify system are correct and executable. To expedite IMRT delivery, an auto-sequencing delivery system is sometimes used. Such delivery systems (in different forms) are currently available from all major accelerator vendors. Items that need to be verified before the first treatment fraction are shown in [Table 44.2](#).

Although the details of what is to be measured or calculated for dosimetric validation will depend on each clinic's needs and may change with experience, it is important to emphasise that new users will need to spend much more time validating IMRT plans than is common with conventional treatments. It is common practice to deliver the IMRT treatment plan to a phantom and to compare the doses measured in the phantom with those calculated by the planning system for that phantom (Paliwal et al. 2000; Ma et al. 2003; Budgell et al. 2005). Unless the phantom is similar in size and shape to the patient there may not be an area of uniform dose in the phantom that corresponds to the target in the patient. This will create difficulties for the dose measurement. Physical measurement will be necessary until reliable independent dose calculation methods are developed and validated (Ma et al., 2000; Pawlicki and Ma, 2001; Yang et al., 2003; see also Part F). However, it will never be possible to substitute dose check calculations (i.e. independent MU checking) for dose measurements entirely because the dose delivered is more dependent on the linac delivery system calibration than is the case with conventional treatments. For example, some calculation algorithms may not correctly model tongue-and-groove effects (Deng et al. 2001; Kamath et al. 2004; Que et al. 2004). Further discussion of these issues can be found in Section 39.3.9.3.

IMRT is a rapidly evolving modality, and the QA program for treatment planning will change with time so that it can handle various new issues that arise (Williams 2003). For example, two new approaches to reducing the time spent on quality control by automatic verification of the leaf positions include using the log of MLC leaf positions on Varian accelerators (Litzenberg et al. 2002; Stell et al. 2004), and using an electronic portal imaging device (Chang et al. 2004; van Esch et al. 2004). Electronic methods of measuring beam fluence are also being developed (Letourneau et al. 2004).

#### 44.3.6 PATIENT IMMOBILISATION, POSITION VERIFICATION, AND TARGET LOCALISATION

The highly conformal nature of IMRT treatment requires satisfactory patient immobilisation to facilitate imaging and target localisation, and to ensure accurate dose delivery. New immobilisation devices may be necessary, such as supplementing thermoplastic masks with bite

block fixation for head and neck treatments and using stereotactic body frames (see Chapter 45) and vacuum-fixation devices for abdominal treatments. Techniques to reduce the effect of organ motion due to breathing, such as respiratory gating (Hugo et al. 2003; Tsunashima et al. 2004; Jiang 2006; see also Section 29.3.3), may be desirable for thoracic and abdominal lesions. The inter-fraction reproducibility and reduction in intra-fraction organ motion that can be achieved with the immobilisation system should be investigated in advance to establish realistic margins for planning different sites. Devices to facilitate soft-tissue target localisation may be needed before each treatment to ensure the accuracy of isocentre placement (see below).

Verification of the patient position will be part of the initial plan validation. However, for subsequent IMRT treatments, patient setup and target localisation are the key to accurate dose delivery. The most critical requirement is that the treatment isocentre matches the planned isocentre. This can be done by comparing orthogonal films taken at simulation, digitally reconstructed radiographs (DRRs, see Section 32.4.5) from the planning system and portal images from the treatment unit. Wherever possible, portal images should be obtained for the fields used for treatment. It is useful to have a portal image showing the boundary of the intensity modulated aperture and compare this to the corresponding DRR from the planning system. Depending on the imaging system available, it may be possible to obtain a portal image of the modulated field superimposed on the patient's regional anatomy, but such images are often hard to interpret. In the case of dynamically delivered fields, one needs to consider how to acquire the MLC *envelope*, how to verify the position of a slit collimator, or how to operate an electronic portal imaging system.

Techniques based on bony structures provide adequate positioning accuracy for head and neck and spinal areas. Specially designed imaging systems based on ultrasound, CT, optical and radiographic detectors may be used for soft-tissue target localisation. The BAT ultrasound system (NOMOS Corp.) ([Figure 44.1b](#)) has been shown to be an effective and efficient target relocation device for prostate and other abdominal treatment setups (Langen et al. 2003; Trichter and Ennis 2003; Fuss et al. 2004), although Langen et al. found some operator variability. The positioning accuracy is between 2 mm and 5 mm ( $2\sigma$ ) and between 3 min and 5 min is added to the treatment time. A CT scanner in the treatment room can provide a better than 2 mm ( $2\sigma$ ) positioning accuracy for targets anywhere in the body ([Figure 44.1c](#)) using either bony structures or surgically inserted fiducial markers (Court and Dong 2003; Paskalev et al. 2004). At least, an extra 5 min will be needed to use this system before each treatment. A body localiser with vacuum fixation ([Figure 44.1d](#)) may reduce the movement of internal organs for high precision beam delivery for stereotactic body surgery or stereotactic IMRT (Wang et al. 2004). A combined optical and radiographic system can correlate the movements of the markers on the patient surface and the internal organs. Based on the real-time organ motion information, gated therapy or target tracking (Keall 2004; Keall et al. 2004; Murphy 2004) can be performed. A 5 mm ( $2\sigma$ ) accuracy may be achieved using such real-time image guidance for breast, thoracic and abdominal treatments.

Because of the importance of patient positioning, the concept of using a diagnostic x-ray beam orthogonal to the therapy beam has been developed by both Elekta and Varian (see Section 40.1.5 and [Figure 40.11](#)). This can be used to obtain high quality verification images to facilitate, for example, matching of the position of seeds placed in the tumor volume, or to obtain cone-beam CT images allowing direct comparison of CT data with the planning CT scans (Jaffray et al. 2002). The use of such techniques can be expected to improve the accuracy and hence the outcome of radiotherapy (Ghilezan et al. 2004).

#### 44.3.7 TREATMENT DELIVERY

As discussed in previous sections, there are several ways to deliver intensity-modulated beams for IMRT. Due to the increased complexity of intensity-modulated beam delivery the

patient throughput on the treatment machine may decrease. IMRT treatments require more MUs, and often use more gantry angles (ports) than are used conventionally. For example, patients previously treated with lateral fields or a *four-field box* may now have many fields, including obliques or arcs. Because of limitations due to MLC leaf over-travel and collimator jaw over-travel, the maximum MLC field size for IMRT is usually smaller than the conventional maximum field size; two or more MLC fields may be required to deliver a conventional treatment field.

Studies have shown that the beam-on time ratio between IMRT and the conventional CFRT is generally 1–2 for prostate treatments and 1.5–5 for head and neck treatments, depending on the delivery system used (Bakai et al. 2003). The increase in beam-on-time is relevant to radiation protection issues both in terms of the increased leakage dose to the patient (see Section 61.5.2) and to the thickness of shielding required (see Sections 61.1.3 and 61.1.1.4). However, the beam-on time is only part of the overall treatment time and, where IMRT is able to simplify a complex conventional treatment, there may even be some reduction in the *overall* time taken to deliver the treatment. The overall time to deliver a fraction may be relevant to cell-killing (see Section 9.4) if this time exceeds that which corresponds to the high dose rate limit for which the LQ-expression is valid (Altman et al. 2006).

## 45.1 INTRODUCTION

The term *stereotactic* means the three-dimensional localisation of a particular point in space by a unique set of coordinates that relate to a fixed, external reference frame. Historically, such a frame has acted as a support for hollow probes that have carried either electrodes or biopsy needles to precise locations within either an animal or human brain, based on the analysis of plane and orthogonal x-ray films of the subject in the frame.

Since the 1950s, the stereotactic principle (Leksell 1951) has been adopted by neurosurgeons for the technique of *stereotactic radiosurgery* (SRS or RS), in which narrow beams of  $^{60}\text{Co}$   $\gamma$ -rays are focused onto a small target within the brain. Since the 1980s, adaptations of medical linear accelerators (linacs), used to produce similarly precise megavoltage photon beams, have made this technique accessible to many radiotherapy centres (Podgorsak et al. 1990; Tepper 1995). With the development of accurately relocatable head frames used in conjunction with CT based fiducial marker systems, precisely planned and accurately deliverable fractionated radiotherapy of the brain is readily achievable. The latter technique is referred to as *stereotactic radiotherapy* or SRT, and although usually applied solely to the brain, can in principle be applied anywhere in the body (SBRT 2006).

Stereotactic brachytherapy, typically using  $^{125}\text{I}$  seeds implanted by stereotactically guided neurosurgical needles, is a complementary technique for very irregular lesions, but has the disadvantage, as with conventional neurosurgery, of being an invasive method, requiring hospitalisation of the patient. Radiosurgery procedures can usually be applied over a single day on an outpatient basis.

Stereotactic techniques using protons or heavy-ion beams (Kjellberg 1986; Steinberg et al. 1990) are described in [Section 46.5.3](#).

---

## 45.2 CLINICAL INDICATIONS

Lesions suitable for treatment with single fraction radiosurgery range from benign arteriovenous malformations (AVMs) to solitary, malignant brain metastases (Plowman 2000, 2002). Such lesions commonly receive doses in the range 15 Gy to 20 Gy. However, to reduce toxicity to sensitive structures, such as the brain stem and optic apparatus, many targets require fractionated treatments (Brada 1991; Shrieve et al. 1996). Such techniques are generally of a highly focused nature, thus they are often suitable for re-treating small recurrent tumours and as a boost to conventional brain and nasopharynx treatments. In these cases, *hypo-fractionated* regimens are sometimes used, typically involving five 5 Gy fractions. Most recent applications of SRT involve conventional fractionation of 25–35 fractions giving between 1.5 Gy and 2 Gy per fraction. Reduced PTV margins around the GTV (ICRU 1993b, 1999; see also [Chapter 29](#) and [Chapter 30](#)) in SRT and RS reflect the improved accuracy of patient fixation, target localisation and treatment delivery, and the capability of making fine geometrical adjustments arising from electronic, megavoltage x-ray verification images.

---

## 45.3 RADIOSURGERY EQUIPMENT

### 45.3.1 GAMMA UNITS

Up until the mid-1980s, radiosurgery was almost exclusively delivered by the Gamma Knife treatment unit, pioneered by Lars Leksell ([Figure 45.1](#)) (Larsson et al. 1974; Leksell 1983; Walton et al. 1987; Lunsford et al. 1989).

**FIGURE 45.1**

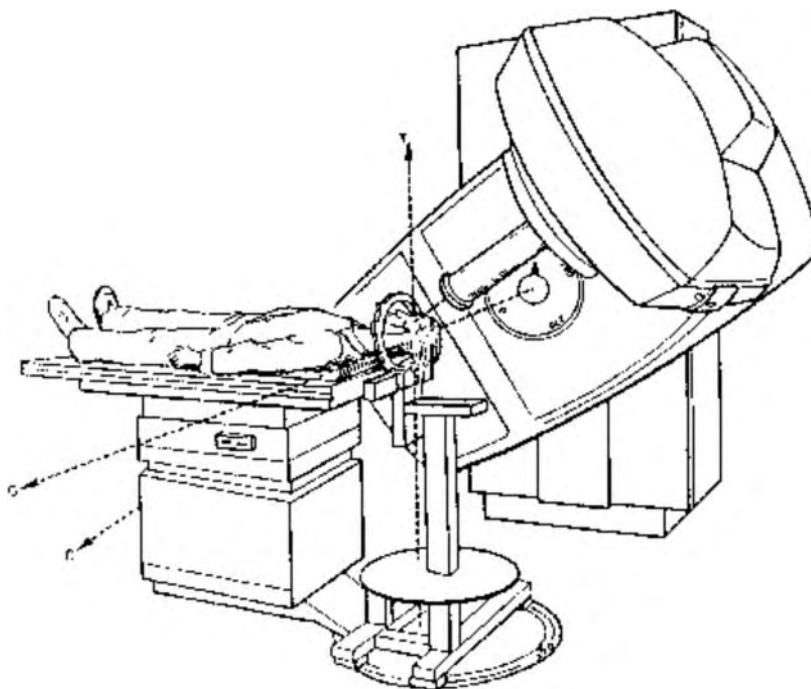

The  $^{60}\text{Co}$  Gamma Knife radiosurgery unit. A tungsten secondary collimating shell is shown positioned over the patient's head prior to treatment, enabled by docking the couch inside the safe, which contains the primary collimator and  $^{60}\text{Co}$   $\gamma$ -ray sources.

This machine utilizes a *helmet* containing 201 separate  $^{60}\text{Co}$  sources arranged in a 160° sectored array. These are focused onto a target with the aid of tungsten secondary collimating shells that define treatment spheres of 4 mm, 8 mm, 14 mm, or 18 mm in diameter. This unit represents the gold standard of geometrical precision, giving a dose delivery to within  $\pm 0.4$  mm (2 SD). It is robust and simple to operate, with mechanical movement restricted to a couch top that longitudinally docks into the treatment head (Figure 45.1). Translational adjustments to the patient's head frame align the planned isocentre with the focus of the cobalt-beam pencils. Its disadvantages lie in its high capital cost, its lack of versatility as a radiotherapy tool and its 201 radioactive sources which need replacing after 5–10 years of use.

## 45.4 LINEAR ACCELERATOR-BASED RADIOSURGERY

From the mid-1980s, linacs have been increasingly used to deliver radiosurgery (Betti and Derechinsky 1983, Colombo et al. 1985; Hartmann et al. 1985; Lutz et al. 1988; Podgorsak et al. 1988; Thomson et al. 1990) for lesions down to approximately 10 mm in diameter. Multiple noncoplanar arcs of circularly collimated x-ray beams directed to the linac isocentre can achieve a similarly focused treatment to that delivered by the sectored array of cobalt sources in the Gamma Knife.

The early linac-based systems used neuro-surgical floor stands (Figure 45.2), which provided accurately engineered, precise vernier movement of the patient's head support. This enabled precision movement of the patient so the centre of the patient's lesion could be accurately positioned at the treatment isocentre. During the last 10–15 years, linac manufacturers have introduced specialised, mechanically improved treatment gantries, patient support couches and beam-shaping devices capable of more precise treatment delivery. These specialised units (Friedman and Bova 1989; Yin et al. 2002) have almost comparable accuracy to the Gamma Knife, but offer greater flexibility for a broader range of treatment options. However, such linac-based facilities require carefully designed quality assurance programs to maintain the

**FIGURE 45.2**

Early system for linac-based radiosurgery, after Lutz et al. 1988. (From Lutz, W., Winston, K. R., and Maleki, N., A system for stereotactic radiosurgery with a linear accelerator, *Int. J. Radiat. Biol. Phys.*, 14, 373–381, 1988.

high precision needed. This, along with the linac's greater operational complexity, servicing needs and potential for breakdowns, all demand greater staffing resources.

The standard stereotactic beam delivery accessories for a linear accelerator are a set of quickly interchangeable, circular holed, tertiary collimators, which define circular cross-section beam pencils ranging typically from 10 mm to 50 mm in diameter in 2.5 mm steps. These can be augmented by the secondary collimators for more flexible conformation if the corresponding treatment planning software is available (Hacker et al. 1997). For fixed field, conformal SRT, the minimum requirement is a specialised blocking system (Figure 45.3), as this can be made more precise and less prone to collision problems compared to conventional blocking trays. Micro-multileaf collimators (Shiu et al. 1997; Cosgrove et al. 1999), although expensive, are very efficient and technically sophisticated for stereotactically guided treatments.

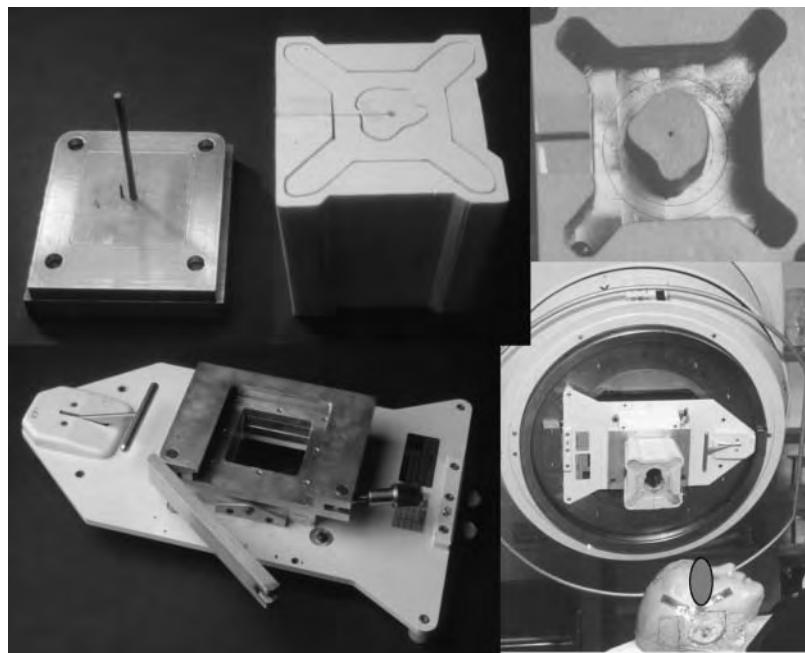

Other hardware requirements include such items as stereotactic frame mounting brackets, fiducial systems, setup boxes, a locking system for the couch top, stable precise room lasers, and a set of customised quality assurance tools for alignment and dosimetry checks (Warrington et al. 1994).

---

## 45.5 STEREOTACTIC FRAMES

### 45.5.1 NEUROSURGICAL FRAMES

Accurate fixing of the stereotactic frame to the patient's head has traditionally been achieved by means of three or four steel pins set into holes drilled into the patient's skull (e.g. the Leksell, Brainlab, or Brown-Roberts-Wells (BRW) surgical frames). Although frame fitting with this procedure requires at least a local anaesthetic, such frames remain the most reliable and stable platform for SRS. Their main disadvantage is that the whole planning

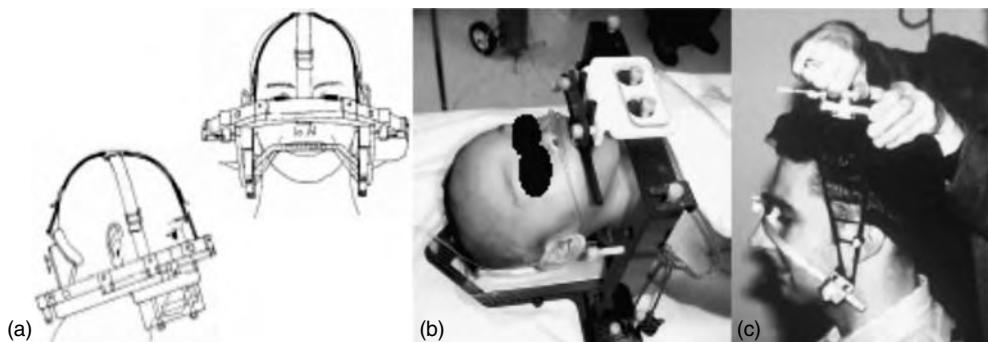

**FIGURE 45.3**

Stereotactic, conformal blocking system: clockwise from upper left; pouring jig and Styrofoam hot-wired pattern, jig before pouring alloy, block system mounted on linac head; coded block mounting device.

and treatment procedure usually has to be carried out in a single day. However, such frames have been removed and refitted for limited fractionation regimes (Schwade et al. 1990).

#### 45.5.2 RELOCATABLE STEREOTACTIC FRAMES

For fractionated SRT treatments of up to 35 daily fractions, there is a need for simple but accurately relocatable fixation of the patient. This has led to developments of traditional thermoplastic masks (Lyman et al. 1989), or specialised frames, which locate onto the patient's upper dentition, as with the Radionics GTC (Gill–Thomas–Cosman) frame and variants (Gill et al. 1991; Kooy et al. 1994a; Adams et al. 1999a), shown in Figure 45.4a and the Medical Intelligence Head Arc frame (Sweeney et al. 1998) in Figure 45.4b. Others (Hariz et al. 1990;

**FIGURE 45.4**

(a) Prototype Gill-Thomas (GTC) frame. (b) Head Arc vacuum bite-block system. (c) Fitting the Laitinen Stereodaptor.

Ashamalla et al. 2003) use the ear canals and bridge of the nose, as with the Laitinen Stereodaptor (Figure 45.4c).

The repositioning accuracy of a relocatable frame used for SRT should be less than 1 mm. Such precision is as much dependent on the skill and training of the staff routinely involved and the cooperation of the patient, as on the frame design itself. Relocation checks are best carried out by overlaying the bony anatomy from repeat sets of orthogonal x-ray, or low dose electronic portal images, and measuring the displacements of reference markers attached to the frame or field edges. Alternatively, nonradiographic checks, such as physical measurements to the surface of the head from a reference *depth helmet*, mounted onto the stereotactic frame, may be made. More recently, optical methods have been used, based on cameras in the treatment room, which track the patient's head position (Schulte et al. 2000; Liu et al. 2003).

---

## 45.6 STEREOTACTIC FIDUCIAL SYSTEMS

Central to the stereotactic method is the requirement for reference markers, or *fiducials*, to be imaged when attached to the stereotactic immobilisation system fixed to the patient (Siddon and Barth 1987). These markers are vital in providing accurate geometrical information on the coordinates of the planned isocentre(s). They are commonly in the form of various rod configurations attached to support rings, etchings or steel balls on the sides of plastic fiducial boxes or wires stretched between rigid spacers. The fundamental and ideal requirements of a stereotactic fiducial system are:

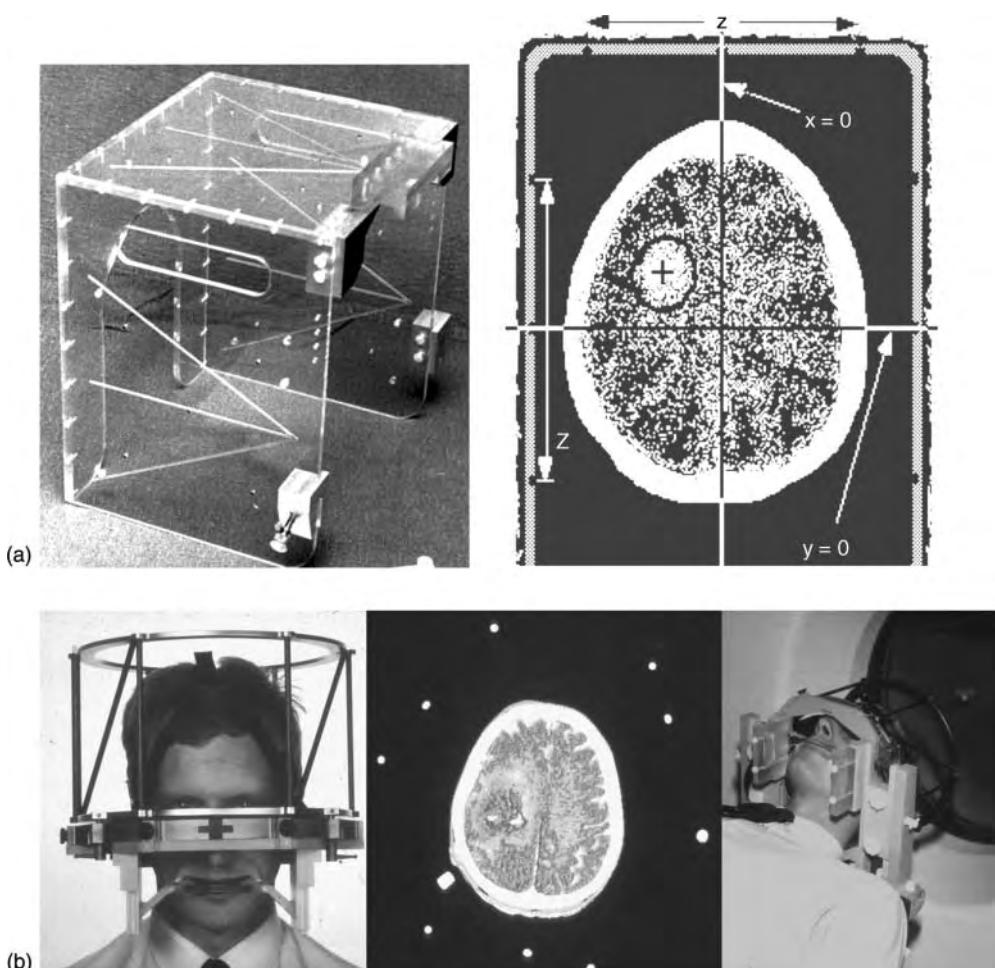

1. No significant scan artefacts generated or obscuring the anatomical images
2. Precise docking onto the patient's immobilisation system
3. An unambiguous (e.g. not window-dependent) and preferably simple marker arrangement, which enables manual checking of computed target coordinates, but has a sensitive, changing geometry from slice to slice
4. Capability of correcting for the effect of imaging slices being nonperpendicular to the cantilever scanner couch, with its tendency to sag from the weight of the patient as it passes through the scan plane

An example of a simple CT fiducial system is a bisected vee of apex angle 53.1°, etched onto the faces of a polymethylmethacrylate (PMMA, known as Perspex or Lucite) box (Figure 45.5a) that attaches to the stereotactic frame, which in turn is fixed to the patient's head. The stereotactic coordinates are obtained from simple linear measurements of the etching separations on the selected CT slice as shown. The BRW (later Cosman-Roberts-Wells, CRW) nine-rod system is also shown in Figure 45.5b with an associated CT slice and CT scan position.

If the scans are slightly oblique to the base frame due to a sagging, twisting CT couch, the unique coordinates of a selected target point can be computed from applying the known three-dimensional geometry of the system to the measurements in the vertical plane.

Although calculation software that generates the unique coordinates from the equations of fiducial markers is readily available, it is often preferable to adjust the frame tilt such that the patient CT scans are orthogonal to the couch. This facilitates ease of checking and retaining an intuitive feel for the precise isocentre setup geometry, which is ultimately transferred to the linac treatment couch.

For x-ray angiography, which is an accurate modality for visualising AVMs for radiosurgery, small 1 mm steel balls are incorporated into the four orthogonal faces of fiducial plates. This fiducial system can be particularly useful for radiographic checks on the relocation accuracy of stereotactic frames.

**FIGURE 45.5**

(a) Etched bisected vee fiducial box mountable on a stereotactic frame for CT scanning with coordinate measurements from a CT slice shown on the right. (b) BRW fiducial rod system and CT scan appearance.

For MRI or PET imaging, sealed tubes containing the appropriate liquid in similar configurations to x-ray CT localisers can be used to assist with the image registration process.

Knowledge of the precise magnification, resolution and distortion of the images used in planning stereotactic treatments is essential (Karger et al. 2003). Digital subtraction angiography (DSA) requires careful commissioning to establish the magnitude and geometry of any distortions that may arise.

## 45.7 STEREOTACTIC TREATMENT PLANNING

Commercially available stereotactic planning systems are often associated with combined neurosurgery, brachytherapy and radiosurgery packages. However, conventional radiotherapy planning systems increasingly offer an optional stereotactic module.

The ability of a planning computer to overlay or register images from various modalities such as x-ray CT, MRI, and PET (Plowman et al. 1997) is highly desirable. With MRI

becoming an essential imaging tool for the brain, distortion-corrected image registration software is very important in high-precision stereotactic planning. X-ray CT scans represent the distortion-free anatomical baseline against which other modality images are co-registered and potentially *fused* (Kooy et al. 1994b; Alexander et al. 1995).

Real-time manipulation of the virtual patient, showing the juxtaposition of the target volume and sensitive structures, has become essential for SRT planning. Beam optimisation software is ever more important as the complexity of sensitive structure avoidance makes intuitive planning more difficult. Plan analysis tools for the rapid calculation of dose-volume data and assessment of optimised cost functions are therefore also required.

Stereotactic treatment planning not only requires the facility to plan multiple noncoplanar arcs focused to a single or several isocentres, but also to plan using multiple fixed noncoplanar conformal beams defined by either conformal blocking or multileaf collimators (MLCs). Table 45.1 shows some of the main planning options available for different target geometries.

Tumours with concavities wrapped around sensitive structures, such as the brain stem and optic apparatus, lend themselves to treatments using IMRT (see Chapter 43 and Chapter 44).

**TABLE 45.1**

Treatment Planning Options for Brain Lesions Using Linac-Based Stereotactic Radiotherapy

Lesion Shape	Treatment Planning Options	Planning Time (h)	Treatment Time (min)
Small sphere (up to 3 cm diameter)	4–6 multiple noncoplanar arcs, single isocentre. Single tertiary collimator	1	30
Large sphere (3–5 cm diameter)	2–4 multiple noncoplanar arcs, single isocentre. Single tertiary collimator	1	15–30
Ellipsoidal	6 multiple noncoplanar arcs, single isocentre, to include some shorter arc lengths with 1 or 2 collimator changes	3	30–45
Ellipsoidal	Double/triple isocentre, 2–4 arcs per isocentre, 0–2 collimator changes. Up to 50% higher hot spot doses relative to prescription isodose surface	4	45–75
Ellipsoidal	Single isocentre, one tertiary collimator plus secondary jaw adjustments, 3–4 arcs	4	30
Ellipsoidal	4–6 fixed, noncoplanar fields using either blocks or multileaf collimation	4	15–30
Irregularly shaped with semi-enclosed sensitive structure	3–5 isocentres, 2–3 arcs per isocentre, evenly separated arc planes. Up to 50% increase in hot-spot doses relative to prescription isodose surface. Up to 3 different circular collimators	6	30–60
Irregularly shaped with semi-enclosed sensitive structure	4–6 fixed, noncoplanar fields using either conformal blocks or micro-leaf collimation. Limited scope for structure avoidance	6	15–30
Irregularly shaped with semi-enclosed sensitive structure	Conformal, dynamic arcing with micro-leaf collimator, 2–4 noncoplanar arcs (Grebe et al. 2001)	6	15–45
Irregularly shaped with semi-enclosed sensitive structure	3–9 fixed field, coplanar IMRT using step and shoot or dynamic mMLC <sup>a</sup>	8–16	15–45
Irregularly shaped with semi-enclosed sensitive structure	4–9 fixed field, noncoplanar IMRT using step and shoot or dynamic mMLC <sup>a</sup>	8–16	15–60

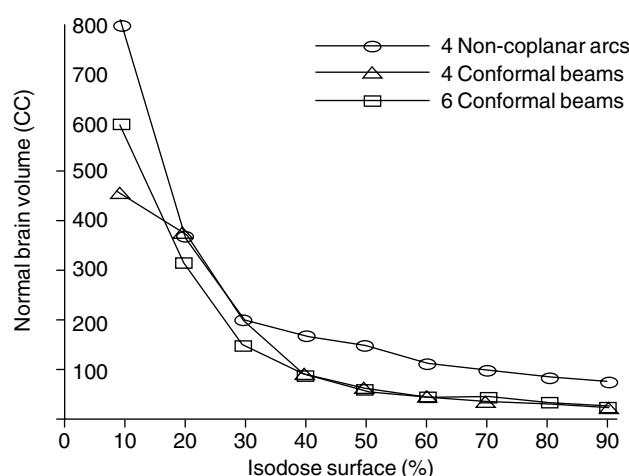

<sup>a</sup> Conformal compensators would provide a less sophisticated alternative.

These treatments, identified in the last two rows of [Table 45.1](#), are designed by an inverse planning or optimisation process ([Section 43.2](#) and [Section 44.3.4](#)), using the detailed specification of dose-volume constraints in and around the lesion to be treated. The inverse planning algorithms can either design conventional compensators or generate, via interpreters, complex MLC leaf sequences for each beam on the linear accelerator. These IMRT options are included in the table as the stereotactic process provides a good basis for such physically optimised methods (Baumert et al. 2003; Nakamura et al. 2003).

The planning physicist must be aware of the limitations of the given treatment machine geometry regarding potential collimator–couch–patient collisions. Customised software, which alerts the planner to such forbidden collision zones on a given linac, is invaluable (Nioutsikou et al. 2003).

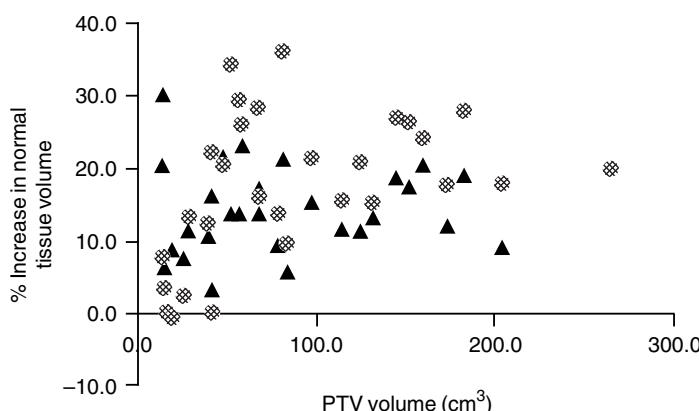

Overlapping of beam entrance and exits should be avoided, and in general, arc planes (as defined by the couch angle) should have maximum separation according to the expression  $180^\circ/N$ , where  $N$  is the number of arcs to be used. Avoidance of sensitive and sometimes previously treated structures means that optimisation software and biological TCP/NTCP modelling (see [Chapter 36](#)) are increasingly important developments.

The final dose distributions should be displayable in any required plane, preferably including adjacent anatomy. Plan comparisons require dose-volume histogram (DVH) analyses (see [Chapter 35](#)) to assist the clinical team in deciding the optimum treatment plan. Analysis of DVHs for various collimator arc regimes suggest that 3–5 arcs produce sufficient normal tissue sparing for RS and SRT (Graham et al. 1991). However, when planning treatments for benign conditions, it is relevant to consider increasing the number of arcs to reduce the exit dose from any given arc, or interrupting, for example, a sagittally orientated arc to avoid possibly sensitive exit doses (Shepherd et al. 1997). For larger, irregular target volumes ( $35\text{ cm}^3$  to  $70\text{ cm}^3$ ), 4–6 fixed noncoplanar fields are likely to be a more appropriate technique. In this case, either conformal blocking or multileaf collimation of each portal, based on the beam's eye views (BEVs) of the target, is more likely to be used. Figure 45.6 shows a comparison of DVHs for three different beam configurations used in a stereotactically planned, elliptically shaped brain lesion (Laing et al. 1993). The sparing effect of conformal beam

**FIGURE 45.6**

Cumulative dose volume histograms for normal brain with a  $30\text{ cm}^3$  elliptical target volume. (After Laing, R. W. et al., *Radiother. Oncol.*, 28, 241–246, 1993.)

**FIGURE 45.7**

Increase in normal tissue volume irradiated to greater than 50% (triangles) and greater than 80% of dose prescription using conventional MLC (10 mm leaf width) compared to conformal blocks. (From Adams, E. J., Cosgrove, V. P., Shepherd, S. F. et al., *Radiother. Oncol.*, 51, 205–209, 1999. With permission.)

shaping for four and six fixed fields compared to a spherical treatment volume produced by single isocentre with multiple arcs and a circular collimator is clearly shown.

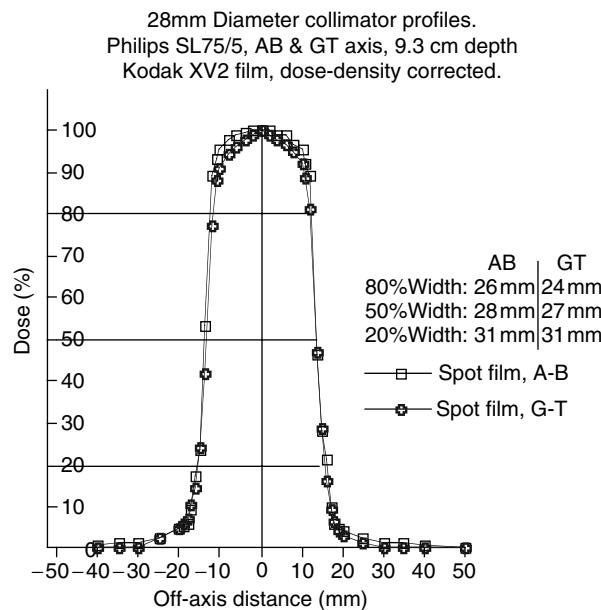

This graph shows only a simple comparison. Elliptical conformation can be achieved with multiple arcing techniques, having an adroit blend of different collimators and arc lengths. Alternatively, use of the secondary collimators to shield regions of circular fields can achieve satisfactory conformation for simpler, nonspherical target geometries. There are many comparisons of different stereotactic treatment regimes in the literature (e.g. Podgorsak et al. 1989; Serago et al. 1992a; Hall and Brenner 1993; Nedzi et al. 1993; Luxton et al. 1993; Philips et al. 1994; Cardinale et al. 1998; Verhey et al. 1998; Benedict et al. 2001). These are based on cumulative DVH comparisons.

Although the increasing availability of multileaf collimators enables efficient production of conformal beams, conventional 10 mm leaf systems are often too coarse for SRT. Figure 45.7 shows the results of DVH comparisons for fixed conformal fields shaped by MLC or lead alloy blocks for small to medium sized malignant brain lesions, planned stereotactically (Adams et al. 1999b). The added efficiency of the MLC device always has to be balanced against the gold standard of target conformation, which is obtained using customised lead alloy blocks.

Although micro-multileaf collimators bridge this gap in technology, they are expensive and generally limited to field sizes below 100 mm, and so have to be removed for conventional radiotherapy treatments on a non-dedicated accelerator. However, recent developments in technology, including the latest integrated MLCs in the linac head, which have leaf sizes of 5 mm or less at the isocentre (Varian 120 leaf, Elekta Beam Modulator), show a convergence of conformality (Monk et al. 2003).

## 45.8 BEAM DATA MEASUREMENT

The measurement of beam data for small, tertiary collimated, megavoltage photon beams typically involves up to five profiles (OARs), a central axis depth dose or TMR curve, output factors, often both in air and water, and build-up curves (see [Section 23.2.1](#)). A potential lack of lateral electronic equilibrium with these pencil beams requires small detectors having high spatial resolution (Rice et al. 1987; Serago et al. 1992b; McKerracher and Thwaites 1999; Yu et al. 2004). Profiles are therefore commonly measured with x-ray verification film, such as Kodak XV2 or EDR (Chetty and Charland 2002; Zhu et al. 2003), corrected for any dose/density nonlinearity ([Figure 45.8](#)).

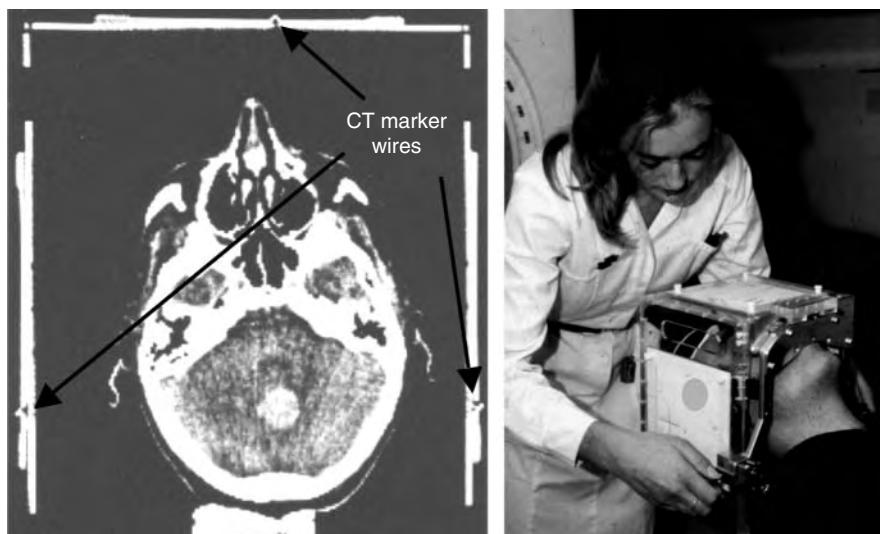

**FIGURE 45.8**

Profiles for a 28 mm diameter collimator at 93 mm depth from Kodak XV2 spot film, scanned across the AB (transverse) and GT (longitudinal) directions.

Small-volume ( $<0.2 \text{ cm}^3$ ) ionisation chambers are generally suitable for the depth-dose or TMR data down to 20 mm diameter fields. It is important to be aware of the diverging beam for depth-dose measurements of pencil beams, where the detector is exposed to different regions of the beam profile with depth. This could significantly distort the depth-dose curves for small fields. A computerised plotting tank system used in conjunction with a p-type electron diode or diamond detector (McKerracher and Thwaites 1999) is also an ideal means of acquiring these data down to about 15 mm diameter collimators. The setup for such measurements should ideally reflect the mean isocentre depth and scatter geometry of the patient. However, as with all beam data, measurements are often a compromise dictated by the needs of the treatment planning system and the size of the tank available. The smallest beams, below 20 mm diameter, for instance, should be measured with film, TLDs and a small diode, where the detector resolution is in the region of 2 mm or less. Overlap with the larger field sizes is recommended for such work so that discontinuities in data, such as output factors, can be investigated and reconciled. Note that tertiary collimators can also give rise to varying build-up depths to the peak dose.

## 45.9 TREATMENT SETUP

Prior to RS or a course of SRT treatment, it is important to be able to confirm the planned setup using the CT scanner, simulator or the treatment machine itself, depending on the type of lesion to be treated and the available facilities. Simulation of treatment fields, although often providing valuable confirmation of the planned isocentre position, can create unwanted confusion. This is due to small systematic and random errors from mechanical, optical and radiological differences between the simulator and treatment unit. Modern multislice CT scanners, increasingly used in radiotherapy for virtual simulation (Aird and Conway 2002), can now produce the high resolution data necessary for quality digitally-reconstructed radio-graphs (DRRs) for on-treatment reference images.

**FIGURE 45.9**

Check CT slice shown with wired setup plates on the fiducial box. The whole jig is shown being placed onto a patient in the stereotactic frame, on the right.

Translating the planned isocentre coordinates safely onto a simple, patient-specific setup system for the radiographers' daily use is a very important feature of the stereotactic process. The setup arrangements are generally of two types:

- Those involving manually setting three  $x$ ,  $y$ , and  $z$  vernier scales to bring the patient's planned isocentre into coincidence with the linac isocentre. This type of system is commonly used in single-fraction radiosurgery and does not lend itself to repeated daily setups with its need for careful checking of finely adjusted vernier settings.
- Those using the setup of boxes with patient-specific plates or computer printouts with the isocentre crosses and beam projections clearly marked for room laser setup. These are more practical for daily fractionation regimes, but ideally require coding to avoid mistakes when a number of SRT patients are being treated in any given session.

If there is ready access to a CT scanner, a check CT slice with the laser setup crosses marked with radio-opaque markers or wires (Figure 45.9) is useful, as this can be directly compared to the corresponding planning slice and an additional frame relocation check. Figure 45.9 also shows a setup box with its attached, patient specific plates being placed on a stereotactic frame in its couch bracket.

Automatic or assisted setups on the linac couch are invaluable in limiting potential errors in setting up the patient. The uniquely positioned couch bracket, holding the stereotactic frame, enables couch position readouts to be included in the assisted setup parameters prior to making fine adjustments against the room lasers for the final setup.

## 45.10 PRETREATMENT QUALITY ASSURANCE

The nature of quality assurance checks (Tsai et al. 1991; Drzymala 1991; Warrington et al. 1994; AAPM 1995) depends on the precise technique used. Table 45.2 provides a summary of quality control procedures as an example of those undertaken in stereotactic radiotherapy, with the suggested tolerances in the right hand column. Figure 45.10 shows some of the equipment referred to.

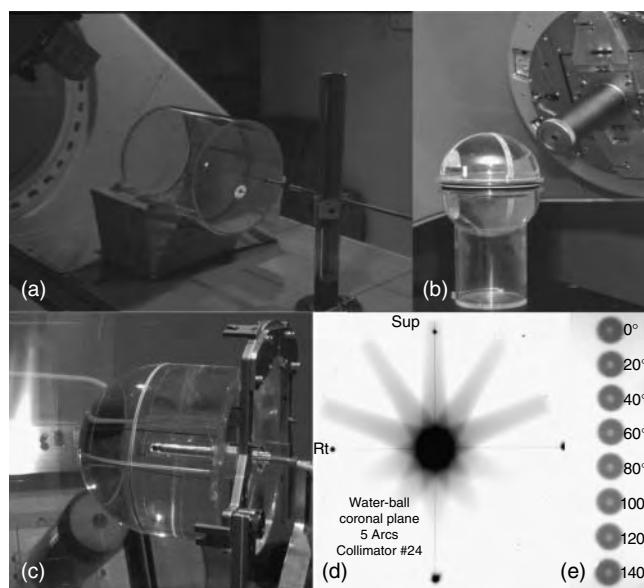

**TABLE 45.2**

Frequency of Stereotactic Quality Assurance Tests

Test	Tolerance
<b>Daily checks immediately before the stereotactic treatment session</b>	
1. Movement of the light field centre cross for 360° collimator rotation	<0.5 mm
2. Comparison of the left lateral, right lateral and ceiling lasers with the corresponding light field centres at the cardinal gantry angles	<0.5 mm
3. Light field symmetry of the selected circular collimator about the field centre cross	<0.5 mm
4. (On-patient) fixation of the frame, using patient response, physical measurement (e.g. depth helmet or ruler measurements) and examination, followed by EPID checks after setup and comparison with DRRs	1 mm
<b>Monthly</b>	
1. Shadow films or EPID images of a radio-opaque object set at the room laser defined isocentre (Lutz et al. 1988) are taken at regular gantry intervals using a tertiary collimator attached to the treatment head (see Figure 38.5, Figure 45.10b, d). The films are measured on a scanning densitometer, and the displacements of the object centre from the irradiated field centres are determined (Note: For radiosurgery of benign lesions, this check is often carried out prior to each single, large treatment fraction and may carry a 0.5-mm tolerance.)	<1 mm
2. A single transverse 240° arc is executed over a water phantom, having a 0.2 cm <sup>3</sup> Farmer chamber at the isocentre. The chamber dose is compared to a computer plan of the same <i>arcing treatment</i> for representative monitor units and collimation used on actual treatments (Perks et al. 1999; McKerracher and Thwaites 2002) On an annual or six-monthly basis, this check can be broken down into separate arc segments and total doses to verify the consistency of arc calibration over the whole 360° range of gantry angles and monitor unit settings	±2%
<b>Annually or at commissioning</b>	
1. A useful geometric and relative dosimetric check is to CT scan, plan and irradiate a <i>water-ball phantom</i> at the isocentre with a film cassette bisecting the two hemispheres (Figure 45.10b). The film is pierced before irradiation in the cassette to mark the laser setup and isocentre points. After irradiation, the film can be compared with the treatment plan, whether using fixed conformal fields or multiple arcs (Figure 45.10e)	
2. Similar to the above, with a humanoid head phantom mounted on the stereotactic frame, CT planning and treatment of a simulated lesion in the phantom is given. TLD pellets stacked along the three cardinal axes through the isocentre are measured and compared with the corresponding multiple-arc plan  This is a very time-consuming procedure that often carries uncertainties in the positioning of the dosimeters in the sliced humanoid phantom head. Alternatively, measurements from verification film loaded into a similarly planned and treated phantom can be undertaken to give accurate geometrical information. Relative isodose information for the higher dose regions can be obtained from such film measurements provided the doses do not cause optical density saturation The more peripheral isodose information can be prone to large errors due to the enhanced response of film to scattered radiation. The new technique of gel dosimetry shows some promise for 3D verification of the isodose envelopes arising from conformal SRT (Cosgrove et al. 2000)	<3% dose at isocentre 1 mm profile displacement

Other checks on an annual basis should include relative output and profile checks, monitoring of the wear and tear on all stereotactic accessories including couch brackets, frames, setup boxes, fiducial jigs, collimators and mountings, couches and quality assurance tools.

Additional checks for the treatment planning computer and peripherals, portal imaging systems and scanners, as they relate to the stereotactic process, also need to be carefully incorporated into the established programmes. As with general radiotherapy QA protocols

**FIGURE 45.10**

Quality assurance tools: (a) Gantry radiation isocentre apparatus; (b) water-ball phantom; (c) arc calibration phantom; (d) developed film from water-ball phantom shown in (b); (e) developed strip film produced using the radiation isocentre apparatus shown in (a).

(see Part H), stereotactic quality assurance should give a practical but focused and secure means of quality control without overburdening the available physics and radiographer staff.

## 45.11 STEREOTACTIC CONFORMAL TREATMENTS AND QA

Low melting-point lead-alloy blocks, (Figure 45.3) based on beam's-eye-views (BEVs) and manufactured with the aid of a computerised block cutter linked to the planning computer, require careful quality checks prior to the first treatment fraction. As with the alternative micro-multileaf collimator beam shaping, comparisons of the projected light fields onto hard copies of the corresponding BEVs are a minimum required check. It is advantageous to have projections of conformal fields marked on the setup box for a quick comparison of the light fields. This reassuring facility is available in some stereotactic planning systems such that a composite printout of all conformal field projections can be positioned on the setup surfaces or plates of the treatment box.

Unambiguous labelling and configuring of these noncoplanar plans, particularly regarding collimator twists, demands very careful checking. Automatic transfer to record and verify systems create an even greater imperative for meticulous quality control prior to the first fraction of treatment.

Electronic portal imaging devices (EPIDs) have become essential tools for completing the quality assurance chain in the stereotactic process. Good quality DRRs from the CT planning data set provide the reference images for the target-checking process. Note that there is limited imager access for fields directed in cranio-caudal directions, and confusion often arises from target-checking small, obliquely angled fields. It is often preferable to acquire orthogonal, AP and lateral images on the first days of treatment to clearly establish the magnitude and direction of any systematic errors in the isocentre position relative to the patient's anatomy. Once this has been done, imaging can take place on a less frequent, weekly basis. The tertiary collimator will

often render EPID checks impractical, particularly for radiosurgery of small lesions. EPID imaging prior to the mounting of the tertiary collimator should be considered to obtain sufficient anatomical (bony) detail for overlay on reference DRRs. When mMLCs are being used, they can have their leaves retracted to enable such images to be taken.

---

## 45.12 ACCURACY AND ISODOSE PRESCRIPTION

The overall accuracy achievable with a linac-based radiosurgery system should be between 1 mm and 2 mm if sufficient emphasis is placed on the importance of quality assurance (Hartmann et al. 1994). However, localisation of the target volume often remains the greatest uncertainty, and it is important to view accuracy of SRT and RS in its full clinical perspective. Assessing the accuracy of a given system involves consideration of the cumulative effect of small (typically 0.5 mm to 1 mm) errors, which generally require a safety margin around the lesion of between 2 mm and 3 mm. Often with such treatments, a variable PTV margin is required with some compromise needed close to sensitive organs. This PTV is then covered by the *prescribed* isodose surface, commonly between 80 and 95% of the central dose. If multiple isocentres are used with arcing circular beams, dose uniformity is sacrificed to achieve more conformal target coverage. In this case, the prescribed isodose may be 50% of the maximum *hot spots* in the overlapping regions of adjacent spherical dose distributions, which correspond to multiple isocentre setups. Dose-volume statistics and radiobiological considerations may need to be applied to the PTV and organs-at-risk to evaluate the best plan. Ideally, single-isocentre treatments should be normalised and prescribed to 100% at the isocentre, ensuring that the required minimum encompasses the PTV.

---

## 45.13 STEREOTACTIC RADIOTHERAPY TO EXTRA-CRANIAL SITES

The stereotactic principle can be readily applied to other regions of the body, notably for head and neck treatments. The head and neck region can be accurately immobilised using either the frames described for upper head treatments, specialised head-and-neck frames or accurately made thermoplastic shells. Often, special emphasis is needed on the reproducible immobilisation of the shoulders and neck for the inclusion of nodal areas down to T1, for example. As with the treatment of the brain, better noncoplanar beam access is obtained if the head and neck system overhangs the end of the treatment couch and the headrest system is radiolucent.

An important development is the *stereotactic body frame* (also known as *extra-cranial stereotaxy*) (Lax et al. 1994; Blomgren et al. 1998). This system has the patient immobilised in an *air equivalent* vacuum bag containing expanded polystyrene granules, which in turn is contained within a rigid outer support box into which fiducial marker rods are embedded. The patient is CT scanned and treated in this box.

The concern with stereotactic radiotherapy applied to such sites as the abdomen and pelvis is the mobility of soft tissue. This causes a departure from the fundamental assumption in the stereotactic method of a fixed relationship between the support *frame* and the PTV. This potential for error requires, ideally, pretreatment soft-tissue monitoring with a CT scanner or ultrasound device, preferably in the treatment room. Breathing motion can also be a serious problem, requiring breathing control and gating of treatments (Hara et al. 2002; Jiang 2006). Fowler et al. (2004) have reviewed the successful use of large fractions (i.e. hypofractionation) when treating lung tumours in an extra-cranial stereotactic frame and a collection of very useful papers on this subject can be found in SBRT (2006). Provided that such facilities are available, the stereotactic body frame can provide a practical set of reference points against which inter- and

**TABLE 45.3**

Summary of Stereotactic Radiotherapy Procedures as Carried Out at the Royal Marsden Hospital

Procedure	Additional Details	Staff Involved	Time (h)
Seeing patient in clinic	Review of diagnosis, notes, clinical examination, discussion, deciding on treatment method, booking scans, planning and treatment slots and consenting patient	Clinicians and team	1–2
Fitting stereotactic fixation device to the patient	E.g. GTC frame: making dental mould, fitting frame including making headrest, checking reproducibility with physical, optical or radiographic measurements	Dentist or mould-room technician	2
CT scanning	Adjusting couch bracket tilt, checking fixation	Radiographer	0.45
MR scanning	Check similar patient head position in head coil (no frame)	Radiographer	0.45
Transfer of image data	Check slice set sequences, patient details, etc.	Physicist or radiographer	0.5
Localising and outlining MR/CT scans	Localising target volume and sensitive structures, fusing or registering images, growing PTV, outline adjustments	Clinician and physicist	1–2
Planning treatment	Viewing target and structures, deciding on technique and collimation, setting isocentre, applying appropriate beams, calculating isodoses, adjusting for optimal geometry/uniformity, obtaining printouts and DVH's	Physicist	2–6
Checking plan feasibility	Eliminate possible collisions by setting up on linac, on a scale model or running computer simulation	Physicist and radiographer	0.5
Obtaining plan approval and dose prescription	Presenting and discussing single or alternative plans to clinician with DVH analysis, if necessary, and write dose and fractionation prescription	Physicist and clinician	0.5–1
Labelling of plan/ setup box/MLC transfer/DRRs/ checking	Preparation of final plan with isocentre dose and coordinate check, DRR production and transfer of all files for auto setup, mMLC shapes and reference images	Physicist and radiographer	1–2
Conformal blocks	Transfer of BEV's to computerised block cutter, pouring of blocks and labelling/checking on unit. Output factor checks, if necessary	Physicist, mould room technician	4–6
MLC prescriptions	Transfer of plan data, checking prescription, monitor unit calculation and optical check of MLC shapes	Radiographers	1–2
CT slice check	Setup patient and take check slice on CT scanner. Check final position of isocentre against planning CT slice	Radiographers, physicist	0.5
Patient pretreatment	Show patient treatment machine and explain details of treatment	Radiographer	0.25
Quality assurance of treatment machine	Extra alignment checks on lasers and relation of mean radiation isocentre, arc calibrations, as appropriate	Physicist	0.5–1.5
Treatment of first fraction	Includes setting up patient, checking conformal fields optically, couch readouts and acquiring portal images	Radiographers and physicist	0.5–0.75
Treatment of each subsequent fraction	As above, according to protocols laid down for EPID verification imaging and isocentre adjustments for systematic error (e.g. after first 3 fractions)	Radiographers	0.25–0.5
Target checking	Checking relation of isocentre to patient's anatomy according to reference DRRs	Radiographer, physicist	0.5–1
Monitoring patient in weekly clinics	Review of patient progress (Also, discuss and review progress with rest of team in weekly audit with relevant clinician, etc.)	Clinicians (radiographer, physicist)	0.25–0.5

intra-fractional soft-tissue target movement can be measured and corrected for. However, in most centres limited to conventional portal imaging, the bony anatomy has to provide the practical baseline reference frame and an additional stereotactic reference system may not be helpful.

---

## 45.14 CONCLUSION

Stereotactic radiotherapy and radiosurgery techniques are increasingly being used where improved accuracy is required for treating well-defined targets inside the head. Their improved methods of patient fixation, multimodality imaging, fiducial marker-based treatment planning, treatment setup, verification and delivery represent a significant step forward in the evolution of high-precision radiotherapy. However, these techniques require the highest level of teamwork and continuity of training among different staff groups and are particularly demanding and time consuming for the radiotherapy physicist who has significant technical responsibilities at most stages of the stereotactic process. Good communication between physicists and radiotherapy engineers is particularly important after servicing or repair of the machines. Changes to various components on the linac or treatment couch, including major retuning of the beams, can profoundly affect the accuracy of stereotactic treatments.

*Table 45.3* summarises the stereotactic planning and treatment process. The times involved can vary considerably depending on the individual patient case and the associated evolving technology. The impact of any technical problems that may arise are not included.

## 46.1 INTRODUCTION

There is significant worldwide interest in the medical use of proton beams with energies ranging between 65 and 250 MeV because of their favourable depth-dose properties (see Figure 46.1), and considerable technological progress has been made (Bonnet 1993; ICRU 1998; Sisterson 2004). This chapter presents the physical and technological basis of proton therapy (Wilson 1946; Fowler 1981; Bonnet 1993; Chu et al. 1993; Webb 1993; Linz 1995), as well as covering the terminology, procedures and tools now available.

## 46.2 PHYSICAL BASIS: THE INTERACTIONS OF PROTONS WITH MATTER

The interaction of protons with matter is the basis for the therapeutic potential of these beams, in particular because of their characteristic of high ionisation density at the end of the

**FIGURE 46.1**

(a) Depth-dose curve for 15 MeV electrons; (b) depth-dose curve for 15 MV photons; (c) fluence vs. depth for 200 MeV protons; (d) stopping power vs. depth for a 200 MeV proton beam; (e) depth dose curve (Bragg peak) for a 200 MeV proton beam, being the result of the combination of (c) and (d). (Data measured at Orsay, France.)

range and their weak scattering. Protons are charged particles and are relatively ‘heavy’ compared to electrons (the mass of the proton,  $M$ , is 1836 times the mass,  $m$ , of the electron). Depending on their energy (represented by their velocity), they interact with the medium through various mechanisms: inelastic or elastic collisions with the nucleus, with the bound atomic electrons and, for certain processes, with the whole atom (see also Chapter 3). In clinical applications, protons are considered as having an *intermediate energy*, larger than  $10^{-4}Mc^2$  and lower than  $Mc^2$ . A detailed discussion can be found in Bichsel (1968).

### 46.2.1 INELASTIC INTERACTIONS WITH THE NUCLEUS

*Inelastic* interactions with the nucleus result in either a significant deflection of the incident proton associated with a nuclear reaction, or bremsstrahlung\*. In nuclear reactions like (p,n), (p,d) and others, the production of an unstable nucleus and some other processes lead to the disappearance of incident protons, with production of neutrons and recoil nuclei as well as activation of the medium with  $\gamma$ -ray production. These interactions create particular problems for radiation protection. The proportion of the nuclear interactions can be estimated by measuring the reduction in the *planar* fluence (see Section 6.3.5) of the protons at different depths in matter, before stopping at the end of the range (Figure 46.1), according to:

$$I = I_0 e^{-t/s} \quad (46.1)$$

where  $I_0$  is the incident planar fluence,  $I$  the planar fluence after a thickness  $t$  of absorber, and  $s$  is the proton mean free path length given by

$$s = \frac{A^{1/3}}{0.032} \text{ in g cm}^{-2} \quad (46.2)$$

where  $A$  is the mass number of the absorber. In practice, for the high-energy proton beams used in clinical applications, a practical figure for the reduction in the proton planar fluence due to nuclear interactions in water or tissue is about 1% per cm.

### 46.2.2 INELASTIC INTERACTIONS WITH ATOMIC ELECTRONS

*Inelastic* interactions with bound atomic electrons represent the principal process by which protons lose energy along their trajectory at the energies and in the materials of clinical interest, creating atomic excitation or ionisation, as well as a small deflection of the incident proton (see also Chapter 3). Although it is possible for electrons to lose a large fraction of their energy and be deflected through large angles in an inelastic interaction†, the energy transferred by protons at each interaction is always small, the maximum possible value being approximately  $4m/M$ , where  $m$  is the rest mass of the electron and  $M$  is the rest mass of the proton. The amount of energy transferred in each interaction has a probability distribution, which results in energy-and range straggling (see Section 3.4.2) after passing through a given thickness of absorber. This is the reason for the *finite* slope of the final part of the depth-fluence curve. The energy-straggling distribution is represented by a *Varilov* distribution, which resembles a Gaussian at high energies (corresponding to very small energy losses) and with a *tail associated with larger energy losses* at low energies (Bichsel 1968). In practice, energy-and particularly range straggling

\* Bremsstrahlung losses are negligible for the proton energies of interest in clinical applications. They only become important for energies larger than the rest mass energy of the particle, i.e. 938 MeV for protons, and even then this energy-loss mechanism very much less probable than bremsstrahlung for electrons (see Chapter 3).

† In practice, the probability for an electron to undergo such large energy losses or deflections is very small but they are allowed in principle (see Chapter 3).

for clinical proton beams can be assumed to have nearly Gaussian distributions. The fluctuation in the pathlength of clinical proton beams in water is of the order of 1–1.3% ( $1\sigma$ ) of the range (Bichsel 1968).

The average loss of energy by collision per unit distance along the path of a proton ( $dE/ds$ ) is represented by the collision stopping power:

$$\left(\frac{dE}{ds}\right)_{\text{col}} = 4\pi z_{\text{eff}}^2 e^4 \frac{N_A Z}{A} \frac{1}{mv^2} \left\{ \ln\left(\frac{2mv^2}{I(1-\beta^2)}\right) - \beta^2 - \sum \left(\frac{C_i}{Z}\right) \right\} \quad (46.3)$$

where the quantities not thus far defined are  $z_{\text{eff}}$  and  $e$ , the effective charge of the particle and the electronic charge, respectively.  $N_A Z/A$  represents the number of electrons per gram;  $m$  and  $v$  are the mass of the electron and velocity of the particle, respectively;  $\beta$  is the ratio of the velocity of the particle to the velocity of light;  $I$  is the mean excitation energy of the atom of the absorbing material; and  $\Sigma(C_i/Z)$  includes density and shell correction terms (see also [Chapter 3](#)).

When one considers only energy transfers below a given value,  $dE/ds$  is termed the *restricted stopping power* or *restricted linear energy transfer* (LET) (see [Chapter 3](#) and [Chapter 6](#)). These two concepts are rather similar for charged heavy particles in the range of energies used in therapy. Tabulated values are available (ICRU 1993a). Stopping power is proportional to the inverse of the square of the velocity  $v$  together with a more complex function of the velocity and the mean excitation energy of the medium  $I$ , including also shell corrections (the final term) when  $v$  is of the same order as the velocity of the electrons in their orbits (see [Chapter 3](#)).

When the proton is almost at the end of its range its capacity to ionise increases rapidly since its velocity is low ([Figure 43.1](#)), giving rise to the *Bragg peak*. The amount of ionisation produced by a beam of protons is a combination of the proton fluence and the energy-transfer function i.e. the stopping power (see [Section 6.6.2](#)). The depth-dose curve for a broad beam of heavy charged particles is known as the *Bragg curve*. For clinical beams, the ratio of the dose at the entrance surface to the dose at the peak varies between 0.2 and 0.4. The dose beyond the peak is practically zero. The *median* range is approximately equal to the depth of the distal 80% of the Bragg curve. The most probable energy at the depth of the peak is approximately 10% of the initial kinetic energy of the particle.

The absence of bremsstrahlung in clinical proton beams means that there is no *tail* in the depth-dose curve beyond the end of the proton range (apart from that due to range straggling). In the case of heavier particles, secondary products of nuclear interactions give rise to a significant tail beyond the peak, with potentially large radiobiological effects, which can, in some cases, limit their clinical application (see [Chapter 49](#)).

### 46.2.3 ELASTIC INTERACTIONS WITH THE NUCLEUS

*Elastic* interactions with the nucleus cause a deviation of the incident proton, with a negligible change in energy; this process is often called *Rutherford scattering*. The total cross section for this process decreases rapidly with the energy of the particle and the differential cross section decreases with increasing deflection angle (Bichsel 1968; see also [Section 3.5](#)). Thus only a very few of the protons undergo single, large deflections. Most collisions involve a *distant* interaction of the particle with a nucleus; the nuclear charge is partially screened by the atomic electrons, and the incident particle experiences only a small deflection. The multiplicity of small-angle deviations along the proton path is known as *multiple Coulomb scattering*. Molière (1947), Highland (1975) and others have evaluated this scattering. This subject has been reviewed by Gottschalk et al. (1993) who also considered scattering in thick absorbers\*.

\* Multiple scattering is employed in the *condensed-history* Monte-Carlo technique—see [Section 5.4](#).

The angular distribution of particles after traversing a thin foil can be represented to first order by a Gaussian, where the mean angle of multiple scattering is given by

$$\bar{\theta}_0 = 14.1 \frac{z}{pv} \left\{ \sqrt{\frac{L}{L_R}} \left( 1 + \frac{1}{9} \log \left( \frac{L}{L_R} \right) \right) \right\} \quad (46.4)$$

where  $z$ ,  $p$  and  $v$  are the charge number (charge/e, which for protons is unity), momentum and velocity of the incident proton, respectively;  $L$  is the thickness of the scatterer;  $L_R$  is the *radiation length* characteristic of the scattering material:

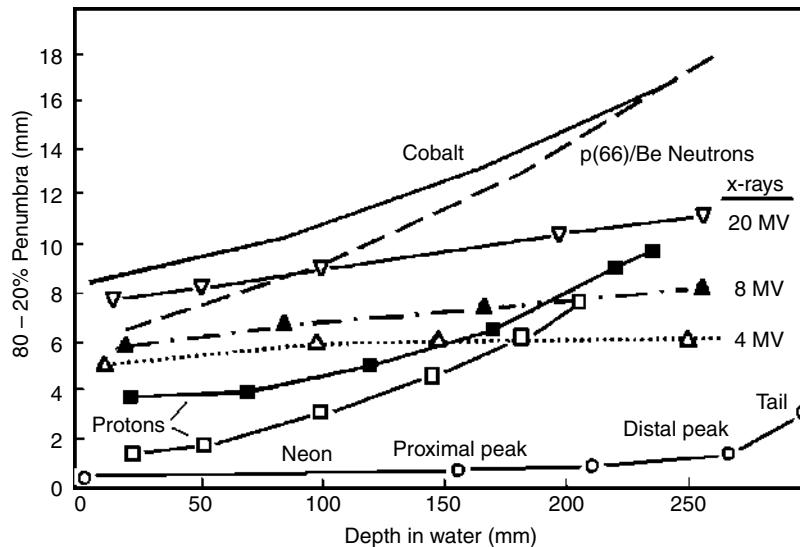

$$L_R \propto \frac{A}{NZ(Z+1)} \log(183Z^{-1/3})$$

where  $N$  is Avogadro's number,  $Z$  is the atomic number and  $A$  the atomic weight of the target material.

The *scattering power* is the mean square scattering angle per unit thickness of an absorber traversed by the charged particles. It is analogous to the concept of stopping power (see Section 3.5).

The dependence of the stopping power and the scattering power on  $Z$  is the basis of the choice of materials for beam shaping: in practice high- $Z$  materials are used to produce strong scattering minimising energy losses (e.g. lead scatterers to increase the beam width), and low- $Z$  materials degrade the energy of the beam while minimising the scattering (e.g. graphite, PMMA, or water degraders to adapt the beam range to a given target). Combinations of these materials are used to achieve specific results: different beam attenuation with constant scattering (as in modulator wheels, see Section 46.3.1.1), different scattering with constant energy loss (as in scattering systems with complex shapes).

The dependence of multiple scattering on an inverse power of the proton (kinetic) energy explains the broadening of a proton (pencil) beam near the end of the range (Figure 46.2).

**FIGURE 46.2**

Lateral penumbra as a function of depth in water for beams of  $^{60}\text{Co}$   $\gamma$ -rays, neutrons, 4, 8 and 20 MV x-rays, protons and neon ions. Proton and photon penumbrae are rather similar at large depth. Clinical light ion beams have intermediate penumbrae between those presented for proton and neon beams. (From Schreuder, N. Personal communication; Mazal 1996a; Chu, W. T., Ludewigt, B. A., and Renner, T. R., *Rev. Sci. Instrum.*, 64, 2055–2122, 1993.)

For *small* proton beams (e.g. diameter 10 mm) with energy of the order of 100 MeV, the multiple scattering at the end of the range leads to the disappearance of the Bragg peak ([Figure 46.9b](#)) as a consequence of a lack of *lateral scattering equilibrium*: i.e. protons scattered *away* from the beam axis are not *replaced* by protons that would be scattered *towards* the beam axis as in the case of a *broad* beam (Vatnitsky et al. 1999a). Complex heterogeneities in the human body combined with this multiple scattering are the cause of beam degradation in clinical applications, even for broad beams (Urie et al. 1991; see [Figure 46.9c](#)).

## 46.3 TECHNOLOGICAL BASIS OF PROTON THERAPY

The principal components of a proton therapy facility are the accelerator with its associated systems, the beam transport system into one or more rooms, the shielding, the beam-shaping devices, the patient-positioning system and the control system.

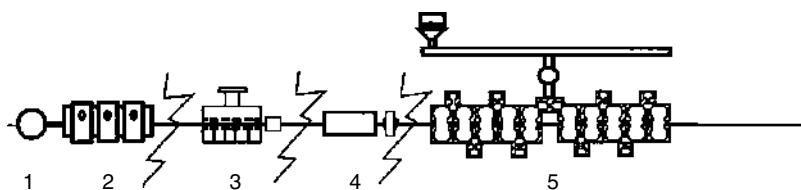

### 46.3.1 TYPES OF PARTICLE ACCELERATOR

Accelerators producing proton beams for medical use (which generally have energies between 200 MeV and 250 MeV and beam intensities of several tens or hundreds of nanoamps) are commonplace in the fields of atomic and nuclear physics research. A review of the current accelerators and projected new systems for proton therapy, including economic and strategic considerations, has been made by Schwartz et al. (1995). Here we present the operating principles of these accelerators.

Static accelerators (van der Graaf, Tandems, etc.) are unable to produce sufficiently high energies. On the other hand, *linear* proton accelerators are able to provide an adequate beam, with a principle similar to the electron accelerators already widely used in medical applications ([Chapter 11](#)). These have been several proposals (Amaldi and Silari 1994) to build a proton linear accelerator for medical use ([Figure 46.3](#)). However, with current technology and considering the cost-performance ratio, *circular* accelerators represent a better solution.

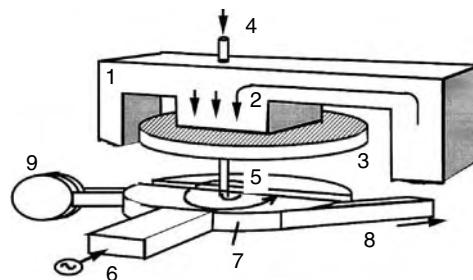

### 46.3.2 THE CYCLOTRON

[Figure 46.4](#) presents a schematic diagram of a cyclotron. The *ion source* injects the protons into the centre of the machine (e.g. plasma is produced by an electric arc from a tungsten filament in hydrogen gas). Two hollow semicircular electrodes, called ‘Dees’ because of their shape, are excited to a high-frequency, alternating high voltage. When a proton is in the electric field between the two electrodes, the sector of negative polarity exerts a force of attraction and, therefore, acceleration. A magnetic circuit and a set of coils

**FIGURE 46.3**

The principle of the proton linear accelerator: (1) source; (2) RFQ (radiofrequency quadrupole) for first bunching and acceleration; (3) associated cavities for acceleration at medium energies; (4) beam bending and focusing; (5) last series of tanks with accelerating cavities for high energy. (Modified from Benincasa, G. et al., *The TERA Project: The RITA Network and the Design of Compact Proton Accelerators*, Vol. 2, Part 1, Amaldi, U., Gandalfo, M., and Picardi, L., Eds., INFN Divisione Ricerca, Frascati, 1995.)

**FIGURE 46.4**

The principle of the cyclotron: (1) magnetic circuit; (2) magnetic field; (3) coils; (4) gas injection; (5) ion source; (6) high-frequency high voltage; (7) accelerating electrodes (Dees); (8) extraction; (9) vacuum systems.

are used to create a strong magnetic field *perpendicular* to the trajectory of the particle (e.g. 1–2 T). When the proton re-enters the cavity of the electrodes, no electric force acts on it. The magnetic field  $B$  bends the particle of charge  $q$  moving with a speed  $v$  into a circle of radius  $r$ . It emerges again into the space between the *Dees* exactly when the electric field has changed its direction, being accelerated again and going on a circular trajectory with a larger radius, and so on.

The operating principle of the cyclotron is thus expressed by equating the centrifugal force on a particle of mass  $M$  at a distance  $r$  to the force exerted on it by the magnetic field:

$$qvB = \frac{Mv^2}{r}, \quad \text{or} \quad qBr = Mv \quad (46.5)$$

The charge, the magnetic field and the mass are constant, and therefore an increase in velocity corresponds to an increase of the radius of the trajectory, with an angular velocity  $\omega$  that depends only on the magnetic field and the mass and charge of the particle:

$$\omega = \frac{v}{r} = \frac{qB}{M} \quad (46.6)$$

The accelerating electric field between the *Dees* remains at this constant frequency, staying in phase with the passage of the particles. There are various other considerations in addition to the above guiding principles of operation. Among the principal ones are the problems of stability of phase, focusing and extraction. The magnetic field tends to decrease near the edges, curving the lines of force and imparting radial components to the field. This results in focusing forces that keep the particles oscillating around the central plane; the magnetic field must decrease with radius to keep these oscillations bounded.

The electric field between the *Dees* not only accelerates the protons, but also focuses and defocuses the beam with a net effect depending on the phase of the particle. To maintain synchronisation, the particle must arrive at the accelerating gap when the voltage is increasing, during a vertical defocusing stage. The beam diameter increases with radius at first, and after half the final radius the magnetic forces focus the beam again. Since the field must decrease with radius to keep the beam focused, there is also a change in the equilibrium between the centrifugal and the magnetic forces. If the field decreases more slowly than  $r^{-1}$ , the net effect is radial oscillations with a final focusing effect. A detailed analysis of these effects lies outside the scope of this chapter and can be studied in specialist references (e.g. Rosenblat 1968).

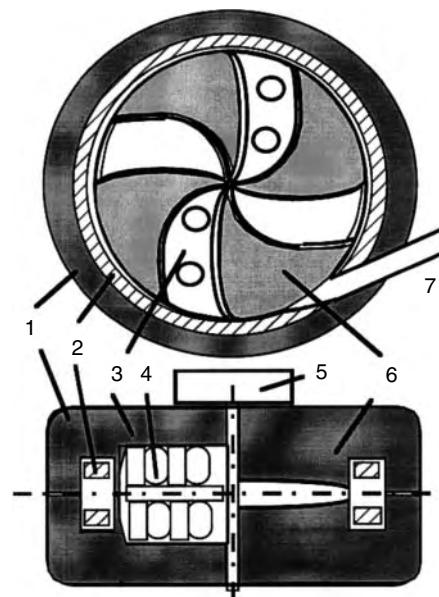

### 46.3.3 THE SYNCHROCYCLOTRON

When the particle energy is such that relativistic effects cause a change in the mass of the accelerated protons, the frequency of the electric field between the Dees of a cyclotron can no longer be constant (Equation 46.6). As the magnetic field in a cyclotron must decrease with radius to provide vertical focusing of the beam, this also affects the frequency of revolution of the particles. To maintain synchronicity between the electric field and the passage of the particles, a modulation of the frequency is necessary (reducing the frequency when the mass of the proton increases with energy at large radius, thus requiring a longer time to move through the Dee). This principle is applied in the synchrocyclotron. The frequency variation is obtained by using a variable capacitor in the high-frequency circuit. In practice this is achieved by a *rotary condenser*, which is a complex device. The disadvantage of the synchrocyclotron is the production of a pulsed beam instead of a continuous one, but the usual repetition frequencies of the *macropulses* (e.g. 450 Hz) are still well adapted to clinical use of the beam. The proton-therapy facilities at Harvard (Boston), Uppsala and Orsay are examples of the use of synchrocyclotrons in proton therapy.

### 46.3.4 THE ISOCHRONOUS CYCLOTRON WITH SEPARATE SECTORS

Another way to solve the relativistic effect on the particle mass could be to increase the magnetic field strength  $B$  towards the outside of the circular Dees (Equation 46.5 and Equation 46.6). This solution, however, has limitations in a cyclotron, because it is associated with beam defocusing. This, in turn, results in a loss of particles due to collisions with the walls of the vacuum chamber and the magnetic pole.

The required focus can be re-established by using alternating gradients of the magnetic field along the trajectory. The accelerator has several sectors in a spiral (alternation of *hills* and *valleys*—Figure 46.5). At the boundary of these sectors, the magnetic field plays a role equivalent to an optical lens, focusing and defocusing the beam. It is then possible to

**FIGURE 46.5**

The isochronous spiral separate sectors cyclotron: (1) magnet yoke; (2) coils (may be superconducting); (3) valley; (4) electrodes, stems and resonators for acceleration in a valley; (5) radiofrequency generator and ion source; (6) magnet "Hill"; (7) extraction (e.g. Boston, Massachusetts).

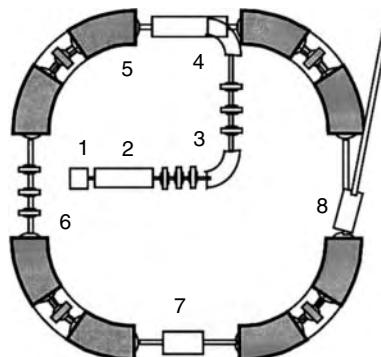

increase the magnetic field with increasing radius by bringing the pole tips closer together (to compensate for the increase in mass of the particles) without losing focus, and thereby maintain a constant frequency for the accelerating potential (and therefore a continuous beam). Such machines are known as *isochronous cyclotrons*. The acceleration is provided by resonating radio-frequency cavities connected to the accelerating electrodes in the *valleys*. Examples of such an accelerator for proton therapy are the ones developed by *Ion Beam Applications* (IBA, Belgium) for centres in Boston, China, Korea and a superconducting version developed by *Accel* (Germany) for centres in Munich and Switzerland.

#### 46.3.5 THE SYNCHROTRON

The diameter of a cyclotron increases with the energy and, in consequence, so does the weight and the cost of the magnetic circuit and other accessories. If we consider only the final trajectory of the particle, Equation 46.5 shows that the speed of the particle can be increased (taking also into account the change in mass) at constant radius  $r$ , with a variable magnetic field  $B$  in the annular region occupied by the acceleration chamber. This is the principle of operation of a synchrotron (Figure 46.6). The particles are accelerated up to several MeV before being injected into the ring. At each revolution, a high-frequency cavity produces an acceleration synchronised with the angular frequency of the particles. The deflecting dipoles modify the magnetic field to maintain the trajectory of the protons at a constant diameter, until they reach the desired energy. This type of accelerator thus makes it possible to produce a beam with variable energy, with the disadvantage that one obtains a pulsed beam of low pulse-repetition frequency. Typical acceleration cycles are between one and three seconds. Examples of synchrotrons developed for proton therapy are those manufactured by *Optirus* for Loma Linda, in California (Slater et al. 1992) and by *Mitsubishi* and *Hitachi* for centres in Japan and the U.S.A. *Siemens* and other companies propose using a synchrotron for carbon-ion therapy (see Chapter 49) that can also produce protons.

#### 46.3.6 NEW DEVELOPMENTS

New approaches to the acceleration and the transport of particles in the range of interest for therapy are being studied. High-intensity lasers (several hundred TW), which can deliver ultra-short pulses (approximately 50 femtoseconds at a wavelength of 0.82  $\mu\text{m}$ , with an energy of 1 J and repetition rate of 10 Hz), will ionise a solid or gas target, creating a plasma state.

**FIGURE 46.6**

Principle of the synchrotron: (1) ion source; (2) RFQ; (3) bending dipoles and focusing quadrupoles; (4) injection; (5) bending dipoles with variable magnetic field; (6) linear section, focusing; (7) radiofrequency cavity for acceleration; (8) extraction. (e.g. Loma Linda, California).

Subsequent interaction of the pulse with the created plasma leads to generation of longitudinal electric fields that ultimately accelerate the charged particles. The generated electric fields can be greater than several hundreds of GV/m, arising from either electron expulsion from the target (in the case of solid targets) or excitation of the plasma waves (in the case of gas targets) induced by the light pressure of the high-intensity laser. These fields can be used to accelerate electrons and protons up to the energies required for clinical applications in a few millimeters (Malka et al. 2002). Fourkal et al. (2002) presented simulations showing that, under optimal interaction conditions, protons could be accelerated up to energies of 300 MeV by a petawatt laser field. Protons at energies between 10 and 50 MeV have been produced experimentally, but with very low repetition frequencies. Increasing the laser intensity, frequency and focalisation, as well as optimising the target design, have been proposed as solutions for developing compact devices for the next generation of particle accelerators. Other aspects like the beam energy spectra (Fourkal et al. 2003), intensity and stability need further improvements.

Recently, a new idea for accelerating protons and heavier ions (like carbon) has emerged, the so-called "non-scaling fixed field alternating gradient" accelerator (Keil et al. 2006). This combines the fixed magnetic field, high current capability and rapid repetition rate of the cyclotron with variable energy extraction of the synchrotron. A major research programme is underway to investigate whether this technology is feasible (<http://gow.epsrc.ac.uk/ViewGrant.aspx?GrantRef=EP/E032869/1>).

The use of plasma techniques or the transport of the beam by using a magnetic "guide" along a superconductor can be considered as promising ideas but their practical feasibility remains to be proven.

An intriguing idea is that of using a beam of *antiprotons*; as a result of antiproton-proton annihilation the height of the Bragg Peak is approximately double that of a proton beam of the same energy and entrance dose level (Hozscheiter et al. 2006; Hall 2006a).

#### 46.3.7 GENERAL TECHNICAL DESIGN CONSIDERATIONS

The extraction of the beam can be achieved by various methods. In a synchrocyclotron, electromagnetic channels cancel the main magnetic field and let the particles come out in a straight line. Electric deflection is often used in conventional cyclotrons. An electromagnet *kicker* can be used, particularly for synchrotrons\*.

To avoid disturbing the acceleration of the beam by absorption or scattering, a high vacuum (e.g.  $10^{-6}$  mbar) is maintained in the accelerating chamber. This vacuum must also be maintained along the path of the beam<sup>†</sup>.

Magnetic fields are limited in strength by the saturation of the iron in the magnetic circuit and by the current necessary in the coils. Superconducting coils and ironless magnetic circuits have been proposed to solve these problems.

Vacuum and cryogenic systems are critical parts which determine the capacity of a facility to return to clinical operation after a breakdown or maintenance. This is of paramount importance for medical applications.

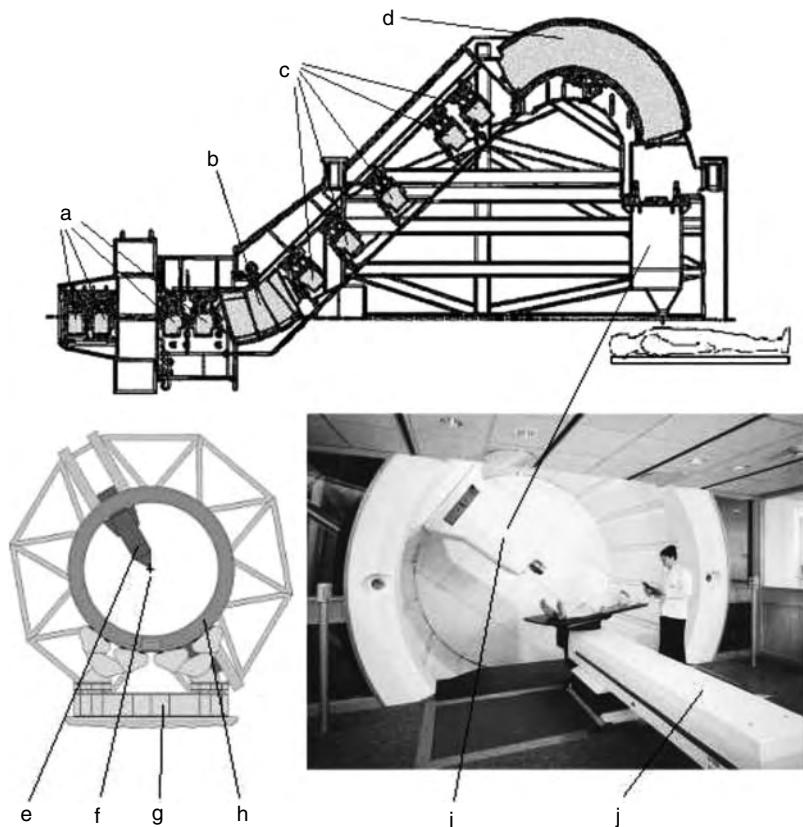

#### 46.3.8 BEAM TRANSPORT

It is common practice for accelerator facilities devoted to physics research to have several beam lines. This is because of the cost and the size of accelerators, the multiple users involved in

---

\* When negative ions are being accelerated a different approach can be used. It is possible to *strip off* the electrons from the ions with a thin target once they have reached the desired energy. The resulting positive ions will emerge from the accelerating chamber with a curved trajectory opposite to that of the orbit of the negative ions.

<sup>†</sup> For negative ions, the vacuum requirements are more severe in order to minimise interactions.

**FIGURE 46.7**

separate research programmes, the complex systems required for beam transport, measurement and focusing the beam, as well as the radiation-protection requirements.

For medical use, the diversity of the *clinical targets* leads to a requirement for different technical specifications for each application, and therefore to a need for specialised lines and rooms. Fast switching of the beam to different rooms can optimise the use of an installation, as the time for patient set-up is usually longer than the *beam-on* time. The beam must therefore be transported after extraction into several different treatment rooms along evacuated conduits. Electric and magnetic systems are used to modify the trajectory (e.g. dipoles) and to focus the beam in a similar way to optical lenses (e.g. quadrupoles). A particular case of optimisation of the beam-transport system, which acts as a constraint on the present development of proton therapy, is the design of compact and isocentric gantries (Figure 46.7), similar to those in use with electron linear accelerators (see Chapter 11), which allow the beam direction to be changed without moving the patient. The basic concepts related to beam delivery and gantries for proton therapy can be found in the following references: Coutrakon et al. (1991), Pedroni (1994), Renner et al. (1994), and Pedroni et al. (1995, 1999).

#### 46.3.9 RADIATION PROTECTION AND NEUTRON SHIELDING

The use of proton beams for radiotherapy requires specific approaches for radiation protection (Sullivan 1992). A review was carried out by Brassart et al. (1995) for the

proton and neutron therapy centre in Nice. Shielding represents a significant component in the total cost of an installation. Whilst the primary beam of protons is easy to stop, the secondary particles resulting from the nuclear interactions, in particular the neutron yield, require a considerable thickness of material containing a high proportion of hydrogen to provide enough attenuation (Alsmiller et al. 1975; Tesch 1985; Hagan et al. 1988; Siebers et al. 1992; Mazal et al. 1997). Concrete is the most common material used for shielding as it represents a good compromise between attenuation, mechanical characteristics and cost.

In practice, the attenuation of the *equivalent dose* (see [Section 59.1.2](#)) is expressed by:

$$H(t) = H_0 \frac{\exp(-t/d)}{r^2} \quad (46.7)$$

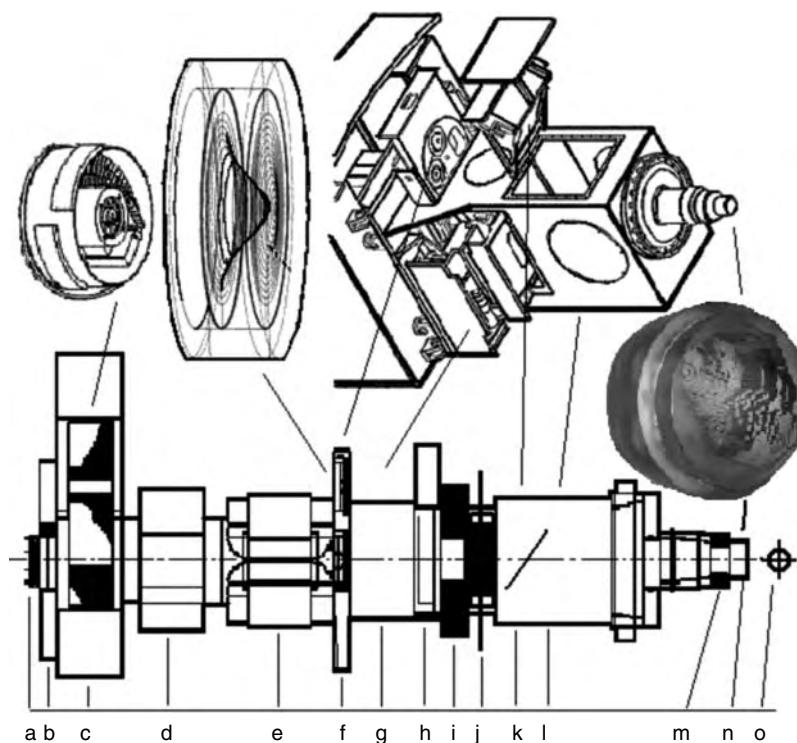

where  $H(t)$  is the equivalent dose behind a thickness  $t$  of shielding,  $H_0$  is the equivalent dose at 1 m with no shielding (or extrapolated to zero shielding thickness) and is known as the ‘source term’,  $d$  is the attenuation length for equivalent dose through the shield and  $r$  is the distance from the source to the surface, or point of interest beyond the shielding material.

For protons with energies in the range for clinical applications (up to 200 MeV) on targets such as water and aluminum, the attenuation length decreases from  $1000 \text{ kg m}^{-2}$  to  $500 \text{ kg m}^{-2}$  for angles from  $0^\circ$  to  $90^\circ$  relative to the beam direction. The source term  $H_0$  is dependent on the angle to the beam direction; different values have been published (Siebers et al. 1992; Mazal et al. 1997) for the source term ranging from 1.3 to 10 at  $0^\circ$  and of the order of unity at  $90^\circ$  for the same kind of beam and targets. In practice proton-therapy facilities have concrete walls exceeding between 1.5 m and 2 m in thickness and up to 5 m in critical areas.

The *raw* protection of the patient (i.e. the dose outside the treatment field) must also be evaluated (Binns and Hough 1997), especially when the degradation of the beam energy is performed in the treatment room. Both the protons and the secondary particles *activate* the hardware close to the beam (Antoni 1996). Consideration to this must be given at each interface in the accelerator and beam lines to guarantee the protection of personnel (in particular from  $\gamma$ - and  $\beta$ -rays). The accelerating chamber, the transport system and collimators, whether made of brass or low-melting-point alloys (containing Bi, Pb, Sn, etc.), are examples of components with high levels of activation after the beam has been running. Some of these are often handled a short time after having been exposed to the beam, with the risk of irradiation or toxic ingestion of radioactivity. The activation in some materials decreases rapidly (of the order of ten minutes) immediately after the irradiation. However, at relatively long times after irradiation, brass contains isotopes of Co, Mn, Fe and Zn, while the standard shielding alloy, Cerrobend, contains a broad spectrum going up to Tl, Bi and, more critically, Po. The activation of air and of water is also a problem to be taken into account: air-ventilation systems and filters are necessary in all the rooms, as well as the use of closed cooling circuits for the accelerator. The possible contamination of the ground and the groundwater must be avoided or maintained within acceptable limits following international and local regulations.

#### 46.3.10 BEAM SHAPING: TOOLS AND DOSIMETRY

[Figure 46.8](#) presents the principle of a beam line, at the end of the transport system. Various devices are necessary for beam shaping and dosimetry, and for adapting the dosimetric characteristics of the beam to the particular volume for each angle of incidence. They have been described in detail by Chu et al. (1993).

**FIGURE 46.8**

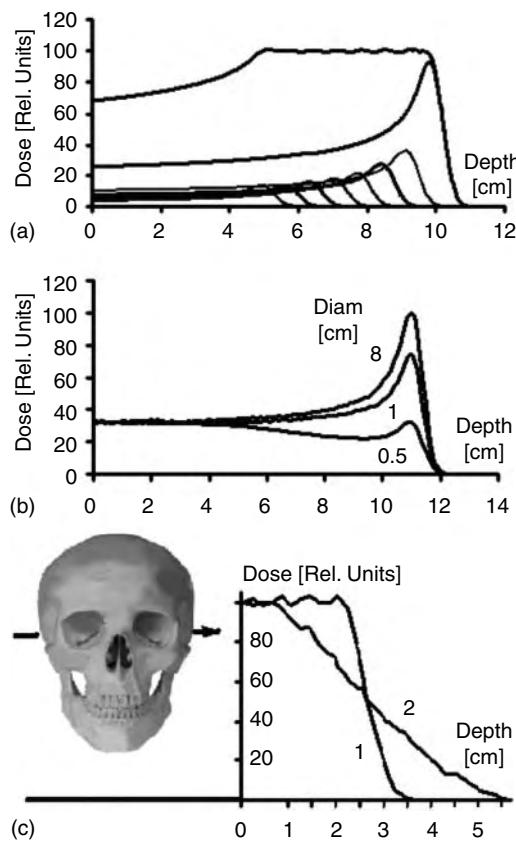

Typical passive and dynamic beam-shaping devices for proton therapy in a fixed beam line or in a “nozzle” of a gantry system: (a) vacuum window and first ion chamber (for monitoring of centering, beam intensity etc.) and/or SEM (secondary emission monitor); (b) first scattering foil; (c) modulator wheels; (d) first scanning magnet; (e) second scanning magnet; (f) second scatterers; (g) on axis, remote controlled x-ray tube for set-up verification (or film holder if tube opposite to beam direction); (h) and (i) collimator jaws, range verification devices; (j) second ion chamber (centering, flatness, monitor units); (k) light field for beam simulation; (l) snout holder; (m) patient aperture (or multi-leaf collimator); (n) patient compensator; (o) isocenter. Other components may be present like absorbers, intermediate antiscatter collimators, multiwire chambers. (Modified from original drawings from Harald Paganetti (personal communication) and IBA, Belgium.)

#### 46.3.11 DEPTH–DOSE CURVES: RANGE AND MODULATION

The *raw* or *pristine* Bragg peak, i.e. that due to a monoenergetic beam (see Figure 46.1) must be adapted for clinical use. The maximum depth of the target volume determines the range necessary, and consequently the energy of the beam. This range can be changed either by using an absorber, or by a change of the energy produced in the case of a variable-energy accelerator.

The *raw* peak is too narrow for clinical applications. One solution is to superimpose, during the irradiation, a certain number of peaks placed at various depths with a *modulator* (Koehler et al. 1975) to ensure a homogeneous coverage of the target volume (Figure 46.9). With this approach, the dose at the surface will be increased relative to that of the resulting *spread out* Bragg peak (SOBP). This is one of the principal limitations of the use of a single beam of protons in therapy; the skin dose could be higher than that caused by a high-energy photon beam (see Chapter 22).

The modulation is produced by interposing in the beam a wheel with sectors of variable thickness. The angular opening of each sector is calculated to obtain a plateau over the desired range of depths. An almost homogeneous dose in this SOBP can be obtained independently of the original quality of the beam. However, the surface dose and especially the distal slope of the depth-dose curve are dependent on the energy dispersion of the original beam.

**FIGURE 46.9**

Modifications of proton depth-dose curves: (a) modulated or spread out Bragg peak (SOBP) as a result of a weighted sum of single energy peaks of different energies using a range modulator wheel, ridge filters or dynamic techniques; (b) single-energy depth doses for small beam sizes showing the effect of the lack of lateral proton equilibrium; (c) effect of inhomogeneities on the distal fall off of a SOBP: (1) after traversing a homogeneous phantom; (2) after the complex inhomogeneities in the base of the skull. (Figure (a) courtesy H. Kooy, Boston; Figure (b) courtesy C. Desblancs, Orsay; Figure (c) modified from Uriel, M., Goitein, M., Holley, W. R., and Chen, G. T. Y., *Phys. Med. Biol.*, 31, 1–15, 1986.)

#### 46.3.11.1 Lateral Dose Profiles and Penumbra

The proton beam transported from the extraction point of the accelerator to the treatment room generally has a narrow Gaussian profile. A larger beam size with the required homogeneity for clinical applications can be obtained by single or double *passive scatterers*, or by sweeping or scanning the beam (Koehler et al. 1977; Grusell et al. 1994b; Nauraye et al. 1995). The lateral penumbra at the entrance of the medium is strongly dependent on the characteristics and the localisation of the elements interposed in the beam, as well as on the position of the final collimator. At depth, this penumbra is largely determined by the multiple scattering in the medium. Figure 46.2 shows the variation of the penumbra width with depth under clinical conditions. Experimental results such as these are used in the development of computational models for treatment planning (Rosenwald et al. 1994).

#### 46.3.11.2 The Shaping of the Dose Distribution around a Target Volume

The shaping of the dose distribution to conform to a target volume is achieved using various devices.

The dose to critical normal tissue is limited laterally by customised apertures. Close to the aperture, strong scattering creates *horns* in the profiles (Gottschalk et al. 1993). Monte Carlo simulations (van Luijk et al. 2001) show that protons that are incident on the entrance face of the collimator and leave it through the aperture wall make the largest contribution to scatter. There will be some very low-energy protons in this scatter component of the incident *beam*, and at very low energies the Relative Biological Effectiveness (RBE) (see [Chapter 7](#)) will be considerably greater than unity. However, by analyzing the energy distribution of protons at different positions in the patient (or a phantom) it has been shown that the net effect of such low-energy protons is to increase the normal-tissue damage probability by no more than 1% at worst. The width of the penumbra at the entrance surface is largely determined by scatter in air.

In the beam direction, isodoses are shaped by a ‘compensator’ (Wagner 1982; Urie et al. 1984; Sisterson et al. 1989; Petti 1997). The compensator causes each *ray* inside the beam to have a different range, adapted to the distal depth of the target volume in the direction of the ray. *Smearing* tools are used to modify ideally calculated compensators to take into account the risk of patient- and organ-intrafraction movements, as well as the consequences of multiple scattering (Urie et al. 1984).

#### 46.3.11.3 Dynamic Techniques of Beam Shaping

Beam shaping can also be done dynamically (Kawachi et al. 1983; Scheib et al. 1994; Pedroni et al. 1995). Sweeping a small pencil beam in position, while varying its energy and intensity, allows control of the dose distribution without using the “passive” components described in [Section 46.3.11.1](#) and [Section 46.3.11.2](#). Using beam scanning, the dose can be *conformed* not only to the distal end of the target but also to the proximal end, thereby reducing high doses to normal tissue overlying the target volume. Beam scanning can be done continuously or point by point, allowing optimisation of the dose distribution using a limited number of beams without the use of patient- or beam-specific hardware and without attenuating the beam. This minimises the problem of radiation protection of the patient and of personnel. On the other hand, the beam control system and the dosimetry are more complex (Boon et al. 1998). In addition, as only a small part of the target volume is irradiated at any given instant with a high dose rate, this can give rise to additional problems of junctions and risks of possible movement. Various groups have presented the potential advantages of this approach, but its clinical use is still very limited with proton beams\*.

The use of dynamic techniques is also the basis of the development of optimisation techniques with intensity-modulated proton beams (IMPT) (Trofimov and Bortfeld 2003, see [Figure 46.13c](#)) following a similar approach to intensity-modulated photon beams (IMRT, see [Chapter 43](#)) but having an additional degree of freedom, because of the finite range of the charged particles. This results in a reduction of the integral dose to healthy tissues.

Fully automated 3D intensity-modulated proton therapy (IMPT) with a spot-scanning system in a compact gantry is employed at the Paul Scherrer Institute, Switzerland, for clinical applications such as base of the skull and thoracic chordomas and chondrosarcomas (Pedroni et al. 1999; Lomax et al. 2001).

\* Dynamic techniques are usually used in preference to passive systems when using heavier ions ([Section 49.3.3](#)) to minimise beam fragmentation.

## 46.4 TREATMENT IMPLEMENTATION

The clinical exploitation of the potential dosimetric advantages of proton beams is only possible if a full set of precision tools is available for the preparation and the delivery of each treatment. Four aspects will be considered:

1. Treatment planning software
2. Patient set-up aids
3. Dosimetry, including radiobiological considerations
4. Quality assurance for the whole procedure

### 46.4.1 TREATMENT PLANNING SYSTEMS

#### 46.4.1.1 Calculation Models

The calculation of the dose distribution in the patient can be done by several methods: the three best known are ray tracing, the pencil beam and the Monte Carlo technique (see [Part F](#)). A short description of these techniques follows, based on the assumption that high resolution CT images of the patient anatomy and target are available. The planning process has been described by Bussiere and Adams (2003).

*Ray Tracing.* Tracing a straight line between the source and each calculation point makes possible the calculation of *radiological depths* into the body, taking into account heterogeneities (Lee et al. 1993; Belshi 1995; Schreuder et al. 1999; Russell et al. 2000). These depths are used to estimate the dose from *Bragg curves* stored in a beam library or represented by analytical expressions. However, this does not explicitly model the effect of multiple scattering. The lateral penumbra can be calculated with models similar to those used for photon and electron beams (Dutreix and Briot 1985; Rosenwald and Drouard 1991; Rosenwald et al. 1994). Parameters having a major influence on penumbra broadening are the depth ([Figure 46.2](#)), the distance from the final collimator, the presence of beam modifiers such as compensators (Urie et al. 1984), the air gap between the compensator and the patient surface (Sisterson et al. 1989), the characteristics and the position of beam-shaping devices and the original beam divergence. In spite of its limitations, this model is still used for fast calculations in clinical applications.

*Pencil Beams.* The multiple scattering of protons can be approximately taken into account by the modelling based on narrow beams with Gaussian profiles (see [Chapter 27](#); Petti 1992, 1996, 1997; Lee et al. 1993; Russell et al. 1995, 2000; Hong et al. 1996; Carlsson et al. 1997; Deasy 1998; Schaffner et al. 1999; Szymanowski et al. 2001). Superposition (or convolution) of these elementary beams gives the distribution of dose for beams of greater cross-sectional area and irregular shape. The pencil-beam approach is a clear improvement over ray-tracing, and yields similar results to Monte-Carlo simulation (see [Chapter 28](#)) in the majority of clinical situations.

*Monte Carlo Method.* The Monte-Carlo technique of modeling the elementary interactions and then combining the “histories” of a large number of particles leads to more accurate calculations of the dose distribution in the presence of heterogeneities ([Chapter 28](#); Petti 1996; Kohno et al. 2003; Paganetti et al. 2005). However, it requires powerful computational capabilities, a good knowledge of the proton interaction coefficients and some means of assigning tissue-composition data to the patient images acquired from the usual methods like CT scanning (see [Chapter 5](#) and [Chapter 28](#)).

#### 46.4.1.2 The Effect of Heterogeneities

When a proton beam penetrates the body, the heterogeneities (bone, air cavities, lung etc.) modify the dose distribution significantly compared to a homogeneous medium such as

water (Goitein 1978; Urie et al. 1984, 1986; Zink 1987; Oozeer et al. 1993). This is due to the dependence on density, and to a lesser extent on atomic number, of the proton stopping power, and hence range, and the degree of lateral scattering. Two types of heterogeneities can be identified: *simple* and *complex*. A heterogeneity is *simple* when it can be modelled by taking into account its global density using a *radiological depth* equivalent to water, which involves a simple modification to the range of the beam, with no deformation of the distal edge, or the flat modulated. The upper part of the skull can, under certain conditions, be modelled using this principle. A heterogeneity is *complex* when its form, its size or its composition implies large variations in depth in contiguous rays, so the amount of multiple scattering is affected and, in consequence, so is the depth-dose curve. In clinical practice, beams are not planned in directions where a sharp heterogeneity must be traversed. The compensation of heterogeneities by the use of bolus or compensators must include the effect of uncertainties in the evaluation of the planned dose distribution. *Expanding* and *smearing* routines are applied when calculating compensators to ensure that the target volume can be covered by a specified dose given prespecified repositioning and motion uncertainties, taking into account the heterogeneities (Urie et al. 1984).

A stoichiometric (*stoicheion*: element, *metron*: measure) method has been described by Schneider et al. (1996) to improve the calibration of CT scans for treatment planning with protons taking into account the anatomical heterogeneities (see also [Section 39.2.1](#)). The relationship between Hounsfield CT units and proton stopping powers (or electron densities for photon beams) is based on measurements using tissue-equivalent materials with known composition.

#### *46.4.1.3 Tools to Assist in the Visualisation and the Evaluation of the Treatment*

The practical implementation of proton therapy requires some advanced treatment planning tools, most of which are common to any conformal technique of high-precision radiotherapy (see [Part G](#); Zink 1987). Some examples are:

1. The determination of the various volumes of interest (i.e. the target volume and critical organs) requires tools to correlate images and contours from different imaging modalities (e.g. CT, MRI, and ultrasound), but the dose calculations are based on CT data.
2. The visualisation of the spatial orientation of structures (e.g. ‘beam eye’s view’) and specific functions such as the automatic determination of the shapes of complex fields.
3. The use of 3D volume expansion algorithms and automatic margins (Belshi 1995).
4. The calculation of the dimensions of beam-shaping devices (e.g. compensators and filters), with the necessary documentation and interfaces for their fabrication and their quality control.
5. The calculation or measurement of dose-delivery parameters (Monitor Units). Many centres still calibrate each treatment field prior to treatment, or use their own database and/or empirical analytical fits to predict output factors. Kooy et al. (2003) have published a predictive model. It is based on (a) the inverse square of the distance between the entrance dose at the patient surface and the monitor chamber reading at the beam line; (b) theoretical derivation of the ratio between entrance dose and dose at the center of the SOBP (Bortfeld and Schlegel 1996); (c) experimental correction factors and analytical fitting to experimental data to correct for specific changes in the beam line (e.g. scatterers and modulators) for different irradiation conditions.
6. The calculation of dose distributions in easily reproducible conditions (e.g. with a flat surface) for quality control purposes.
7. Presentation of the calculated doses in various formats: isodoses superimposed on anatomical images, dose–volume histograms, doses on anatomical surfaces (e.g. observer’s eye view).

8. Systematic analysis of uncertainties associated with collimator-compensator-patient misalignment, patient movements, beam range, etc. Among the suggested solutions, is the calculation of the distributions of nominal, maximum, and minimum doses taking into account these uncertainties (Goitein 1985; Uriel et al. 1991).
9. Tools for comparison and for optimisation of treatment plans (Zink 1987; Brahme et al. 1989; Hoffmann et al. 2006) using dosimetric or *biological* figures of merit (see [Chapter 36](#)).

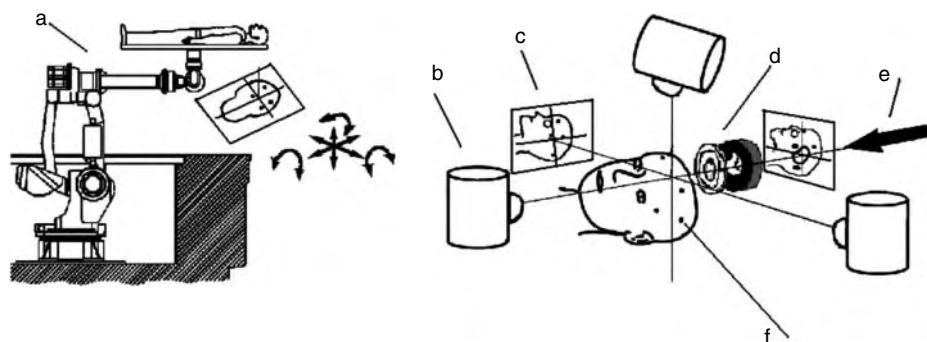

#### *46.4.1.4 Comparison with Photon Dose Distributions*

Comparative treatment planning has been extensively used to investigate potential improvements in the treatment of different clinical targets with protons, compared with photon beams, either with conventional conformal approaches or with intensity modulation. Lomax and coworkers amongst others (e.g. Lee et al. 1994; Isacsson et al. 1998; Johansson et al. 2002) have performed such studies for varying indications and lesion sites (Lomax et al. 1999) including paranasal sinus (Lomax et al. 2003a) and breast and regional nodes (Lomax et al. 2003b). In general, better conformation of dose distributions around the target volume can be achieved with protons or, when conformation of the high-dose regions is equivalent, better homogeneity in the dose distribution in the target and a significantly lower *integral dose* in healthy tissues is achieved with protons (Lee et al. 1994).

#### **46.4.2 PATIENT SETUP**

The precision and the reproducibility of the patient set-up required for proton therapy are of the order of millimeters, or even better for certain applications like ophthalmology (Verhey et al. 1982; Bonnett et al. 1993; Meyroneinc et al. 2001). To achieve this, attention must be paid to at least four aspects:

1. *The treatment planning software* must provide the specification of position needed to guarantee that the patient is set up according to the treatment plan. This can be achieved with digitally reconstructed radiographs (DRR see [Section 32.4.5](#)) but, in practice, anatomical reference marks or external fiducials having a fixed link with the target volume are also used. Markers may also be inserted into internal structures, such as tantalum clips sutured on the sclera and steel or gold marker seeds implanted in the skull.
2. *The patient immobilisation* must guarantee almost perfect reproducibility between the acquisition of the CT scan and each treatment session and minimise intrafraction movements. Present systems are based on masks, foam moulds, carbon fibre supports, orthopaedic devices and invasive or noninvasive stereotactic frames.
3. The *system of verification of patient positioning* must ensure that the reference fiducials are identified at each treatment session. Radiological systems installed in the treatment room must facilitate fast and reliable identification of the anatomical structures or reference marks. By establishing their position in space, relative to the isocentre of the beams or the field boundaries and comparing this position with the planned positions, the corrections necessary for patient repositioning can be calculated. Optical methods are also used based on video cameras and reflective reference marks or using real-time digital stereophotogrammetry techniques (Jones et al. 1994). The activation in phantoms of positron-emitting radionuclides induced by proton irradiation has been measured with on-line PET by Hishikawa et al. (2002) and Parodi et al. (2002), and correctly predicted by calculation. Thus in situ proton therapy monitoring by means of in-beam PET may be feasible, as already clinically implemented for the monitoring of carbon ion therapy at GSI Darmstadt (see [Chapter 49](#)).
4. *The patient positioning system* must enable corrections to the patient's position to be carried out with high precision. Present solutions are sometimes based on robotics concepts ([Figure 46.10](#)). These systems allow linear and angular corrections, in general with six degrees of freedom and accuracy better than 1 mm and 0.5°.

**FIGURE 46.10**

Patient set up: (a) robotic patient positioner; (b) x-ray tube; (c) films or electronic detector; (d) patient aperture and collimator; (e) proton beam; (f) implanted fiducial clips.

Such a level of precision and reliability can only be assured by a comprehensive quality assurance programme (Mazal et al. 1996b).

#### 46.4.3 DOSIMETRY

Proton-beam dosimetry is carried out using several different detector systems: ionisation chambers, Faraday cups, calorimeters and semiconductors (Figure 46.11). It has many similarities with the dosimetry of electrons and photons, which is described in Part D.

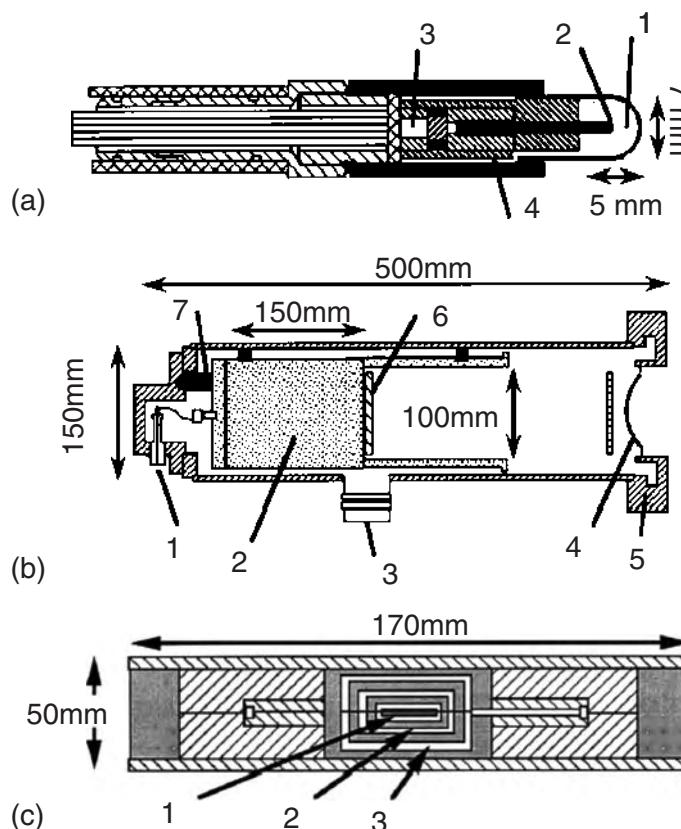

The *ionisation chamber*, generally calibrated in a  $^{60}\text{Co}$  gamma-ray beam, is well adapted for routine measurements and is also considered the reference for intercomparisons and calibration of a proton beam (see Chapter 15 and especially Section 18.7).

The *calorimeter* measures the energy deposited in an absorber by the associated temperature increase in the core of the detector. Sensitive thermistors are inserted in the core and connected to a measuring Wheatstone bridge and DC amplifiers to measure temperature rises of the order of several milli-Kelvin. The core is thermally insulated from the room temperature by means of a vacuum and different layers of ‘equilibrium shells’ or jackets which have electrical circuits to measure and maintain a stable temperature. Calorimeters in graphite (Palmans et al. 2004), tissue-equivalent material or distilled water have been built and used for proton and neutron beam calibrations, usually working in quasi-adiabatic mode. The total energy  $E$  imparted to the core is given by:

$$E = TC(1 - b)^{-1}$$

where  $T$  is the temperature increase,  $C$  is the total heat capacity of the core, and  $b$  the heat defect (the fraction of absorbed energy not converted into a temperature rise in the absorber). The heat defect is about 0.01–0.03 for tissue-equivalent calorimeters in proton beams used in clinical applications, and somewhat lower for water calorimeters, and in both cases increases slightly with increasing LET (Brede et al. 1997). Ohmic heating elements are also inserted in the core to allow electrical calibration of the calorimeter.

The main factor introducing uncertainties in the absolute measurement of absorbed dose is the heat defect. The experimental conditions for the use of a calorimeter are critical and require that the detector be in thermal equilibrium in the room. Consequently the initial time to achieve thermal equilibrium, together with the time for data acquisition and then to re-establish equilibrium after each irradiation, is long, limiting the use of calorimetry for routine calibrations of a clinical beam.

**FIGURE 46.11**

Detectors used for proton dosimetry: (a) Ionisation chamber: (1) gas cavity; (2) central electrode; (3) signal conductor; (4) vent to the atmosphere. (b) Faraday cup: (1) signal conductor; (2) absorber (e.g. copper, graphite); (3) vacuum; (4) entrance window; (5) steel cup; (6) permanent magnet; (7) insulators. (c) Tissue equivalent calorimeter: (1) core; (2) inner jacket; (3) outer jacket; (4) vacuum chamber.

The *Faraday cup* measures either the beam current directly or, by integration, a charge  $Q$ . Then the fluence,  $\Phi$ , is given by  $\Phi = Q/Ae$ , where  $A$  is the beam area and  $e$  the electronic charge. It follows then (see [Section 6.6](#)) that the dose at the surface is

$$D_{\text{med}} = \Phi \left( \frac{S(E_z)}{\rho} \right)_{\text{col,med}}$$

where  $\Phi$  refers to the fluence in air and  $(S(E_z)/\rho)_{\text{col,med}}$  is the mass collision stopping power for the medium evaluated at (mean) energy  $E_z$ . The stopping power is strongly dependent on the beam energy, and any contamination (e.g. coming from the collimator) gives significant errors in dose calculation. Grusell et al. (1995) proposed the use of uncollimated beams to correlate ionisation chamber and Faraday cup measurement, with an estimated accuracy of 1.6% (1 SD). The Faraday cup method is only of practical use for *monoenergetic* proton beams at the surface of a phantom. However, it has the advantage of being completely independent of other methods.

Because of the uncertainties in these dosimetry systems it is essential to carry out dosimetric intercomparisons between detectors and between centres (Vatnitsky et al. 1996, 1999b; Delacroix et al. 1997) to standardise methods and results.

Several different protocols for absolute dose determination have been proposed: the American ‘AAPM protocol’ (AAPM 1986) and a ‘European’ code of practice (Vynckier et al. 1991, 1993) have been the basis for the development of international protocols such as ICRU 59 by the ICRU (ICRU 1998) and TRS 398 (IAEA 2000) by the International Atomic Energy Agency, to determine the absorbed dose in water according to well defined procedures (see Chapter 18). A thimble ionisation chamber is recommended as reference dosimeter, calibrated in a  $^{60}\text{Co}$  beam in terms of air kerma or in terms of absorbed dose to water. In the latter case, the general equation is:

$$D_w = MN_{D,w}k$$

where  $M$  is the chamber reading corrected by the usual factors (temperature, pressure, etc.),  $N_{D,w}$  is the chamber calibration factor for absorbed dose to water and  $k$  is a factor to correct for differences between the quality of the calibrating beam and that of the user’s beam.

Newhauser et al. (2002a, 2002b) applied the ICRU 59 protocol to calibrate proton beam lines for eye treatments and for radiosurgery. Differences of 1–2% were found compared to calibrations with a Faraday cup. Medin et al. (2000) compared the formalism and data in ICRU Report 59 and the IAEA TRS 398 Code of Practice including five different cylindrical ionisation chamber types commonly used in proton beam dosimetry. Differences of the order of 2% were found mainly because of differences in the recommended values of perturbation factors and  $(W/e)_{\text{air}}^{\text{proton}}/(W/e)_{\text{air}}^{\text{cobalt-60}}$  (mean energies required to produce an ion pair in the chamber air cavity at the beam qualities of the proton beam and in the reference condition, respectively), depending on the chamber type, beam energy and calibration formalism.

*Plane-parallel chambers* are well suited to the measurement of depth–dose curves and also for calibrating beams in Gy/monitor unit (MU) (for the analogy with photon-beam therapy see Section 20.1.2 and Section 38.7.3). Palmans et al. (2002) presented experimental data and Monte Carlo calculations on perturbation correction factors for four plane-parallel ionization chamber types in 75 MeV modulated and nonmodulated proton beams. They confirmed, within the experimental uncertainties, that the overall perturbation correction factor for a plane-parallel chamber in a low-energy proton beam is unity, as had been assumed in IAEA TRS-398 and other dosimetry protocols.

*Semiconductors* are used to make *relative* measurements (depth–dose curves, profiles and isodose distributions) (Koehler 1967), because of their spatial resolution, high sensitivity and low cost. The dependence of the response of solid-state detectors on the particle energy (or LET) are not yet well known. De Angelis et al. (2002) studied the response of high doped Hi-pSi diodes to low-energy proton beams (26.7 and 12 MeV nominal energy). The diode response was linear with dose and the standard deviation of repeated readings was less than 2.5%. After performing corrections to the depth-dose measurements for dose rate and for the water-silicon mass collision stopping-power ratio, the difference, at the Bragg peak, with respect to the reference chamber was about 4%. They ascribed this to inadequate knowledge of the materials in front of the sensitive volume of the diode.

*Radiological films* are widely used in proton dosimetry, especially for measurements perpendicular to the beam axis, as in general the film response is nonlinear at high ionisation density such as at the end of the range of charged particles (Dutreix et al. 1978). Experimental data and a model for calculating the response of films to heavy charged particle irradiation as a function of particle type and energy have been published by Spielberger et al. (2001, 2002, 2003), based on the particle’s track structure. These data enable three-dimensional dose verification to be carried out in ion beams with film. The feasibility of using *radiochromic films* for proton dosimetry (Vatnitsky 1997) for verification of an ophthalmic proton beam (Troja et al. 2000) and for verification of the proton Bragg peak in stereotactic radiosurgery with multiple beams has been studied (Vatnitsky et al. 1999a). In this latter study, the authors validated the prescribed dose delivery within  $\pm 5\%$ , one standard deviation, by comparing calculated doses with measured values.

*Thermoluminescent detectors* are also used for proton dose determination. TLD-100 detectors have been used to measure transverse and longitudinal distributions of 62 MeV unmodulated proton beams for a line devoted to eye treatments (Sabini et al. 2002). The analysis of the response of these detectors has elements in common with studies related to dosimetry in space (Olko et al. 2002).

Nichiporov et al. (1995) studied *alanine-based detectors* for their possible use as passive transfer dosimeters for clinical proton beams. Measurements from a number of experiments yielded agreement between the dosimetry standards of the Institute of Theoretical and Experimental Physics (Russia) and the National Institute of Standards and Technology (U.S.) to within 2.5%.

Significant efforts are being made to develop multidimensional detectors to enable the rapid acquisition of “dynamic” beams. A *scintillating screen* ( $\text{Gd}_2\text{O}_2\text{S:Tb}$ ) mounted at the beam-exit side of a phantom and coupled to a low-noise, charge-coupled device (CCD) camera gives a fast and accurate two-dimensional image of the dose distribution at the screen position, with high spatial resolution (SD 1.3 mm) (Boon et al. 1998). In the Bragg peak, where the ionisation density is high, some quenching of the light output has been observed, though this is described well by existing models.

The dosimetric properties of *Ferrous sulphate gels* (see Section 17.3) irradiated with proton beams and evaluated in three dimensions using MRI have been studied by Bäck et al. (1999). The relative  $1/T_1$  at the Bragg peak was 15–20% lower than the corresponding ionisation chamber data for the monoenergetic proton beam. The change in sensitivity with depth was explained in terms of a dependence on LET. BANG polymer gel dosimetry was used for the dosimetric verification of an ophthalmologic 68 MeV proton beam by Heufelder et al. (2003), with similar *quenching* effects of the Bragg maximum due to the high LET.

A 3D ‘Magic cube’ detector has been developed and used with proton beams (Brusasco et al. 1997; Amerio et al. 2002). It is based on a stack of 12 parallel-plate strip or pixel segmented ionisation chambers interleaved with interchangeable tissue-equivalent slabs. A *Very Large Scale Integration* (VLSI) electronic readout device is connected to a PC-based data acquisition system. Sixty four strips, 4 mm wide and 25 cm long, cover a sensitive area of  $25 \times 25 \text{ cm}^2$ , while for the pixel chamber 1024 channels are available.

#### 46.4.4 RADIobiological CONSIDERATIONS

From a radiobiological point of view, the behaviour of protons is very close to that of photons and electrons (see Part B). The various studies carried out on this subject are based on *in vitro* or *in vivo* measurements, such as the technique of Withers based on the regeneration of the intestinal crypts in mice. With this technique, Gueulette et al. (1997, 2001) found *in vivo* RBE values, relative to  $^{60}\text{Co}$  gamma radiation, which were slightly larger than the currently accepted value of 1.10 and independent of fractionation for one, three and 10 fractions. In this study, and in several other radiobiological and microdosimetric studies, variations of RBE with depth (Robertson 1994) have been found, with the RBE increasing at the end of the range of the particles. This is consistent with predictions from microdosimetric studies (Cosgrove et al. 1997; Tilly 2002; Tilly et al. 2005).

Paganetti et al. (2002) analysed published RBE values for *in vitro* and *in vivo* endpoints. The values for cell survival *in vitro* indicated a substantial spread between the diverse cell lines. The average value at the middle of the SOBP over all dose levels was approximately 1.2 *in vitro* and approximately 1.1 *in vivo*. Both *in vitro* and *in vivo* data indicated a statistically significant increase in RBE at lower doses per fraction, this increase being much smaller *in vivo*, and a measurable increase in RBE over the final few millimeters of the SOBP. The experimental *in vivo* data indicate that continued use of a generic RBE value of 1.1 (relative to  $^{60}\text{Co}$   $\gamma$ -rays) is reasonable (Raju 1980). Thus, in clinical practice, one commonly encounters the quantity *cobalt Gray equivalent*.

At present, there seems to be too much uncertainty in the RBE value for any one human tissue to propose tissue-specific or fraction-size-specific RBE values (Tilly 2002; Tilly et al. 2005). There are data which indicate enhanced biological effectiveness for low doses of protons of very low energy (<10 MeV); these findings are also of interest for human interplanetary missions (Yang 1999).

## 46.5 CLINICAL APPLICATIONS

Details of the clinical basis of proton therapy are beyond the scope of this chapter: the interested reader should consult the extensive literature on this subject (e.g. Habrand et al. 1995, 1996; Loeffler et al. 1997; Krengli et al. 1998; Glimelius et al. 2005; Lundkvist et al. 2005). This includes clinical results and trial protocols for the treatment of skull-base and cervical-spine chordoma and low-grade chondrosarcoma, skull-base meningioma, pituitary tumours, paranasal sinus carcinoma, glioblastoma multiforme, artero-venous malformations, uveal melanoma, macular degeneration, retinoblastoma, thoracic spine-sacrum tumours, prostate carcinoma and other lesions. This section is limited to some technical and dosimetric considerations related to the common uses of proton therapy in treating ophthalmic and intracranial sites as well as radiosurgery or stereotactic radiotherapy.

### 46.5.1 OPHTHALMIC APPLICATIONS

The principal ophthalmic application is the treatment of uveal melanomas (Gragoudas et al. 1978; Austin-Seymour 1985; Pignol et al. 1994; Courdi et al. 1999; Munzenrider 2001; Desjardins et al. 2003; Damato et al. 2005a, 2005b). Other ophthalmic targets, such as angiomas and haemangiomas (Munzenrider 1994) have also been treated with protons with promising results. Dosimetric studies (Mazal et al. 1998; Adams et al. 1999c) and recent clinical trials have been initiated to treat age-related macular degeneration (Flaxel et al. 2000; Zur et al. 2001; Ciulla et al. 2002). A miscellaneous number of other ocular tumours are also treated with protons, such as retinoblastomas under general anaesthesia and metastatic lesions (Munzenrider 1994).

For uveal melanomas, the differential diagnosis and the collection of data are carried out by a clinical examination of the fundus of the eye, eye biometry, A-scan and B-scan ultrasound images of the tumour and angiography. It is also important to assess the potential metastatic dissemination to other parts of the body. For special cases (e.g. invasion of optic nerve), CT or MRI scans are carried out. In some clinics CT or MRI scans are used for all cases.

Radio-opaque clips are sutured onto the sclera around the base of the tumour (rendered visible by transillumination) by the ophthalmic surgeon under general anaesthesia in the operating theatre. The clips (made of tantalum) have a diameter of 2.5 mm and a thickness of 0.5 mm, and will stay in place permanently. They are used for radiological verification of the position and the orientation of the eye at each treatment session ([Figure 46.12](#)). The immobilisation system is prepared (a thermoplastic mask with a bite block) and orthogonal x-ray films are taken at the first planning session. The patient is seated on a mechanical chair which enables the position of the eye to be adjusted with a reproducibility better than 1 mm and less than 1°. The information collected at the planning stage allows the reconstruction of the principal anatomical characteristics of the patient in a computer model of the eye. The model is adjusted according to the size of the eye. Based on the clinical data and the clip positions the tumour is drawn onto the eye model. Bondiau et al. (2003) have described a fully automatic technique for 3D reconstruction of a virtual eye from CT slices and merging of the CT slices with fundus retinography. These data can then be used for the simulation, planning and control of the proton therapy.

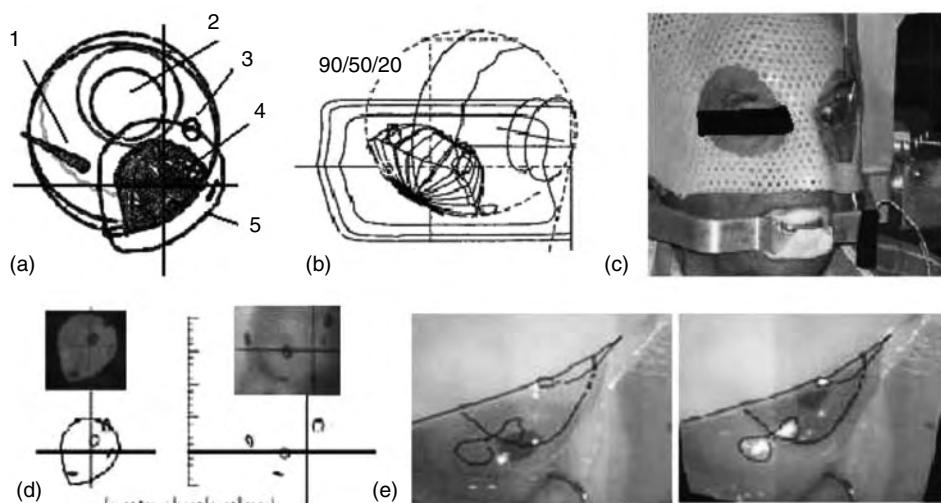

**FIGURE 46.12**

Image guided treatment of eye tumours with fixed proton beams. (a) Virtual model of the eye for planning, frontal beam's eye view: (1) optic nerve; (2) lens; (3) clips; (4) target; (5) aperture. (b) Isodoses on a lateral view from EYEPLAN. (c) Immobilisation devices: thermoplastic mask, bite block, eyelid retractors. (d) Orthogonal x-rays and clip coordinates for patient set-up. (e) Video verification of the gaze and eye position with audio coaching during treatment. (Figure (b) from Goitein, M. and Miller, T., *Med. Phys.*, 10, 275–283, 1983; Figure (e) is courtesy of the Centre de Protontherapy d'Orsay.)

By optimising the position of the eye and the direction of the gaze, an optimal plan of treatment based on a single anterior beam is produced. The EYEPLAN software, developed in Boston (Goitein and Miller 1983), established the definitive requirements of a treatment planning system. Some improvements have been added through a collaboration between the Paul Scherrer Institute in Villigen, Switzerland and Clatterbridge Centre for Oncology in the United Kingdom. This software is used in the majority of proton therapy centres in the world (Sheen 2001). The available functions include beam's eye view, isodoses in any plane of the eye (including complex surfaces like the fundus of the eye), dose–volume histograms and associated tables, files for the computerised fabrication of customised personal collimators and the documents necessary for patient set-up during the treatment, including the position of the clips as they will be seen on the x-ray images taken in the treatment room (or *x-ray eye view*).

The treatment plan is validated during a simulation session; the patient fixates a luminous reference point whose coordinates in space have been determined at the planning stage. Controlling the direction of gaze requires the active participation of the patient; except in particular situations, the eye is not fixed mechanically (e.g. with a sucker lens). Eyelid retractors are used to immobilise the eyelids during the session and to minimise the irradiation of the tear glands and eyelids. Additional measurements are carried out at the simulation session which includes determining the thickness of the eyelid and the curvature of the eye. Consideration is then given to possible modification of the irradiation parameters such as the range and the modulation of the beam, or the use of filters. The treatment is carried out in four or five sessions, delivering doses of around 15 Gy (cobalt-equivalent) per session (the value usually adopted for the RBE is 1.1).

At each session, orthogonal x-ray images are taken using film, Polaroid or fluoroscopic systems to verify the position of the eye relative to the proton beam. A conventional or an infrared video camera giving a magnified view of the eye allows the position of the eye to be monitored during the irradiation, so that the beam can be interrupted if the movements are out of tolerance. To achieve the precision required, specific procedures are observed: at each session a radiographer (radiation therapy technologist), a doctor and a physicist are usually

present. Dosimetric characteristics of the beam such as the Bragg curve, beam profiles and Gy/MU are checked on each treatment day. These are time-consuming tasks and the procedures adopted depend on the experience and the beam characteristics at each centre.

#### 46.5.2 INTRACRANIAL TUMOURS

Commonly occurring intracranial targets that are particularly suited to treatment with proton beams include chordomas and chondrosarcomas of the base of the skull (Austin-Seymour et al. 1985; Habrand et al. 1995). The approach to treatment is similar to that described in the [Section 46.5.1](#) for ophthalmic treatments. Much of the development of proton therapy techniques was carried out with fixed beam lines at a time when isocentric gantries were uncommon. Consequently the techniques developed for patient positioning and fixation were designed either to treat the patient in a chair or to facilitate repositioning the patient between beams. For seated patients, some centres have installed a specially constructed CT scanner which operates in the horizontal plane.

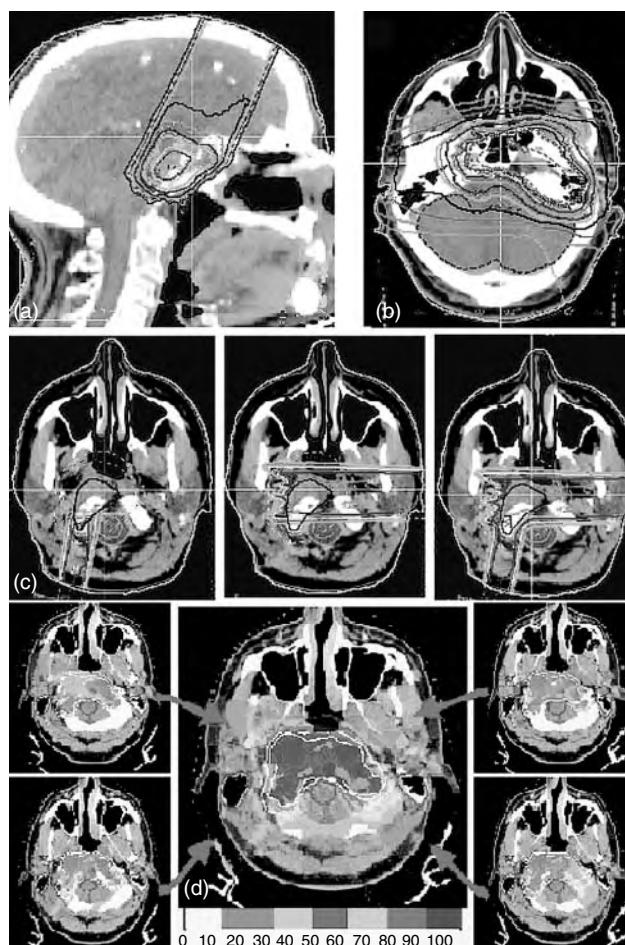

Fiducial reference markers made of gold or steel can be surgically implanted onto the skull surface and used in a similar way to the clips used for eye treatments. Implantation can be carried out under local anaesthetic. The markers can be visualised either radiographically or using a CT scanner or even cone-beam CT (see [Section 40.1.5](#)). Using two orthogonal x-ray images it is possible to calculate the translations and rotations necessary to correct the patient position. These corrections can be applied using a precision patient positioning system such as that shown in [Figure 46.10](#) (Grusell et al. 1994c). Interfraction reproducibility of approximately  $\pm 1$  mm and  $\pm 1^\circ$  can be achieved. To achieve this level of accuracy a corresponding CT scan slice thickness must be used. If necessary the slice thickness can be smaller in the region of the fiducial markers. Ideally coregistered MR and CT images should be used.

Volumes of interest should be defined following the recommendations of ICRU 62 (1999) (see also [Section 29.2](#)), although these are not entirely suited to proton therapy. With proton beams, very precise demarcation of the beam is possible even in the direction of the beam and this should be borne in mind when considering the appropriate margins to use. However, uncertainties in the beam range may exist, especially in the presence of inhomogeneities. The definition of a proton beam requires the specification of the collimator, compensator, beam range and modulation. The treatment plan consists not only of the isodose distributions (see [Figure 46.13](#)) and dose-volume histograms as in photon therapy, but also data to allow the production of collimators and compensators.

A variety of different materials can be used for the collimators: e.g. low melting point alloy, lead or brass. Compensators are made of wax or Plexiglas usually with the aid of a computer numerical control (CNC) milling machine using ‘cutting files’ produced by the treatment planning system.

Before the start of treatment, quality control of all the parameters and devices must be carried out. These include profiles and depth dose curves of the beam to verify the range and modulation, monitor units and dose at the surface. The patient documentation, including the setup instructions must also be checked. Each day or before each treatment session, checks of the beam characteristics and beam calibration must be carried out. For proton beams the depth of treatment varies rapidly with beam energy and it is therefore particularly important to check this. Other considerations specific to proton beams include estimation of the neutron and gamma dose from the direct beam, which may be measured using radiation protection film dosimeters. Although much research work has been done on in vivo dosimetry with thermoluminescent dosimeters, their use is not yet routine.

Because of the complexity of the treatment and the difficulty of achieving the necessary precision, it is common practice for a radiation oncologist and a physicist to be present to oversee the treatment setup in addition to the radiographers.

**FIGURE 46.13**

(See colour insert following page 590.) Treatment planning systems and dosimetry of intracranial targets with high energy proton beams: (a) noncoplanar beams, ray-tracing algorithm; (b) combined treatment with photons and protons, pencil beam algorithm; (c) “patching” techniques to boost targets surrounding a critical structure; (d) intensity modulated proton therapy with four coplanar scanned proton beam. (Figures (a–c) courtesy of Centre de Protontherapie d’Orsay with Isis system, Paris; Figure (d) is courtesy of Trofimov, A. and Bortfeld, T., Boston with KONRAD system, German Cancer Research Center (DKFZ), Heidelberg.)

#### 46.5.3 STEREOTACTIC RADIOSURGERY

Proton therapy is ideally suited to single-fraction brain treatments using stereotactic methods (see Chapter 45). Targets include both tumours and benign conditions such as arteriovenous malformations (AVMs) and functional surgery (Kjellberg and Abe 1988; Fabrikant et al. 1992). The stereotactic radiotherapy programme established at the Lawrence Berkeley Laboratory (where protons were first used for radiotherapy treatment in 1954) was moved to the new proton facility at Loma Linda, California. In Uppsala, Sweden, Grusell et al. (1994a) have developed techniques for the treatment of AVMs and in Faure, South Africa, Jones et al. (1994) have established cross-fire techniques.

A variable number (between 3 and 10) of small noncoplanar beams with diameters between 5 mm and 40 mm are used in a similar manner to photon radiosurgery. The precise positioning of the patient is achieved with the aid of an invasive stereotactic frame (see Section 45.4.1). Early work was based on the use of the cross-fire technique taking advantage of the small lateral penumbra of the proton beam in the plateau region of the depth dose curve

(see [Figure 46.2](#)). Subsequently more use has been made of the depth-dose characteristics associated with the Bragg peak to minimise the number of beams. Collimator design techniques are similar to those described for intracranial tumours in [Section 46.5.2](#).

Compared to *photon-beam* stereotactic radiosurgery, protons offer better conformation to the target volume, excellent dose homogeneity within the target volume and a lower *integral dose*. However, for small diameter proton beams there is a loss of lateral scattering equilibrium. This manifests itself as a reduction in the proton fluence on the beam axis, as discussed in [Section 46.2.3](#). The relative amplitude of the Bragg peak is reduced and it can even disappear when the beam diameter is only a few millimetres. These effects must be taken into account in the beam modelling and in the calculation of the dose and the design of beam-modifying devices.

#### 46.5.4 OTHER SITES SUITABLE FOR PROTON THERAPY

In addition to the ophthalmic and intracranial tumours already described, there are many other sites where proton therapy is of clinical benefit. These include tumours in the vertebral and paravertebral regions, head and neck (paranasal and nasopharynx), central nervous system (meningiomas and gliomas), lung and pelvic tumours (prostate, sacral chordomas and sarcomas) (Munkel et al. 1994; Munzenrider 1994; Lundkvist et al. 2005).

The toxicity of paediatric radiotherapy can be significantly reduced through the use of proton beams while maintaining or improving tumour control. This is not only related to the improved degree of conformality of the high doses encompassing a given target, but also to the significant reduction of the *integral dose* to the healthy tissues, making protons a treatment of choice for paediatric tumours in a number of different locations (Hug et al. 2002; Noel et al. 2003; St Clair et al. 2004). The expected reduction in the probability of second cancer induction is of particular significance for young patients (Mu 2005; Hall 2006b).

---

## 46.6 ECONOMIC AND FUNCTIONAL CONSIDERATIONS

The hospital-based facility in Boston, which has three treatment rooms attached to a 230 MeV isochronous cyclotron and which became operational in 2001, cost a total of US\$46M. Two of the treatment rooms have a gantry, the third has two fixed beam lines dedicated to eye treatments and radiosurgery respectively. Each gantry costs around the same as the accelerator itself. Goitein and Jermann (2003) compared the cost per fraction of proton therapy to the cost per fraction for x-ray therapy. They estimated the current construction cost of a two-gantry proton facility complete with its associated equipment at €62.5M (US\$80M) compared to a two-linear-accelerator x-ray facility at €16.8M (US\$21.6M). Considering the construction, operating and business costs, the costs per fraction were estimated to be €1025 (US\$1320) for protons and €425 (US\$550) for x-rays. This represents a cost ratio of  $2.4 \pm 0.35$  (85% confidence interval). If more proton facilities are built the costs of proton therapy are likely to fall due to economies of scale in the manufacture of proton accelerators and gantries. Goitein and Jermann estimated that were the costs of the capital investment to be written off, the cost ratio would be in the range of 1.3–1.6.

The investment necessary to convert an existing nuclear physics research accelerator to provide the facilities necessary for medical use is very dependent on the detailed local arrangements. In general this will require changes to the beam energy (e.g. degrading from high energies) and modifications to the beam-transport system and shielding and additional safety features. Facilities specific to the patient treatment include an isocentric gantry and patient support system together with the standard hospital clinical facilities. Physics support for dosimetry and a workshop to prepare the patient-specific hardware described in [Section 46.5](#) will also be needed. In the case of the Orsay Centre in France, which did not include an isocentric gantry, the cost of the necessary conversions was similar to the cost of a modern

linear accelerator with its associated equipment (about US\$2M in 1991). However, such converted facilities require a large technical staff and a significant amount of maintenance.

The capacity of existing proton treatment centres range between 20 and 300 patients per year, as some share their activity with physics research programmes. In new, dedicated facilities it is expected that approximately 1000–2000 patients can be treated per year with one accelerator servicing several treatment rooms. The number of fractions per patient is strongly dependent of the clinical protocol in use: 1 fraction for stereotactic irradiations, 4–5 fractions for the ophthalmic treatments, 10 fractions for a boost after a photon treatment, and more than 25 fractions for a treatment given entirely with protons.

The estimation of the number of staff necessary is sometimes difficult, particularly when maintenance and development personnel are shared with a research centre. From the reported figures, the current average is 1 member of staff for every 10 patients treated per year. However, at dedicated treatment facilities treating a large number of patients the staff to patient ratio is much lower. Estimates of the cost of operation (excluding staff salaries) for these facilities vary between US\$250 and US\$400 per hour of operation. In facilities which share their activity with physics research, the running costs are probably higher than this.

---

## 46.7 CONCLUSION

There is worldwide interest in the development of proton therapy as a tool for conformal radiotherapy. Whereas the first treatment units were based around nuclear physics research facilities, the present trend is towards dedicated facilities integrated within a hospital, with modern equipment developed specifically for proton radiotherapy. Due to their inherent depth-dose qualities, proton beams can deliver the same dose to the target volume as photon beams, whilst lowering the integral dose delivered to the patient and, in some cases, reducing the probability of damaging critical organs. For some clinical indications, proton-beam radiotherapy is already established as the treatment of choice with evidence provided through clinical trials. For other indications, the potential benefit of protons still requires clinical validation, but it is expected that their advantages will be demonstrated. Proton-beam radiotherapy is seen as the radiotherapy technique of the future (Suit 1992; Suit et al. 2003; Lundkvist et al. 2005). Cost-effectiveness studies comparing protons with conformal techniques using photon beams (see Chapter 43 through Chapter 45) have been carried out (ANDEM 1995) but these must be kept up to date. Protons should also be compared with the use of heavy ions described in Chapter 49.

### 47.1 CLINICAL GOALS

Total body irradiation (TBI) is used primarily as part of the treatment for leukaemia, but *hemi-body* irradiation can also be used for pain control. For the treatment of leukaemia, the aim is to destroy the patient's leukaemic bone marrow and then to replace it with a bone marrow transplant. Systemic diseases such as leukaemia are usually treated with chemotherapy. However, TBI is able to make two contributions to therapy (Barrett 1995):

---

\* Section 47.5.2 includes contributions by Ginette Marinello.

- Killing leukaemic cells
- Suppressing the immune system to combat rejection of subsequent bone marrow transplants.

Although the first of these is also the goal of the chemotherapy administered at the same time, radiotherapy has the advantage that there are no *sanctuary sites* (Doughty et al. 1987). Opinion is divided on the relative importance of the above two effects and it may also depend on the type of leukaemia being treated. The dose selected is to some extent determined by the philosophy being followed. If immunosuppression is considered the primary aim, then the required dose will be lower (Novitzky et al. 2004). Two reviews of this topic have been written by Vriesendorp (1990, 2003). It has been suggested that Tomotherapy (see [Section 43.3.4](#)) could also be used for TBI, which would allow sensitive organs to be spared (Hui et al. 2005), but there is a concern that this may spare leukaemic cells as well.

---

## 47.2 DOSE AND DOSE RATE

The dose-limiting organ is generally regarded as the lung, which can develop radiation-induced interstitial pneumonitis. Pneumonitis is also associated with chemotherapy and graft versus host disease, and it is difficult to establish an exact dose-response relationship. For single-fraction TBI there is evidence that dose rate is a significant factor. Barrett et al. (1983) argued that the lower rate of mortality due to interstitial pneumonitis, 4.5% at the Royal Marsden compared to 35% in the early days in Seattle (Thomas et al. 1977) might be due to the lower dose rate used (2.5 cGy/min compared to 5.5–8.0 cGy/min). However, this difference in mortality might have been associated with a slightly lower total dose or with patient selection. Kim et al. (1985) compared the results between patients treated on a Cobalt unit at 4.7–6.3 cGy/min and patients treated on an accelerator by a swept beam technique that was associated with instantaneous dose rates of 21–23.5 cGy/min. In the first group, 2/11 died of pneumonitis, compared to 8/11 in the second group. Ringdén et al. (1983) obtained a significantly higher death rate for patients treated at a dose rate of 7 cGy/min compared to 4 cGy/min. Beyzadeoglu et al. (2004) also found that less than 4 cGy/min produced significantly less interstitial pneumonitis, whereas the median total dose to the lung, which ranged from 8.9 to 10.9 Gy, was not a significant factor in their study. The need for an even lower dose rate is suggested by O'Donoghue (1986) based on radiobiological considerations. Treatments at these very low dose rates are very time-consuming and most centres that do not have a specialised facility have opted for fractionated treatments, although there is some evidence that single-fraction treatments may provide better leukaemic cell kill (Cossett et al. 1990). A single fraction dose of 10–10.5 Gy is generally considered to be equivalent to a fractionated total dose of around 12 Gy (a discussion of these issues can be found in [Chapter 9](#)). However, Beyzadeoglu et al. (2002) showed that there is a statistically significant increased incidence in cataract formation at dose rates above 4 cGy/min, even for fractionated TBI. In a study by Ozsahin et al. (1996), the effect of dose rate was apparently independent of fractionation. They reported that low dose rates (<4.8 cGy/min) were less effective in controlling the disease, but that high dose rates (>9 cGy/min) were more toxic to the lungs. They therefore recommended the use of a dose rate between these two limits. The effect of the dose rate in fractionated TBI has also been demonstrated by Carruthers and Wallington (2004), who found a significantly increased rate of pneumonitis when 15 cGy/min was used compared to 7.5 cGy/min. The effect of radiation dose rate can also be dependent on the chemotherapy regime. Safwat et al. (1996), using a mouse model, found that when TBI was combined with cyclophosphamide, low dose rates were more toxic to lung than high dose rates, whereas without chemotherapy, high dose rates were more toxic.

---

## 47.3 DOSE SPECIFICATION

The point at which the dose is specified is an important consideration. It has been recommended (Dutreix and Broerse 1982; Leer et al. 1990) that the dose be specified at the centre of the abdomen, but some centres, such as the Royal Marsden, prefer to specify the dose to the lung since this is the dose-limiting organ. (In the survey carried out by Leer et al. (1990) only two out of 18 centres followed this latter practice.) In contrast, the American College of Radiologists practice guidelines (ACR 2001) do not specify the dose prescription point, although they suggest the abdomen at the level of the umbilicus. This choice will depend partly on whether the dose to the lungs is controlled by shielding. If no lung shielding is used, it makes sense to prescribe a maximum dose to the lung. In any case, it is recommended that the dose to head, neck, shoulder, thorax, abdomen, pelvis and ankle be recorded (Briot et al. 1990); the dose to upper thighs and knees may also be recorded. European guidelines on reporting TBI have been published (Sanchez-Doblado et al. 1995).

Dose homogeneity is regarded by some clinicians as important (Doughty et al. 1987), but by others (Barrett 1995) as less so because they consider that the aim is to give as much dose as possible to the areas most likely to contain disease. This can be taken further by the application of a boost dose to the brain or to the spleen (Lapidot et al. 1988).

---

## 47.4 AVAILABLE TECHNIQUES

Useful reviews of the many techniques in use are given by Quast (1987) and Thomas (1990). Apart from hospitals such as the Fred Hutchinson Cancer Research Center in Seattle and the Royal Marsden in the United Kingdom, which have specialist TBI facilities (see Section 47.4.1), most treatments are done using a horizontal beam with the patient located as far away from the source as possible. The size of the field available will depend on the distance from the source that can be achieved. On a conventional treatment machine, the head can be rotated to 45° to achieve the maximum field size. The patients may then be treated lying on their side with an anterior-posterior (AP) beam or lying supine with a lateral beam. In either case, it is necessary to rotate the patient so that an effectively parallel opposed beam will be achieved. Knees may be bent to reduce the length of the patient (see Figure 47.1). In some centres, the patient sits in a chair. From the point of view of reproducibility of the setup, the supine position is undoubtedly superior, but has the disadvantage that the lateral separation is always greater than the AP separation, which may be more of a problem when using lower-energy beams (e.g. cobalt-60).

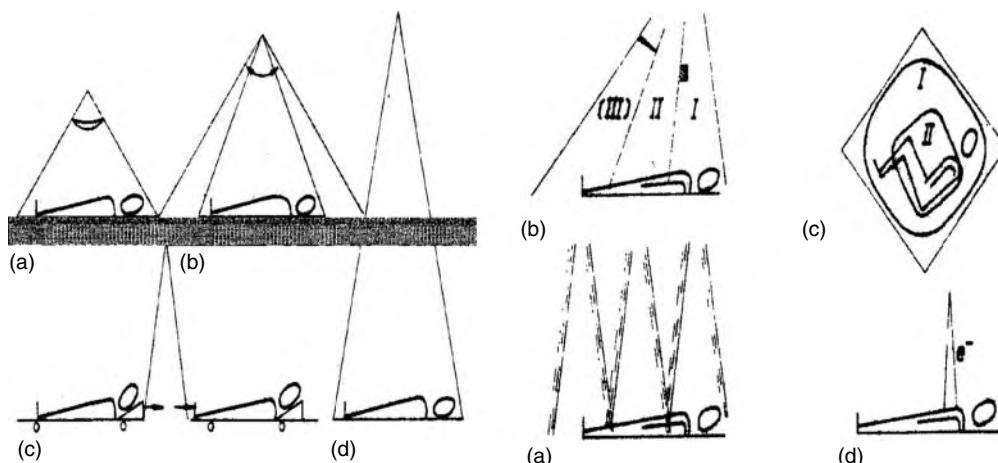

Umek et al. (1996) describe a cobalt-60 technique in which the couch is moved during the treatment, thus reducing the need for extended source-skin distance. Couch speed is altered depending on the thickness of the patient to produce a relatively homogeneous dose distribution.

### 47.4.1 CUSTOM-DESIGNED FACILITIES

The Royal Marsden is one of three centres in the world that has a specially designed treatment facility for TBI (Edser 1988; Lewis and Rosenbloom 1988)\*. Two Theratron-780 heads are mounted on a frame, which allows them to be up to eight metres apart in the vertical direction. This enables a routine treatment distance of 3.50 m to be used. In a cobalt-60

---

\* The other two are the original centre in Seattle (Thomas et al. 1977) and the Joint Center in Boston, where there are two linear accelerators mounted to give a horizontal beam.

**FIGURE 47.1**

Alternative approaches to TBI. (From Quast, U., *Radiother. Oncol.*, 9, 91–106, 1987. With permission.)

Co beam, the dose rate drops towards the edge of the beam and so a compensating or flattening filter has been designed to reduce the dose at the centre of the beam relative to the periphery. The machine is equipped with a set of four attenuators, which are used to alter the machine dose rate as the source decays. One of the attenuators was designed to flatten the beam and is left in at all times; a second thick filter reduces the dose rate to about 0.2 Gy/min. Combinations of the other two filters allow the dose rate to be altered in four steps. One of the attenuators is equivalent to one year's decay and the other to two year's decay. This enables the dose rate to be kept to within 20% of its original value over a four-year cycle. The collimators are designed to provide a field length of 2 m at a treatment distance as small as 2 m.

The choice of a vertical AP beam was made on the grounds of patient reproducibility. However, when measurements were made, it was found that the dose rate at the patient's head was reduced because of loss of scatter, which could not be corrected by placing scattering material around the head. For this reason, patients had to be treated lying on their side as well. In practice, one of the problems of single-fraction TBI is that the patient may vomit, and it is easier to cope with this when the patient is not supine; also many patients find lying on their side more comfortable. Patients are treated either 50% supine and 50% on side or 33% supine and 67% on side for single-fraction TBI. For fractionated TBI, patients are less likely to vomit, but the dose distribution is improved by including the lateral treatment position. From the point of view of the reproducibility of dosimetry, however, it can be clearly demonstrated that the lateral position is less satisfactory.

#### 47.4.2 USE OF A STANDARD LINEAR ACCELERATOR

Figure 47.1 illustrates a number of different ways of treating patients using an accelerator beam. When carrying out TBI on a linear accelerator, logistical considerations dictate that treatment is either fractionated or carried out at a weekend. Fractionation is the preferred method, as there is less concern about dose-rate effects (but see [Section 47.2](#)). If single-fraction TBI is to be used, it is important to lower the dose rate; this can usually be achieved by altering the pulse-repetition frequency (PRF) of the accelerator (see [Section 11.3.2](#)). The patient will normally be placed as far away from the source as possible to obtain a large field with a horizontal beam. Again, for reasons of setup reproducibility, patients are best treated supine rather than lying on their side. With a lateral beam and a supine patient, the dose to the head will normally be too high. This can be corrected either by including treatment with the patient lying on their side or by some form of compensating filter (see [Section 47.5.4](#)). For

fractionated TBI, the latter option is clearly preferable because of the improved ease of setup, but if single fractions are being used the difficulty of maintaining the patient in exactly the same position for three hours or so may make the use of any form of compensation impractical. Doughty et al. (1987) have described the technique used at St. Bartholomew's Hospital, which aims to ensure that the dose is homogeneous within 5% throughout the body, although as mentioned above, it is questionable whether an increased dose to the legs is necessarily a bad thing.

Miralbell et al. (1994) have developed a technique in which the patient is supported in an upright position, thus allowing treatment with a horizontal AP beam. This has the advantage that the thickness of the patient is smaller in the AP direction and partial lung shielding is easier. Methods of treating with a vertical AP beam are shown in [Figure 47.1](#).

Because there are "horns" at the edge of the (conventionally flattened) beam, it may be necessary to use an *inverse* flattening filter (Doughty et al. 1987) to achieve a flat beam. The design of this additional flattening filter should be based on measurements at depth (e.g. 10 cm) rather than on in-air measurements. It can take the form of a series of concentric rings of Perspex, which can be mounted on the shadow tray of the accelerator. It is wise to check that the beam is flat before *each* treatment. This can conveniently be done using the diodes used for measurement (see Section 47.5.2).

---

## 47.5 DOSIMETRY CONSIDERATIONS

The dosimetry of TBI gives rise to a number of problems that are not normally found at shorter SSDs and with smaller field sizes. A thorough analysis has been presented by Briot et al. (1990). Measurements made in a cuboidal phantom may not be appropriate, as scatter from throughout the long thin patient will contribute to the dose. Attempts at dose calculation have proved difficult, although with high energy x-ray beams (Houdek and Piciotta 1987; Jani and Pennington 1991) the results have been more successful than with cobalt-60 beams. In addition to the problems of scatter, there is also the effect of the density of lung. Lung densities vary between patients, and since this is the region of greatest risk to the patient, it is important to achieve the highest possible accuracy. For these reasons it is common practice to carry out a *test dose* on a previous day so that measurements can be checked and monitor units calculated. For a cobalt-60 beam, the in-air scattered electrons associated with the very large field size (Kassaei et al. 2001) are sufficient to eliminate the build-up effect, but if an accelerator is being used it is necessary to use a Perspex™ sheet in front of the patient. It is not particularly critical how far from the patient this sheet is placed (Planskoy et al. 1996a). A 1 cm thick sheet is sufficient to bring the surface dose to 99% for an 8 MV beam.

### 47.5.1 CHOICE OF ENERGY

The energy chosen will often depend on what is available. There are advantages to being able to use a high-energy machine, as this reduces the difference between the dose at the mid-line of the patient and the dose at  $d_{\max}$ . [Table 47.1](#) compares the ratio of mid-line doses to peak doses for cobalt-60, 6-MV x-rays and 10-MV x-rays for a 30 cm thick patient. The table illustrates clearly the advantages of using higher energies.

### 47.5.2 DOSE MEASUREMENT

Because of the importance of accurate dosimetry in this potentially life-threatening treatment, it is usual to carry out *in vivo* dosimetry (van Dyk et al. 1986; ESTRO 1987;

**TABLE 47.1**

Effect of Energy on the Ratio of Maximum to Minimum Dose

	SSD = 2.5 m	SSD = 3.5 m
Cobalt-60	0.909	0.923
6-MV x-rays	0.940	0.953
10-MV x-rays	0.967	0.976

Indovina et al. 1989; Briot et al. 1990; Mege et al. 1994; Planskoy et al. 1996a, 1996b; Mangili et al. 1999). Doses delivered during TBI are difficult to evaluate accurately because of:

- The very large fields employed. These frequently require that the patient is positioned very close to the floor or to the walls of the treatment room, which may produce significant electron and photon backscattered components that reach the patient's skin (Lam et al. 1979; van Dyk et al. 1980; van Dam et al. 1988)
- The necessity to correct for tissue inhomogeneities (Marinello et al. 1982) and to monitor the dose to the organs at risk (lungs, liver, etc.)
- The difficulty of achieving a reproducible setup and the possibility of the patient movement during the treatment, especially for low dose-rate single fraction treatments.

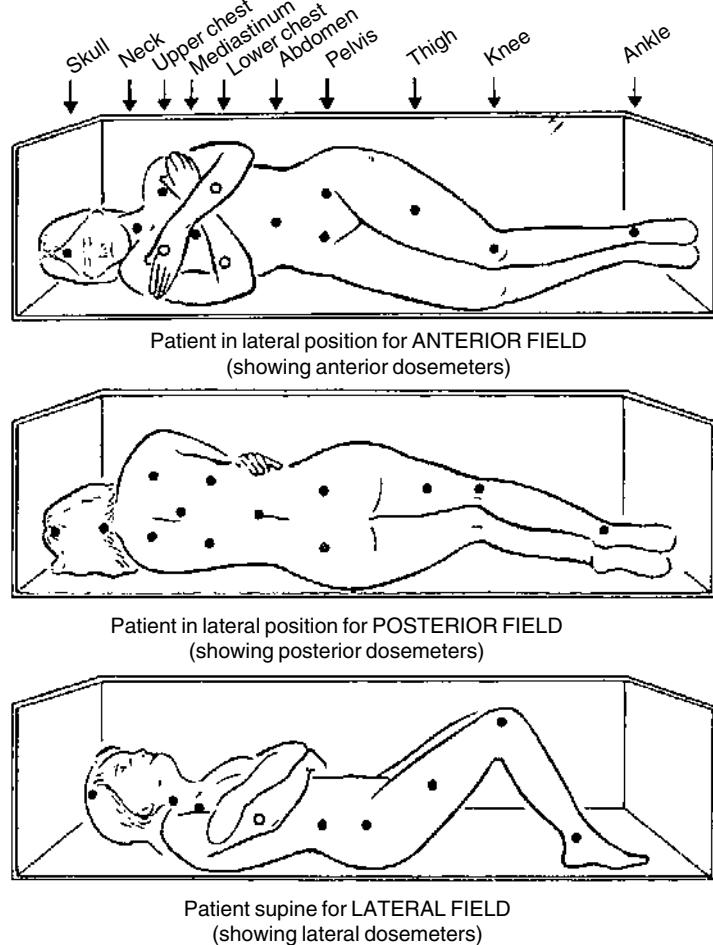

The in vivo measurements can be used either as a check of the calculated doses or calculated doses may be used to check the measurements.

Because the treatment technique is designed for clinical reasons to have the minimum possible build-up region, both the skin and the in vivo detectors are almost in full-build up conditions. The build-up cap required can therefore be thin or may even be unnecessary with some dosimeters (consequently there is no risk of target underdosage due to the attenuation caused by in vivo detectors in TBI conditions).

In vivo dosimetry generally consists of entrance and exit dose measurements performed on different regions of the patient's skin (Figure 47.2). The points of measurement must be chosen such that they allow for both verification of the dose delivered at the point of dose specification (usually taken at mid-pelvis or mid-abdomen) and estimation of the homogeneity of the midline dose distribution in the cranio-caudal direction of the patient using the general methodology detailed in van Dam and Marinello (1994). Theoretically, the lung dose can also be deduced from entrance and exit dose measurements, but the problem of the inaccuracy of its estimation from a measurement at a single point has been pointed out by several authors (Marinello et al. 1982; Briot et al. 1990; Planskoy et al. 1996b).

Either diodes or thermoluminescent dosimeters (TLD) can be used. If the department has access to the necessary specialised and expensive readout system, alanine dosimeters are particularly suitable. The nondestructive readout of the electron spin resonance signal can be advantageously exploited to monitor the dose increment fraction-by-fraction in fractionated therapy, the final objective being to check the total dose, provided that the same dosimeter is applied each day at the same position on the patient (Indovina et al. 1989).

Diodes provide an immediate response, which enables the immediate correction of any patient movements. Care must be taken when making measurements behind shielding blocks, because low-energy scattered radiation contributes a substantial fraction of the dose, which can introduce inaccuracies in dose determination due to possible variation of dosimeter response with (lower) energy. For the low dose rates used in single-fraction TBI, it becomes very important to balance the diode measurement circuit accurately to minimise the *offset current*. It is also important to consider the effects of temperature (see Section 16.3.4.7) on the diodes, which will be in contact with the patient's skin for a long time and will therefore reach body temperature. This may affect both the offset current and the sensitivity of the diodes.

**FIGURE 47.2**

Example of in vivo dosimetry practiced at the Royal Marsden Hospital for total body irradiation: filled circles show the position of dosimeters nearer irradiation sources and open circles the dosimeters shielded by the arms. (From Rosenblom, M., Hickling, P. A., Chow, M., Chittenden, S., Machardy, J. et al., *J. Eur. Radiother.*, 3, 246–248, 1982.)

Diodes have directional asymmetry and it is important to consider this aspect when calibrating them for use in TBI, in which the contribution of electron contamination and scattered photons may be much greater than at standard SSDs and field sizes. The type of diode must be selected according to the energy in use, but diodes that are recommended for normal use at a lower energy may be appropriate because of the reduction in build-up (see above).

TLDs allow a large number of sites to be measured at the same time and give accurate results even behind shielding blocks because of their closeness to tissue equivalence over a wide energy range. With automatic TLD readers adapted for medical use, the dose readout can be obtained approximately 15–30 minutes after irradiation. Moreover, most TLD readers can be connected to a portable computer so that stored data can be processed immediately after readout and the results directly integrated into the patient's file.

Doses to the head, the lungs, the abdomen and the pelvis should be measured (see **Section 47.3**). Extremity doses should also be measured, at least occasionally. When using a horizontal accelerator beam, it is important to guard against the effect of low-energy back-scattered radiation from the wall of the treatment room. This can be reduced by placing a low-atomic-number absorber between the patient and the wall (van Dam et al. 1988).

Whatever method is being used, the calibration of the detectors must be done in the TBI geometry.

A useful approach to the assessment of the homogeneity of the dose distribution is to take a portal film (Signorotto et al. 1996). This can be scanned with a densitometer to obtain the dose distribution on the exit surface of the patient. If no compensators are used, this should ideally show a uniform field, but if the input dose distribution is not uniform, the exit dose will not bear such a straightforward relationship to the mid-line dose distribution. Some authors have proposed the use of a combination of *in vivo* measurements at specific points and portal dosimetry (films or electronic portal imaging) to overcome this problem (Essers and Mijnheer 1999; Mangili et al. 1999).

When making measurements in large fields with ionisation chambers it is important to bear in mind the possibility of stem and cable effects (van Dyk 1987; Planskoy et al. 1996a). The amount of charge arising from outside the chamber itself can be assessed by shielding the chamber (see [Section 15.4.3](#)). The expected decrease in dose due to the shielding can be calculated and compared to the actual measurement.

It is important to remember that the dose measured by surface dosimeters is the maximum dose; to obtain the mid-line dose, a correction must be applied. For treatments from a single portal, closer agreement to the mid-line dose may be obtained by using the geometric mean of the entry and exit doses (Mijnheer 1996). However, the best approach is to use a graph of the mid-line dose against patient separation. In comparing doses between treatment clinics, it is important to find out exactly how the dose is measured. For example, at the Royal Marsden the surface doses from the lateral and the anterior-posterior beams are added together, even though they do not represent the dose at the same point. This practice arose because of the intention to stay within lung tolerance. The difference between the dose calculated in this way and the mid-line dose is about 7%.

#### 47.5.3 DOSE CALCULATION

A number of centres have sought to calculate the dose as opposed to measuring it (van Dyk 1985, 1987; van Dyk et al. 1986; Doughty et al. 1987; Houdek and Piciotta 1987; Thwaites et al. 1990; Jani and Pennington 1991) with varying degrees of success; a key paper is that by van Dyk (1987). A satisfactory approach is to make measurements at a constant Source Chamber Distance in a phantom designed to represent a full-size patient\*. These measurements can be used to produce a graph of tissue-phantom ratios (see [Section 23.2.1.6](#)) relative to a measurement at 5 cm deep in a phantom. Then it simply remains to measure the absolute dose at a depth of 5 cm to be able to predict the dose at the mid-line in the abdomen. This is particularly convenient if the patient is always set up with the mid-line at a fixed distance from the source. To obtain doses in the region of the lung, it may be possible to take a few CT scans. For an 8 MV beam, this gives satisfactory results simply using the equivalent pathlength method (C. D. Lee unpublished results). Abraham et al. (2000) obtained satisfactory calculations of the lung dose using a standard treatment planning system with a full CT representation of the patient. The extended geometry of the TBI situation can create problems for standard planning systems (Well et al. 1991). To overcome these problems Planskoy et al. (1996a, 1996b) adapted the Bentley–Milan-based electron algorithm<sup>†</sup> of the *Target* system (International General Electric) to calculate dose distributions around the lung.

\* This can be created using *solid water* close to the ionisation chamber and hardboard or large containers of water to make up the rest of the shape of the patient.

† The *electron* algorithm allowed more fan lines to be used than the *photon* algorithm; the words *photon* and *electron* here are essentially just labels. It is characteristic of the Bentley–Milan model that it simply reproduces the measured dose distribution in a structured way.

Doses at the extremities will be reduced due to lack of scatter, as will doses close to the lung. It is probably sensible to concentrate on calculating mid-line doses since these are less likely to be affected by the electron contamination experienced at the surface of the patient (van Dyk 1987). It is also important to remember that very young patients may also be treated and the scatter dose will be less in this case.

#### 47.5.4 COMPENSATION

To achieve a uniform dose throughout the body, it is common practice to use various forms of compensation. Because skin sparing is not desirable, the use of bolus is not counter-indicated, and in the St. Bartholomew's technique (Doughty et al. 1987) bolus is extensively used with the aim of achieving a constant separation equivalent to that of the hips. The disadvantage is that the increase in the uniformity of surface dose measurements may be at the expense of the dose at mid-line. For the lung, *lead rubber* can be used, usually attached to the Perspex screen close to the patient, or brass compensators may be made to the thickness required. These may also be mounted on the head of the accelerator, which has the advantage that the borders are rather less sharp, in keeping with the fuzziness of the border of the lung. A simple and effective approach to lung shielding which is convenient for single-fraction TBI is to use the patient's arms (which is the technique used at the Royal Marsden).

Port films taken on the treatment machine provide a transmission map of the patient. These data can be used to design lung compensators (Hussein and Kennelly 1996) that accurately reflect the transmission through the patient. Another technique of compensation is described by Galvin et al. (1980).

There may be problems associated with beam *softening* towards the edge of an accelerator beam, which will mean that the attenuation of any absorber will be increased. van Dyk (1987) reports that (effective) linear attenuation coefficients may vary by about 10%, depending on the field size, and this should be borne in mind when designing flattening filters and compensators (Table M.3 can also be consulted).

---

## 47.6 SUMMARY

The main points are summarised as follows:

- TBI delivers a potentially lethal dose of radiation and thus the accuracy of the dosimetry is particularly important.
- Care must be taken to ensure that the dose is specified in the same way if dose comparisons are made between centres. The dose rates and fractionation used must also be considered.
- The concurrent chemotherapy has a synergistic effect with the radiation and the treatment regime must therefore be considered as a whole.
- The lung is the dose-limiting organ and thus particular care must be taken to ensure that the lung doses are correctly determined.
- Measurements must be made in *TBI conditions* rather than at standard SSDs.
- Measurements at depth are more reliable than surface measurements (although only the latter are possible on the patient). The effects of electron contamination close to the surface must be borne in mind.
- In vivo dosimetry is an essential check, even when calculation is used as the method of setting the monitor units.
- Calculation of doses is an important safeguard, even when monitor-unit settings are based on measurements.
- The possible effect of beam *softening* off-axis should be considered.

## 48.1 INTRODUCTION

The technique of total skin electron irradiation (TSEI), or total skin electron therapy (TSET), is used to treat a variety of cutaneous malignancies where most or all of the skin is involved. The aim is to treat the whole skin to as uniform a dose as possible, both circumferentially around the patients as well as along their length. The uniformity requirement comprises an acceptably uniform and high surface dose, uniform dose at  $d_{\max}$  (that should be

---

\* With contributions by Ginette Marinello.

at, or close to, the surface), and also a uniform penetration and dose delivery to the required therapeutic depth, selected to match the presenting disease and stage. At the same time, the treatment should spare other underlying organs and minimise the whole-body dose from the bremsstrahlung x-ray component of the beam.

The main use of TSEI is in the treatment of *mycosis fungoides*, a cutaneous T-cell lymphoma arising in a very small number of people per million each year, and related conditions (Szur 1975; Hoppe et al. 1977). However, a range of other rarely presenting malignant diseases requires a similar approach, including inflammatory breast disease and Kaposi's sarcoma. TSEI techniques have also been used for other dermatological conditions covering large areas that do not respond to alternative treatments (e.g. Kavanagh et al. 1997). There is no clear consensus on the prescription dose, being typically in the range of 20–40 Gy, delivered over a period from 2 to 6 weeks, or longer. Dose per fraction and fractionation schedules are often dictated by a compromise between clinical requirements and pragmatic technical and time restrictions. TSEI is not widely practised because of the rarity of the diseases for which it is appropriate, and also due to the technical complexity of commissioning the technique and of the treatment itself, coupled with long patient set-up and treatment times.

Some of the techniques and practical considerations necessary to implement TSEI are reviewed in AAPM report 23 (1987).

---

## 48.2 GENERAL CLINICAL AND PATIENT-RELATED PROBLEMS

The patient-related problems are mainly linked to the marked irregularities in surface shape and to the variations in the cross-sectional dimensions of different areas of the body, making it intrinsically difficult to achieve uniform distributions. Additionally there is always some self-shielding of one part of the body by others and some areas of the body may be omitted from treatment due to the patient position (e.g. the soles of the feet if the patient is standing). Other areas may always receive low doses because their position dictates some self-shielding and poor penetration because all beams are tangentially incident (e.g. the perineum or the top of the head). Such areas may require subsequent boosts with small-area fields, if deemed clinically necessary. A significant number of the patients referred for TSEI are elderly and may not be able to stand for long periods, or may have difficulty taking up complex positions, if these are required to minimise self-shielding. TSEI patients can present for treatment at various stages of their disease (e.g. for mycosis fungoides: with superficial involvement only, through a generalised plaque stage, to a tumoral stage). Consequently, variable depth penetration may be required for different patients. Some may present having previously received treatment to a number of areas with electrons or kilovoltage x-ray beams. There may be a requirement to treat only part of the body but a large area, or to shield specific areas (e.g. fingernails, toenails, and eyes). The same patient may return subsequently for repeated treatment or treatments.

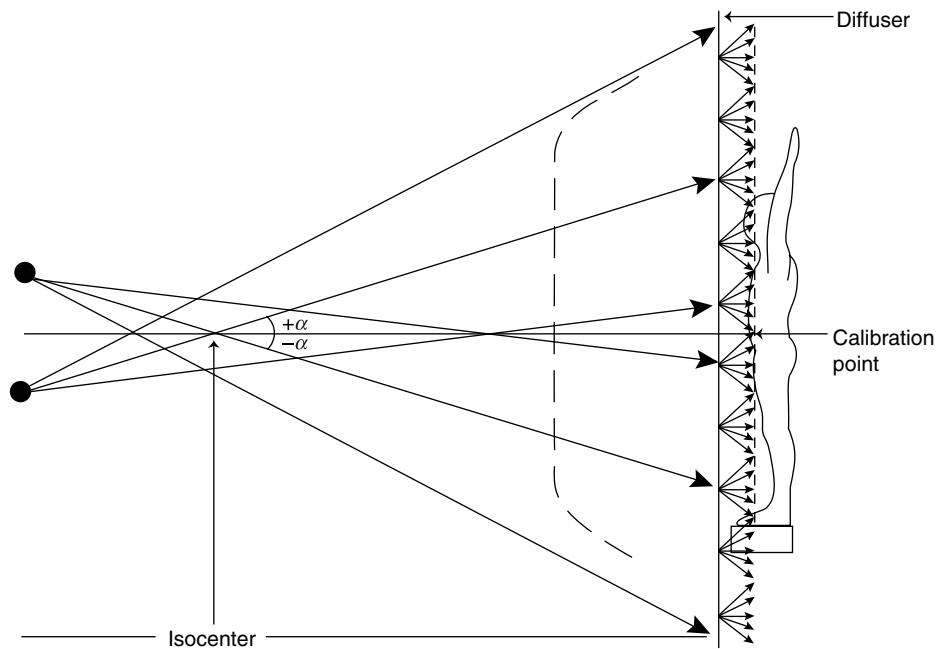

---

## 48.3 PHYSICAL AND PRACTICAL REQUIREMENTS

### 48.3.1 DOSE DISTRIBUTION ALONG THE PATIENT

A uniform distribution, to around  $\pm 5\%$ , is required. This covers the entire length of the patient, generally positioned with arms above the head (i.e. with dimensions of around 80 cm  $\times$  220 cm). This has been achieved in a variety of ways:

1. Using medium SSD (1.5–2 m) with the patient in a lying position and either adding large fields with wide penumbra (Thwaites 1988), translating the patient through the beam (Williams et al. 1979) or by arcing beams longitudinally (Wu et al. 1997);

**FIGURE 48.1**

Schematic illustration of the dual-beam technique showing how two scattered distributions can combine to produce a uniform profile over the patient length.

- Using longer SSDs (3–5 m) and the patient in a standing position. In this case the unmodified beam profile approaches a wide Gaussian, due to scattering in the air. A uniform distribution over the patient's height is achieved either with dual added fields angled both up and down from the horizontal by  $\pm 10\text{--}20^\circ$ , such that the combined distribution is uniform (Figure 48.1) e.g. the Stanford technique (Karzmark 1967; Page et al. 1970) or the Memorial technique (Edelstein et al. 1973; Holt and Perry 1982); or with a single field utilising a customised scattering filter to produce the uniform distribution (Podgorsak et al. 1983; Kim et al. 1984); or with vertical arcs (Sewchand et al. 1979).

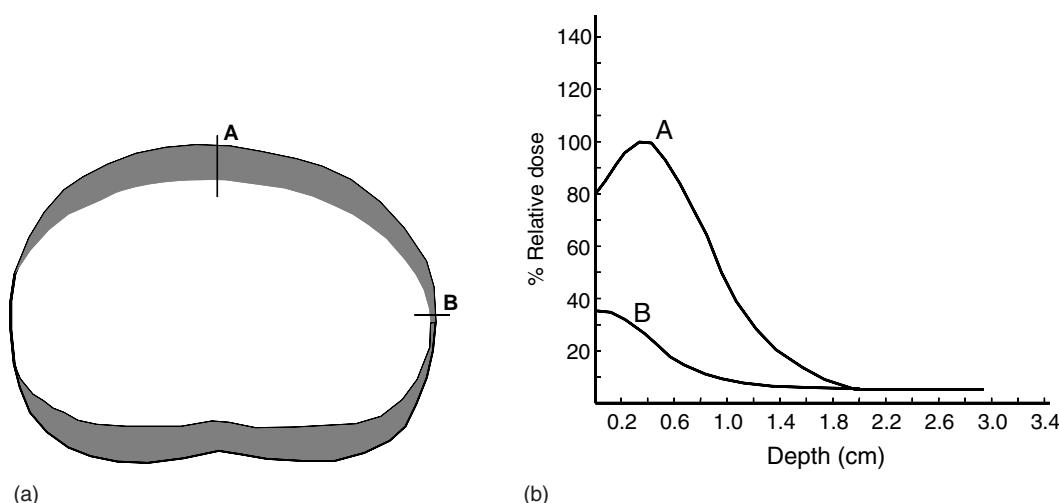

The distribution may be affected by scatter from the floor toward the feet of a standing patient and this should be taken into consideration. A low platform of Styrofoam, or similar material, can be used to minimise this.

It is important to take account of the effect of the intervening air in these extended-distance treatments. Three metres of air will add a relatively small contribution to the mean-square angle of scatter, but this amounts to a significant lateral displacement over 3 m. Therefore, it is important not to restrict the aperture of the scattered radiation at the linear accelerator head, so that in-scattering of electrons from air outside the target area can help to maintain beam uniformity.

#### 48.3.2 DOSE DISTRIBUTION AROUND THE PATIENT

A uniform distribution and penetration is required around the patient and this requires multiple beams. Some early reported techniques suggested the use of only two beams, but this gives very variable distributions across the patient, particularly at the edges, where the electrons are more and more obliquely incident, eventually being tangential with minimal penetration (see Figure 48.2 for two single opposed fields).

The distributions are improved by increasing the number of fields (or effective number) around the patient:

**FIGURE 48.2**

The effect of two single electron fields incident on the pelvis of a patient from the anterior and posterior directions. (a) Section through the pelvis. The shaded area is the part of the patient that receives a dose greater than 10% of the peak dose as measured with a film in the transverse plane of a phantom. (b) Depth dose curves along the two lines A and B in (a). (Adapted from Kumar, P. P. and Patel, I. S., *Clin. Radiol.*, 33, 495–497, 1982.)

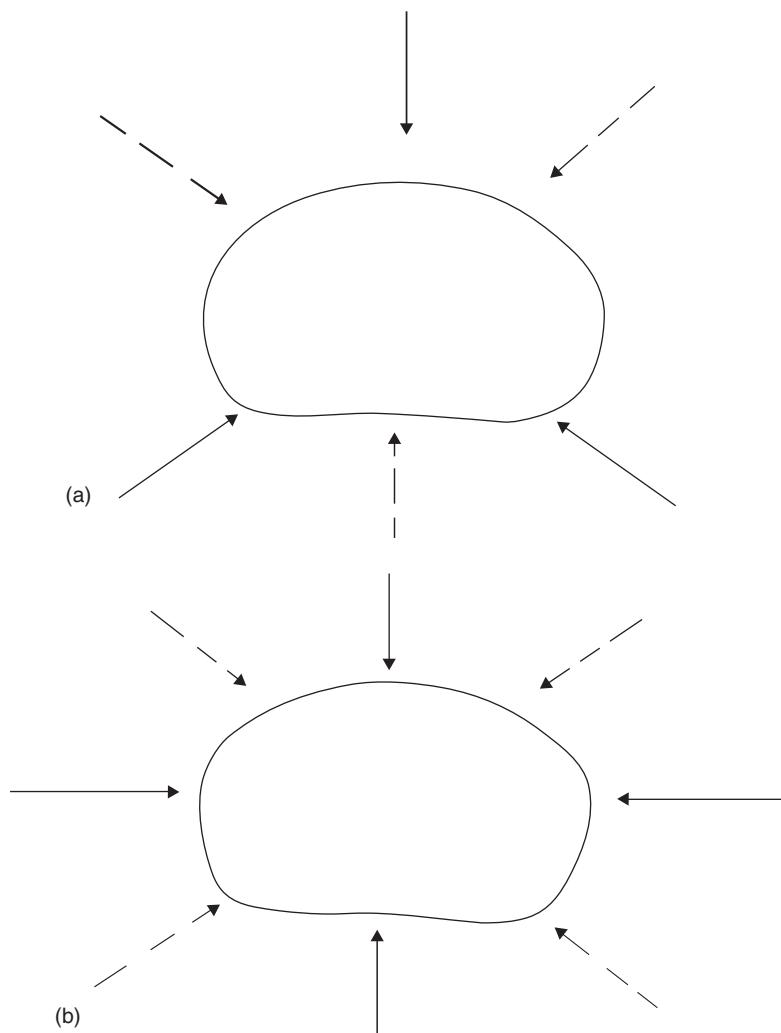

- Two fields with varying angulation of the patient (Williams et al. 1979)
- Four-fields also with changing angulation at different fractions (Thwaites 1988)
- Six-fields (Figure 48.3a, Stanford technique)
- Eight-fields (Figure 48.3b)
- Continuous (slow) rotation (McGill technique, Podgorsak et al. 1983).

For patients lying horizontally, this means positioning prone, supine, on left or right side as necessary, with the aspect to be irradiated presented to a nominally zero gantry angle beam, with angulation achieved either by small gantry-angle changes, or by modifying the angulation of the couch surface using supporting wedges. For standing patients, a number of pre-set positions can be selected on a rotatable platform. Using more fields improves the uniformity of the dose distribution around the patient in terms of the magnitude of the surface dose, the depth of penetration of the electrons and the depth (and magnitude) of the maximum dose.

#### 48.3.3 BEAM ENERGY

The penetration needs to be matched to the required clinical depth. Generally, for superficial involvement only, or where shallow plaques are present, this requires the therapeutic range to be in the range 3–6 mm. The beam penetration of interest here is the final effective penetration achieved by the total combination of all field positions and directions. This produces a significantly smaller depth of dose maximum and therapeutic range than for a single field, due to the effects of oblique incidence, scattering, etc, although the practical range and bremsstrahlung are similar, all other things being equal. The beam energies that are used for TSEI are generally chosen to be in the range of 6–10 MeV as they emerge from the accelerator. These are typically reduced to 3–6 MeV at the patient surface partly by the energy loss in the air (approximately 0.25 MeV/m) and partly by the addition of plastic (e.g. PMMA) energy-degrader sheets, typically of 5–10 mm thickness, close to the patient\* (i.e. approximately 20 cm). The depth

\* These sheets also maintain a high surface dose and help to scatter the beam at this position, thus increasing the doses in less directly accessible areas and improving the distribution.

**FIGURE 48.3**

The beam directions around the patient in (a) six-field and (b) eight-field techniques. Typically, half the fields are delivered on alternate fractions (full lines) and the other half on the other fractions (dashed lines).

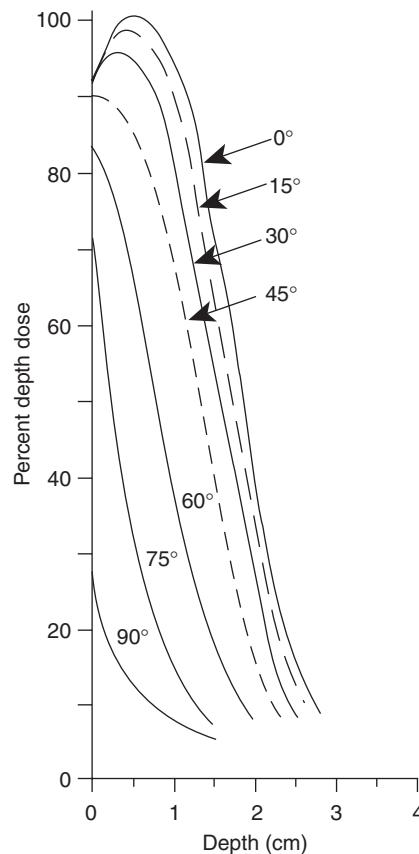

doses of the single field vary with angle of incidence across the beam (i.e. around the patient surface as illustrated in [Figure 48.4](#); Bjarngard et al. 1977; Pla et al. 1988).

Using a dual-angled technique, the penetration will be reduced even on the central axis. The final effective depth-dose will depend on appropriate weighted addition of all possible penetrations at any point on the skin from all incident beams, dependent upon the technique being used (Kumar and Patel 1982) (see [Figure 48.5](#)). Changes in the effective penetration can be achieved by varying the thickness of the degrader.

The distribution around the patient and the penetration will vary somewhat with the size of patient cross-section and, therefore, with anatomical position on the patient. This will be more marked for shorter SSD techniques.

#### 48.3.4 X-RAY CONTAMINATION

Typically, for beams of 6–10 MeV initial energy, the bremsstrahlung tail of the electron depth-dose curve is around 1% (0.5–2%) of the maximum dose. For TSEI treatments, the

**FIGURE 48.4**

Percentage depth dose curves at different angles from normal incidence, for a nominal 4.5 MeV surface energy electron beam measured as part of TSEI commissioning. Each curve is normalised to the 100% value at  $0^\circ$ .

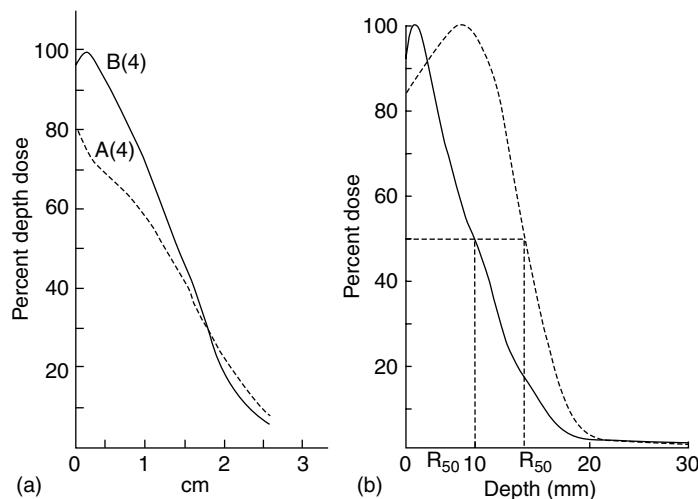

**FIGURE 48.5**

Illustration of the combined depth-dose curve at two extreme positions on a cylindrical phantom for (a) a four-field technique for the same beam as in Figure 48.4 and (b) for a dual-beam six-field technique.

x-ray component will irradiate the whole body and the contribution from each field direction will therefore be additive. The higher the number of fields employed, the lower the given dose on each individual field. For typical multiple-field irradiations, or for rotational techniques, the single-field percentage x-ray contribution is approximately doubled when measured at the patient midline (Holt and Perry 1982; Podgorsak et al. 1983) to approximately 2% (1–4%) of the total TSEI dose. One advantage of the dual-angled technique is to minimise the effect of the x-ray contribution, as the x-rays are predominantly forward-thrown (see [Section 3.3](#)) and the angling aims this mainly above and below the patient.

#### 48.3.5 DOSE RATE AND TREATMENT TIME

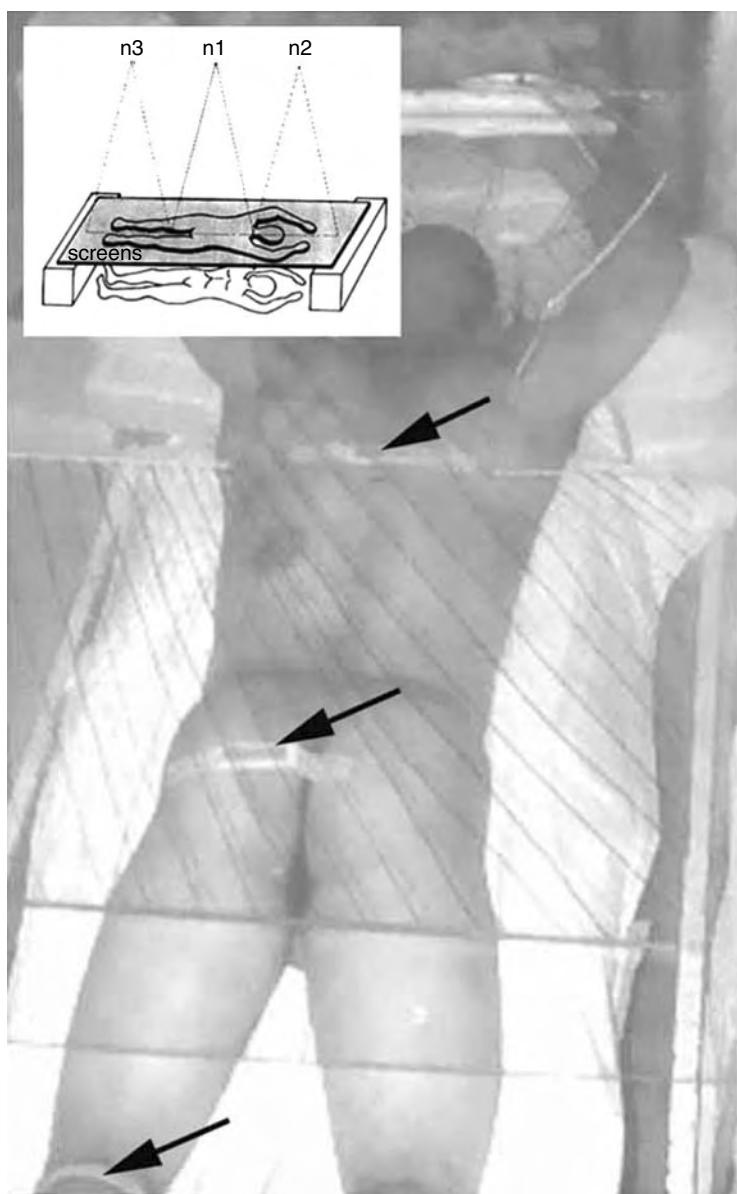

Some shorter SSD techniques were dictated by the available dose rates available, as a long SSD reduces the dose rate faster than that due to the inverse square law alone because of scatter, and to such a degree that the treatment times became excessively long. High dose-rate modes are available on at least one electron energy on most current multi-modality accelerators. These typically provide dose rates up to a factor of nearly 10 times higher than normal at 100 cm SSD, with appropriate safety interlocks. This, in turn, allows dose rates to be achieved on the order of 1 Gy/min at 3–5 m SSD. However, for either short or long SSD techniques, the set-ups and treatments are complex and typically the treatment times are long in any case. As a result, compromises are often introduced in centres where the accelerators have a heavy workload and where too much time cannot be dedicated to one treatment. In these cases, not all fields are given at each fraction. For example, three of the six Stanford-technique directions (six separate fields in practice if dual-angling is employed) may be given on half the fractions, alternating with the other three on the other fractions. Main fields may be given on four fractions a week, with top-up fields to under-dosed areas on the fifth day etc. In this way, the uniform dose distribution is delivered over a cycle of treatment, with the treatment time being acceptable on any given day.

#### 48.3.6 DOSIMETRY

The dosimetry of TSEI is reviewed in AAPM (1987). In addition to beam uniformity, depth doses, and x-ray contamination discussed above, the single beam must be calibrated (dose/MU) in TSEI conditions of distance, degrader etc., using a suitable ionisation chamber. Generally, at these beam energies, this should be a parallel-plate chamber (see [Section 15.3.2](#)). Cable effects must be checked carefully and minimised in large-field irradiations. The combined beam skin dose per MU must be ascertained as a measured ratio to the single-field value, using film or TLD on the surface of representative cylindrical phantoms. This value will depend on the technique, but can also be checked by calculation from a weighted addition of the contributions from the different beams (Pla et al. 1984).

For TLD measurements, the dosimeter set-up must be planned with care. The TLDs should be embedded level with the phantom surface rather than be placed on it, to measure appropriate values. For the reasons described in [Section 40.2.3.1](#), thin thermoluminescent dosimeters are the best suited for this particular application (Marshall and Docherty 1971; Marinello et al. 1980; Cotento et al. 1984; Anacak et al. 2003). Small samples of monocoated silver-bromide or radiochromic films can also be used, but are less convenient. In any case the dosimeters, enclosed in thin protective sachets, are attached to different measurement points on the patient in order to check both the homogeneity of the dose distribution and the absolute dose ([Figure 48.6](#)). Care must be taken that there is no layer of air between the skin and the dosimeters because otherwise the results may not be representative of the surface dose.

The results of in vivo measurements taken during the first treatment fraction provide a check of the patient set up (always difficult for TSEI) and if necessary, corrective action can be taken for the subsequent treatment fractions. The series of in vivo measurements made during all the treatment fractions will enable the cumulative exposure to all areas of skin to be

**FIGURE 48.6**

Example of in vivo dosimetry practised at Henri Mondor Hospital for total electron irradiation: TL dosimeters, shown in the figure by arrows, are placed on each beam entrance, along the 2 field junctions and at curvatures. (Marinello, G. and Le Bourgeois, J. P., Radiotherapie Oncologique, Editions Hermann, Paris, 1992.)

determined and, in particular, to point out the unavoidable zones of overdosage or underdosage due to the patient's anatomy. For instance, the supplementary dose to be added to the interior of the thighs, which are always underdosed, can be deduced from in vivo measurements.

*The Stanford Technique:* Many techniques are variations of the 'Stanford' technique (Karzmark 1967; Page et al. 1970). Therefore, although the principles have been outlined above, it is worth reiterating a few practical points. In the original Stanford approach, a treatment plane 2 m high and 0.8 m wide was defined 3 m from the end of the linear accelerator treatment head. Field coverage was achieved by placing a 1 mm thick aluminum

scatterer at the end of the treatment head, together with a slab of tissue-equivalent material sufficiently thick to reduce the energy of the electrons to the required level at the patient treatment plane. The resulting beam spread is sufficient to cover the treatment plane laterally with acceptable uniformity, but, in the vertical plane, coverage is achieved by abutting dual beams, one above the other, with the central axis of the lower beam aimed below the patient's feet and that of the upper beam aimed above the patient's head, using gantry angles approximately 20° below and 20° above the horizontal. In practice the optimum angles would be tested in an individual centre by measuring the distribution in the overlap region using film for the specific conditions of the particular beam, distance and irradiation set-up.

As noted above, this dual-beam geometry also has the advantage of reducing the intensity of x-ray contamination in the treatment plane to less than 1% of the peak electron dose in the dual field, compared with around 2% on the central axis of each of the two component beams. This is an important consideration, because adequate dose uniformity around the patient is achieved with an arrangement of six dual beams at intervals of 60°. Because three beams generally contribute to the surface electron dose, but all six contribute to the x-ray dose, the percentage x-ray contamination for the complete treatment is effectively double that of one dual beam. For a 0.7% x-ray contamination in one dual beam, a typical prescribed skin dose of 36 Gy would result in an x-ray dose of  $2 \times 0.7\% \times 36 \text{ Gy} = 0.5 \text{ Gy}$ , which is clinically acceptable.

Total energy loss from the linear accelerator head to the patient, including the energy degradation of the scatterers, is typically 2–4 MeV. Because of the contribution of oblique beams, in a typical full six dual-beam treatment, where the incident electron energy at the treatment plane is 4 MeV, the depth of the 90% dose will be of the order of only 2–3 mm, and the dose maximum will be at a depth of 1 mm or less. Using the six dual beams, the mean dose in a cylindrical phantom at the depth of maximum dose will be typically 2.5–3 times that of only one of the six dual-beams measured at the centre of the patient treatment field at the depth of maximum dose.

Patients support themselves by holding a light frame or an overhead grip that arranges the arms in a position to minimise self-shielding on at least one arm. The arms are alternated in position on alternate fractions.

Throughout treatment consideration must be given to shielding parts of the body as the accumulate dose. Typically this will include nails, hands and feet, but additional areas may be selected to be excluded from treatment due to non-involvement. Internal eye shields positioned beneath the eyelids to protect the lenses pose problems of backscatter. Another choice may be to shield the eyelids and to boost the lids later with low-kV x-rays using an eye shield under the lids. Shielding must be done with 2–3 mm of lead placed close to or on the patient's skin, rather than close to the linear accelerator head. Dose should be monitored during treatment with a dosimeter such as an ionisation chamber placed close to the treatment plane (e.g. attached to the degrader sheet). Thermoluminescent dosimeters may be used to monitor dose on selected areas of the body if required. Careful assessment of the dose to under-dosed areas will provide the basis for calculating boost doses if these are deemed clinically necessary, but it can be noted that some centres only use boost doses in exceptional circumstances, yet report results that are apparently no worse than at other centres.

---

## 48.4 CONCLUSIONS

Total skin electron irradiation is a complex technique that can never fully meet its ideal aims. Dose uniformity to  $\pm 5\%$  can be readily achieved in the basic distribution across an area large enough to cover the whole patient. However, the addition of these distributions around variable-size body cross-sections will produce further variations in dose of up to typically  $\pm 10\%$  at best. Even in the best circumstances there will be under-dosed regions

that will not be clearly defined, so that even when boost doses are added to these regions the variation will probably still be between +10% and -25%. Where under-dosed regions are not boosted, variations may be significantly greater.

All the techniques employed for TSEI are specialized and time-consuming, requiring extensive development and careful dosimetry, planning, execution, and quality control. Referral to centres specialising in TSEI is often the preferred option, thus balancing the effort required to implement and maintain such techniques against the number of patients for which it is provided.

## 49.1 THERAPY WITH NEUTRONS

### 49.1.1 INTRODUCTION

The interest in neutron beams in radiation therapy is based solely on their radio biological effectiveness (Raju 1980; Withers 1985; Griffin et al. 1988; see also [Section 7.14](#)). The depth-dose characteristics of the early neutron beams were poor, resembling those of kilovoltage x-ray and  $^{60}\text{Co}$   $\gamma$ -ray beams (Fowler 1975). In [Table 49.1](#) it can be seen that the depth-dose

Source: From International Commission on Radiation Units and Measurements (ICRU), Report 45, Clinical neutron dosimetry part I: Determination of absorbed dose in a patient treated by external beams of fast neutrons, ICRU, Bethesda, MD, 1989; Maughan, R. L. and Yudelev, M. *Med. Phys.*, 22, 1459–1465, 1995. With permission.

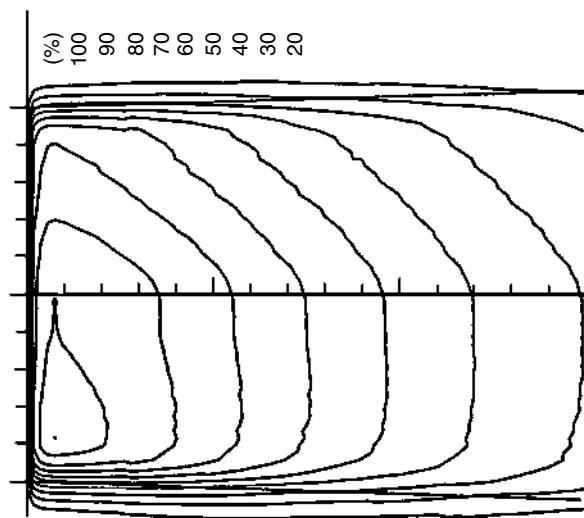

characteristics of the current neutron facilities resemble those of 4-MV to 8-MV x-ray beams. The very high density of ionisation (or high LET [linear energy transfer]) along the path of secondary particles in neutron-irradiated media is associated with a greater response of (radio-resistant) tumours and the reduced influence of conditions such as oxygen status, cell line, mitotic cycle and repair phenomena (see [Section 7.14](#)).

The first patients were treated with neutrons in the late 1930s. Currently, only about 10 facilities worldwide are involved in external-beam neutron therapy. Some of those programs were initiated two decades ago. Some old neutron facilities are ceasing operation, while there are few, if any, current proposals to build new facilities for fast neutron therapy. This small number of facilities is partly due to the relatively high cost of equipment compared to photon therapy but principally to the high frequency of late sequelae of the preliminary clinical trials done in the 1930s and some poor clinical results reported in the 1980s. Those results can now be clearly attributed to the difficulties experienced by all the pioneer teams in dealing with the radiobiological properties of neutron beams and the suboptimal technical quality available at the early facilities. These early facilities had beams of low energy and hence poor penetrating power and more recent higher energy installations did not have satisfactory facilities for producing irregular fields or the necessary advanced treatment planning systems (Scalliet 1991). Because of the reduction in the differential biological effects between tumour and normal tissues observed with high-LET particles, it is essential that neutron therapy be applied with conformal techniques.

## 49.1.2 FAST NEUTRON BEAMS

### 49.1.2.1 Fast Neutron Interactions in Biological Tissues

Neutrons, which are indirectly ionising, interact with nuclei of biological tissues through elastic and inelastic scattering, nuclear reactions and neutron capture. Ionisations are produced by charged secondary particles such as protons,  $\alpha$ -particles and recoils of heavy nuclei (carbon, oxygen, and nitrogen ions) (Bewley 1989). Because of the relative masses of hydrogen, oxygen, carbon and nitrogen in soft tissues, the relative cross-section values and the mean energy transferred to nuclei by incident neutrons are such that hydrogen atoms are responsible for the major part of the energy transfer. One consequence of using neutron rather than photon beams is a smaller risk of bone necrosis but a higher risk of fibrosis in fatty (or *adipose*) tissues (due to their high hydrogen content).

**FIGURE 49.1**

Partially wedged isodoses for a p(34)+Be neutron beam, field size: 10×10 cm. (From the Orléans facility, France. With permission.)

Neutron dose distributions at a *macroscopic* level (on-axis depth doses and isodoses curves) are quite similar to those of photons (Figure 49.1; see also Figure 46.1).

However, dose distributions at a *microscopic* level (i.e. subcellular level) are very different, due to the high values of LET associated with the charged secondary particles generated by neutrons (Figure 49.2). High neutron energies give rise to a broad spectrum of LET values. This is because the mean energy of recoil protons increases, and the associated LET decreases, with increasing neutron energy.

The secondary  $\alpha$  particles produced by neutron interactions are especially important because of their very high LET. The part of the LET spectrum above 250 keV  $\mu\text{m}^{-1}$  is due to heavy recoils such as carbon or oxygen ions.

#### 49.1.2.2 Beam Production

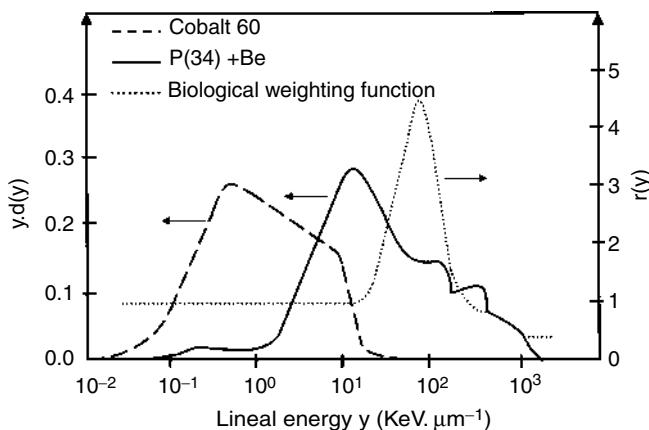

Many deuterium–tritium generators were used in the 1980s. Fusion reactions

produce neutrons at 14 MeV to 15 MeV. These monoenergetic neutron beams had a percentage depth-dose value at 10 cm depth on the central axis of about 50% for a source-surface distance (SSD) in the range 80 cm to 100 cm, with a typical dose rate of about 15 cGy min<sup>-1</sup> at 80 cm. The 80% to 20% penumbra at 10 cm depth was larger than 2.4 cm. These facilities, which were designed to accelerate deuterium nuclei to energies of the order of 250 KeV, are no longer used because of the poor physical characteristics of the neutron beams and the relatively short lifetime of tritium (in the range 80 to a few hundred hours). Another important limiting factor was the high activity of tritium (typically 20 TBq) which had to be contained\*.

Current facilities are all based on cyclotrons accelerating either deuterons (stripping reaction) or most frequently protons (inelastic reaction) on a beryllium target.

\* The twenty-first century version of the deuterium–tritium neutron generator uses a sealed tube containing a solid target made of titanium, scandium, or zirconium metal hydrides and an acceleration potential of 80–180 keV, but this does not solve all the associated problems.

**FIGURE 49.2**

Comparison of microdosimetric spectra (dose distributions in lineal energy  $d(y)$  for a  $2 \mu\text{m}$  simulated diameter—see footnote to Section 49.1.2.5) for  $^{60}\text{Co}$  photons and  $\text{p}(34) + \text{Be}$  fast neutrons (left ordinate). A biological weighting function  $r(y)$  for an early effect in mice (right ordinate) is used to calculate the corresponding weighted distributions  $r(y)d(y)$  for radiobiological intercomparisons of various neutron beams. (From Wambersie, A. and Menzel, H. G., *Radiat. Prot. Dosim.*, 70, 517–527, 1997. With permission.)

Deuterons produce neutrons because the neutrons are *stripped* from the deuteron as it passes close to a nucleus whereas protons interact directly with the nucleus of the atom resulting in the ejection of a neutron. Beryllium is the most effective target for neutron production (Bewley et al. 1984) and is able to dissipate the heat generated (typically 1–2 kW) because of its high thermal conductivity and stability at high temperatures. Deuterons and protons interacting with beryllium give different neutron energy spectra and dose rates. The higher the energy of the incident particle, the higher the energy of the neutron beam with consequently better penetration.

The maximum energies used today in neutron therapy facilities are 66 MeV for protons and 50 MeV for deuterons (Jones 1999). For deuterons and protons of the same energy, the neutron dose rate is higher with deuterons but the neutron energy (and hence penetration) is greater with protons. An even better way to increase the penetration of the neutron beam is to use protons with semi-thick targets and hydrogenous filters (such as high-density polyethylene) to reduce the high fluence of low-energy neutrons. A disadvantage of the proton-induced reaction is the broader angle of emission of the neutrons, requiring more shielding around the target and the primary collimator. The large size of treatment heads results in SSDs generally greater than 150 cm. Details of some neutron facilities are given in Table 49.1. For these high-energy neutron beams the 80% to 20% penumbra width is less than 2 cm but is still larger than that obtained with high-energy x-rays.

As observed with high-energy photons, the on-axis depth dose increases from the surface to a maximum depth at which charged secondary-particle equilibrium is reached (see Section 6.5). The depth of maximum dose is less than that for megavoltage photon beams because of the shorter ranges of the secondary particles, as shown in Table 49.1. For D-T generators, the depth-dose maximum is at only 2 mm.

In practice there is a limit to the incident proton energy of about 70 MeV because of the decrease in the LET of the neutrons at higher energies, which reduces the radiobiological benefit. Seventy mega-electronvolt protons produce a neutron beam with depth-dose characteristics similar to those of an 8-MV x-ray beam.

### 49.1.2.3 The Treatment Head and Equipment

The treatment head of a neutron machine is larger than that of an x-ray machine due to the larger size of the magnets and the necessary shielding. They are, however, designed in a similar

way: target, flattening filter, transmission ionisation chambers, and beam modifiers (see [Section 11.4](#)). Beam monitoring can also be performed by measuring the total electric charge of particles incident on the target.

Various collimation and shielding systems have been proposed, including compound shields: steel for high-energy neutrons, followed by polyethylene to absorb low-energy neutrons and an outer layer of lead to attenuate gamma rays emitted from the second layer. Borated wood collimators have also been used.

It is clearly established that the *shape* of the neutron field has to conform to that of the clinical target volume for each beam direction (i.e. the beams's eye view; [Section 32.4.2](#)) (Austin-Seymour et al. 1994; Russell et al. 1994). A minimum requirement is therefore to have shielding blocks adapted for each beam with transmission as low as for those used with high-energy x-rays (see [Section 22.5](#)). For the highest energies (typically above 50 MeV), the weight of the blocks needed to shape the fields is quite high, and the high levels of radioactivity induced in the shielding blocks makes it difficult to limit the doses received by the radiographers. Multi-leaf collimators (see [Section 22.5.4](#)) are therefore essential to optimise the use of high-energy neutron beams.

Many of the existing facilities are non-isocentric or not-fully-isocentric. An example of an isocentric facility with multi-leaf collimator is that in Seattle (U.S.A.), in clinical operation since 1985. In Detroit, a compact isocentric cyclotron with a multirod collimator has been used since 1990. For nonisocentric facilities, heavy and complex patient fixation devices have been designed to achieve the patient positions required for the different beam directions required by the treatment plan.

The ancillary equipment such as light-beam simulation and lasers is quite similar to those used for photon-beam therapy machines.

#### 49.1.2.4 Dosimetry

The dosimetry protocols for therapeutic applications of fast neutron beams in U.S. and European centres were standardised in 1987 and the common protocol is described in ICRU Report 45 (1989) and by Mijnheer et al. (1987).

A clinical neutron beam always consists in practice of a mixed field of neutrons and photons. Their respective contributions to the total absorbed dose have to be determined separately because of the large difference in relative biological effectiveness (RBE) of each component. The photon component which is generated in the target, collimation devices or the patient, accounts for a few percent of the total dose\*. For routine measurements, the neutron and photon dose components are separated by a double-detector method based on two instruments with different sensitivities to the two types of radiation: typically an A150 ionisation chamber and a Geiger–Müller (GM) counter. The GM counter is primarily sensitive to the photon component of the dose, but the neutron sensitivity of the counter,  $k_u$ , has to be taken into account. Data from microdosimetric measurements with tissue-equivalent proportional counters are used to derive a value of  $k_u$ .

The combined neutron and photon dose is measured with a tissue-equivalent plastic (Shonka A150) ionisation chamber filled with tissue-equivalent methane-based gas (to correspond to *Fano-theorem* conditions; see [Section 6.7.7](#)). Such homogeneous chambers are used because the conditions for a *Bragg–Gray* cavity (see [Section 6.7.3](#)) cannot be fulfilled in practice and because there is no *cavity theory* applicable to fast neutron dosimetry with inhomogeneous chambers. Chambers filled with gas are calibrated in terms of air kerma in a  $^{60}\text{Co}$   $\gamma$ -ray beam at a National Standards laboratory.

\* The photon dose can be expressed as a percentage of the total dose at 2 cm and 10 cm depth. Typical percentages are, respectively, 5.2% and 7% (Orleans), 6.5% and 8% (Seattle), and 3.1–4.1% (Louvain) (ICRU 1989; Sabattier et al. 1990).

An A150 calorimeter is the most fundamental instrument for measuring absorbed dose in a neutron beam (see the Introduction to Part D) with the minimum uncertainty in the determination of the total absorbed dose. Caumes et al. (1985) described the calibration of an ionisation chamber in terms of absorbed dose in A150 determined using a calorimeter directly in a clinical neutron beam.

For clinical applications, dose distributions have to be measured in a water phantom but the dose should be specified in ICRU muscle as reference material. Kerma ratios can be calculated from neutron energy spectra. For neutron energies higher than 15 MeV a full calculation cannot be made and the dosimetry protocol (ICRU 1989) recommends a value of 0.95 for the  $K_{\text{tissue}}/K_{\text{A150}}$  ratio.

Kerma in fatty tissue with a high percentage of hydrogen is 13% to 15% higher than kerma in ICRU muscle (for the same neutron fluence). By contrast, kerma in bone is only 59% to 66% of the kerma in reference ICRU muscle.

#### 49.1.2.5 Microdosimetry

Specification of radiation quality is important for clinical neutron beams because, although radiobiological parameters are dependent to some extent on the proportion of photons in the beam, the principal determinant of the RBE is the secondary charged-particle spectrum (ICRU 1983; Pihet 1989).

Microdosimetric measurements provide an effective way to describe the beam quality. Microdosimetric spectra (Figure 49.2) and data such as dose-mean lineal energy\* ( $y_D$ ) or dose-mean lineal energy corrected for saturation ( $y^*$ ) can be obtained with A150 proportional counters containing tissue-equivalent gas at low pressure to simulate micrometer-sized volumes (Liu 2000). Relevant radiobiological data can be derived from variations of  $y_D(y)$  vs.  $y$  spectra or from the parameters  $y_D$  and  $y^*$  at different depths, or at off-axis points in a clinical neutron beam as well as at a reference point common to several facilities (Pihet et al. 1988; Menzel et al. 1990; Wambersie and Menzel 1997).

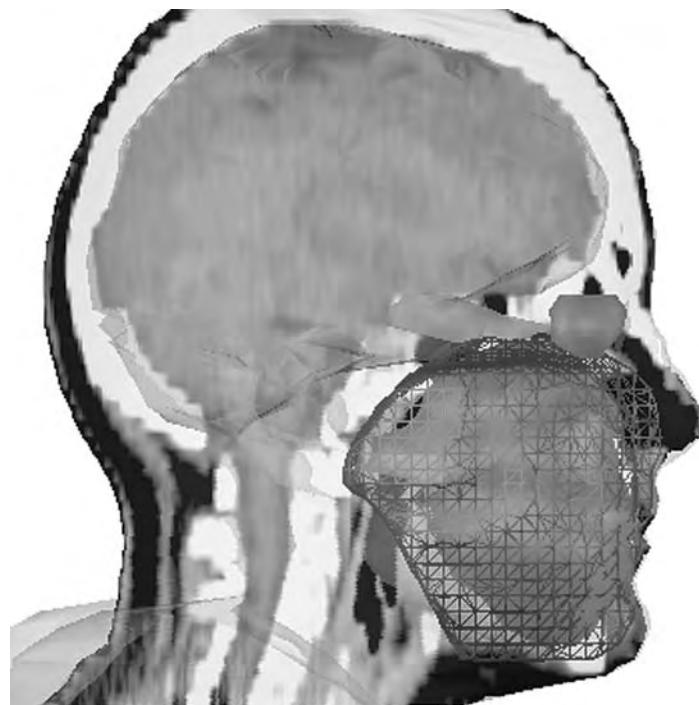

Proportional counters are frequently used to analyse a mixed photon–neutron field both inside and outside the beam and are therefore useful for radiation protection measurements around medical facilities or high-energy accelerators. A powerful technique for obtaining values of the quality factor  $Q$  for a beam of mixed energy is to use the values of  $Q(L)$  as a function of LET,  $L$ , published in ICRP 60 (1990) to weight the  $y_D(y)$  vs.  $y$  spectrum, for any point of interest inside or outside the beam (Folkerts 1988; Vynckier et al. 1988).

#### 49.1.2.6 Clinical Use of Fast Neutrons

For identical absorbed doses, dose distributions at a microscopic scale are vastly different according to whether one uses low-LET radiation such as photons and electrons or high-LET neutrons. Figure 49.3 shows the physical dose distribution, which is similar to that obtained with a photon beam, but the very high density of ionisation along the path of the secondary particles (high LET) results in high RBE values. RBE values for neutrons are much higher than those observed for high-energy photons or electrons (which are low-LET radiation; see Section 7.14). They are also higher than the RBE of protons and low energy x-rays. For fast neutrons, the RBE varies within wide limits (about 2 to 5) depending on the neutron energy spectrum, dose, and biological system (Wambersie and Menzel 1997) and therefore an

---

\* Lineal energy is defined by ICRU as  $\varepsilon/l$ , where  $\varepsilon$  is the energy imparted to matter in a volume of interest by an energy deposition event and  $l$  is the mean chord length in that volume. This is not the same as the LET, (see Section 7.14) which is a *macroscopic* quantity. Lineal energy can be described in terms of the *frequency-mean* lineal energy which is the mean of the lineal energy distribution or the *dose-mean* lineal energy which is the mean of the distribution weighted for dose. The quality factor,  $Q$ , (see Section 59.1.2) expresses the relationship between the absorbed dose and the *equivalent dose* and is related to the lineal energy.

**FIGURE 49.3**

(See colour insert following page 590.) Example of 3D dose distribution for a large tumour of the maxillary sinus with irregular fields and partially wedged neutron beams at the Orléans neutron therapy facility. The wireframe represents the prescribed dose distribution around the clinical target volume.

accurate determination of the RBE relative to photons is necessary before starting clinical applications and when exchanging clinical results (Gueulette et al. 1984, 1996; Grégoire 1993). Some heavy-ion beams (e.g. carbon, see [Section 49.3](#)) have RBE values similar to those of neutron beams.

Differential biological effects (e.g. dependence on oxygenation) observed when using low-LET radiation (i.e. photons and electrons) are significantly reduced with high-LET radiation. Clinical interest in neutrons is based on this fact. Radiosensitivity is less dependent on cell type and other related factors with high-LET than with low-LET radiation. Environmental conditions (e.g. oxygen status), position in the cell cycle and repair mechanisms, all play a less important role than with photons. The large proportion of time spent in the radiation-tolerant resting phases of their cycle makes the cells in slowly growing tumours relatively resistant to low-LET radiation. The similar responses observed for all cells in all conditions under high-LET irradiation lead us to expect radio-resistant tumours to have a greater response to treatment with neutrons than with photons, for a similar response from the surrounding healthy tissue.

The most promising results reported for external neutron therapy are in the treatment of large, slow-growing or radioresistant tumours such as salivary gland tumours, locally advanced prostatic adenocarcinomas, low-grade soft-tissue sarcomas and some sarcomas of bone (Wambersie and Menzel 1996).

#### 49.1.3 CONCLUSIONS

Tumour response to irradiation with fast neutrons is much less dependent on the differential biological effects currently observed with photons and electrons (see [Part B](#)). Basic radiobiological data justify neutron therapy for some radioresistant tumours but it must be

emphasised that all treatments require a conformal approach. Conformal neutron therapy did not exist for the pioneers in the 1980s, but was also not available at some more recent facilities because of the difficulties of designing irregular fields and isocentric gantries. The use of fast neutrons necessitates investigations in the fields of radiobiology, microdosimetry and dosimetry. For more details, readers are encouraged to consult the historical review of fast neutron therapy including current trends and future needs by Wambersie and Menzel (1996).

---

## 49.2 BORON NEUTRON CAPTURE THERAPY

A potentially promising way to treat highly malignant tumours like glioblastomas and melanomas is to enhance the biological effects of neutrons on tumour cells using thermal boron neutron capture therapy (BNCT) in which  $^{10}\text{B}$  atoms are incorporated within tumour cells and then irradiated with thermal neutrons (Zamenhof et al. 1975; Barth et al. 1996). Boron has a very large cross section for absorbing thermal neutrons. In consequence, the thermal neutron components of the beam spectrum produce a selective enhancement through the  $^{10}\text{B}(\text{n}, \alpha)^7\text{Li}$  reaction. The secondary  $\alpha$  and recoil  $^7\text{Li}$  ion particles have an average total kinetic energy of 2.33 MeV, with ranges of 9  $\mu\text{m}$  and 5  $\mu\text{m}$  respectively, i.e. close to tumour-cell diameters, delivering a differential dose to the boron-loaded tumour cells. The thermal neutron capture in  $^{10}\text{B}$  is two orders of magnitude greater than in tissue, but a minimal and differential boron concentration must be ensured at the tumour level (Bartelink et al. 1996). This can be achieved, for example, where a tumour breaks the blood-brain barrier allowing large boron compounds to selectively enter tumour cells in the brain.

Patients were treated by BNCT in the U.S.A. in the 1950s at two facilities (Brookhaven [Farr et al. 1954] and MIT [Asbury et al. 1972]) and the technique was improved in Japan in the late 1960s, giving rise to new projects like the European Centre at Petten, The Netherlands (Sauerwein and Zurlo 2002).

Two ways to implement Boron capture therapy are being investigated:

- BNCT with thermal neutrons from a reactor or from low-energy, high-current accelerators (Chadha et al. 1998).
- Boron neutron capture enhancement of fast neutron beams (BNCEFNB) with the thermal component of the neutron beam (Pignol et al. 1999).

Barth et al. (2004) also report some success in combining BNCT with external beam therapy.

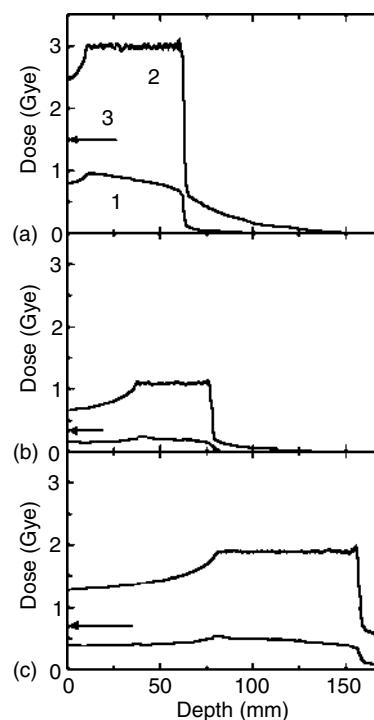

In parallel, the likely degree of success of BNCT is related to the design of boron compounds with a differential selectivity for tumour cells (Bartelink et al. 1996; Cumberlin 2002; Barth 2003).

---

## 49.3 LIGHT AND HEAVY IONS

### 49.3.1 INTRODUCTION

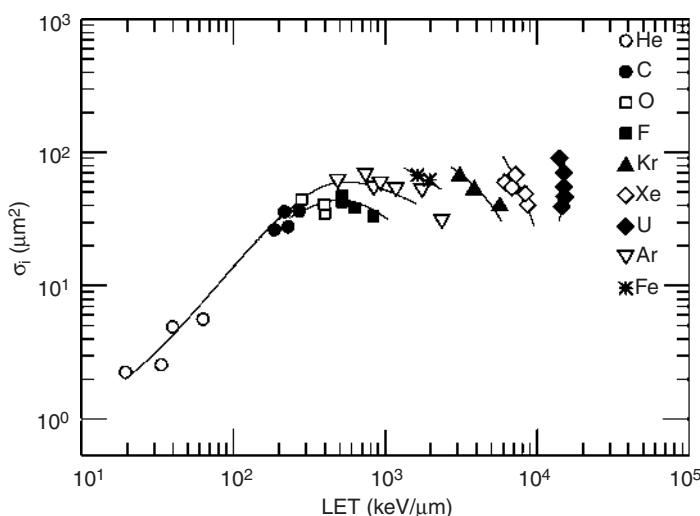

Nuclei heavier than protons are of interest for radiation therapy (Raju 1980; Kraft 2000) as they combine excellent dose-distribution properties similar to proton beams ([Chapter 46](#)) with radiobiological properties similar to neutron beams ([Figure 49.4](#)). If these two high-LET modalities are compared, the relationship of neutron therapy to heavy-ion therapy is akin to that of high-energy x-ray therapy to proton therapy ([Chapter 46](#)).

**FIGURE 49.4**

Modulated depth-dose distribution for a carbon-ion beam for various modulation depths and dose levels, corresponding to different RBE values in the center of the SOBP: (a) RBE = 3.4; (b) RBE = 5.5; (c) RBE = 4. In the diagram, curve 1 shows the modulated *physical* depth-dose. Curve 2 shows that because of the increase of the RBE with depth, the resulting biologically effective dose is homogeneous throughout the target volume. It can be seen that the RBE is higher for lower dose levels and that the depth modulation is not constant. The arrow (3) indicates the effective skin dose. The latter differs from curve 1 because the biological effectiveness of ion beams depends on cell type.

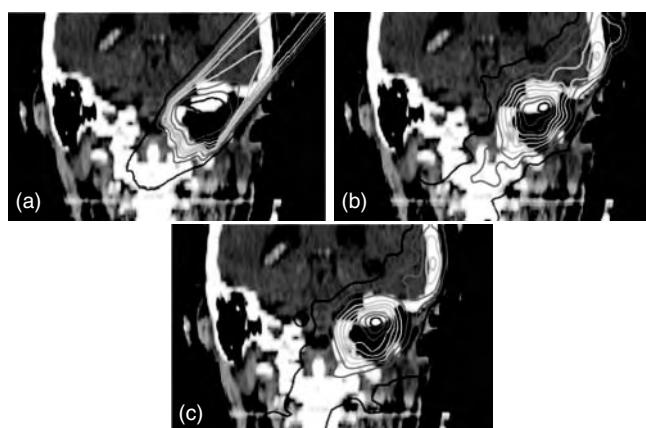

The rationale for the use of ion beams in radiotherapy, including the practical clinical limitations, is as follows:

1. Multiple-scattering processes are less important for heavier ions compared to protons, due to the greater mass of the former. Consequently, range straggling as well as lateral scattering (see Figure 46.2) is reduced; the resulting lateral and distal dose gradients are therefore steeper than for proton beams. However, in contrast to protons, nuclear interactions of heavier ions with matter occur primarily as so-called projectile fragmentation. These light fragments are mainly produced close to the Bragg peak and the range of some fragments is greater than that of the primary ion. This leads to a tail of secondary particles beyond the Bragg peak (Figure 49.4), which becomes more pronounced for heavier ions. Due to this tail, ions heavier than neon are less advantageous for radiotherapy.
2. The LET is higher for heavier ions, and consequently the RBE is greater. For high-LET radiation the oxygen enhancement ratio (OER) is lower and the cell-survival curves become more and more linear so that fractionation effects become smaller. This can be expressed in terms of a higher  $\alpha/\beta$  ratio (see Section 7.14). This is the rationale for hypo-fractionation using ion beams, i.e. treatment protocols with a smaller number of fractions and a shorter overall treatment time (see Chapter 9). However, the lack of fractionation sensitivity is limited to the high-LET region in the Bragg peak. Normal tissue in the entrance region, where the LET is lower, will still benefit from fractionation. For very high LET values (beyond  $1000 \text{ keV cm}^{-1}$ ), the RBE decreases again, and this is another factor limiting the use of ions heavier than neon (Figure 49.5). As an example, for argon ions the RBE close to the surface is higher than that in the Spread-Out Bragg Peak (SOBP) region.

**FIGURE 49.5**

Variation of the inactivation cross section (and consequently RBE) for mammalian cells after irradiation with various heavy ions with different LET values. The increase with higher LET and for heavier ions is clearly visible. At very high LET values (reached with ions with  $Z > 9$ ) a reduction in the inactivation cross section is observed. (Courtesy of G. Kraft.)

3. Due to the nuclear fragmentation, heavy ions produce some radioactive isotopes in the body which are positron emitters, creating the possibility of monitoring the stopping point of the projectile ions using online PET (Positron Emission Tomography) techniques (see Figure 49.6). The use of a radioactive beam (e.g.  $^{11}\text{C}$  ions) for therapy is currently being investigated at Heavy Ion Medical Accelerator (HIMAC) to increase the PET signal (Li et al. 2004). However, the intensity of these beams is very low, which increases the treatment time.
4. The costs of beam production, beam transport (including an isocentric gantry) and shielding, are considerably higher than for protons.
5. Although some experience has been gained, patient numbers are still low and it has not yet been demonstrated in large clinical trials which tumours would benefit from heavy-ion therapy.

**FIGURE 49.6**

(See colour insert following page 590.) Example of the online PET imaging of the induced activity in a patient treated for a tumour of the skull base. The figure shows the absorbed dose distribution of one of the treatment fields (a), the expected activity as calculated from the treatment plan (b) and the measured PET activity (c). Due to wash out effects in soft tissue, the measured activity is in general somewhat lower than the calculated activity, while in the bony structures the measured and calculated activities agree very well. (Courtesy of W. Enghardt.)

The biological characteristics of helium beams ( $Z=2$ ) are similar to those of proton beams. Beams of nuclei with atomic numbers up to neon ( $Z=10$ ) are called *light* ions, including carbon ( $Z=6$ ) and oxygen ( $Z=8$ ). Beams with higher atomic number (silicon  $Z=14$ , argon  $Z=18$ , and so on) are called *heavy* ions. There is also interest in the use of *radioactive* beams, based on the optimal use of PET techniques for *online* dose-deposition monitoring.

#### 49.3.2 PHYSICAL PARAMETERS, RADIobiological DATA AND TREATMENT PLANNING

As the LET and RBE increase towards the Bragg peak, the *physical* dose has to be modulated in such a way that the resulting *biologically effective* dose is constant throughout the target volume. Modulated depth-dose curves for heavy-ion beams therefore show a significant decrease towards the distal end (Figure 49.4). While the entrance dose is lower and the distal gradient is higher than in proton beams, there is a tail of secondaries behind the Bragg peak that increases with the atomic number of the particle. Ions in the region around carbon are considered nowadays as optimal for clinical applications, since they combine very high RBE values with only a moderate fragmentation tail. An overview of the medical physics aspects of carbon-ion therapy can be found in Jäkel et al. (2003a).

Dosimetry intercomparisons have been performed between one of the Japanese facilities (HIMAC) and the German facility, Gesellschaft für Schwerionenforschung (GSI), using cylindrical ionisation chambers (Fukumura et al. 1998; Hartmann et al. 1999). The Japanese and the German dosimetry protocols are very similar to dosimetry protocols for proton beams (see Section 46.4.3). While the Japanese protocol is based on ionisation chambers calibrated in air kerma, the German protocol uses chambers calibrated in absorbed dose to water (see Section 18.2 and Section 18.3).

There are small differences between the values adopted by the above two institutions for ( $W_{\text{air}}/e$ ) and for the water-to-air mass stopping-power ratio ( $s_{w,\text{air}}$ ) for carbon ions. However, the product of these parameters differs only by about 0.5%, which is also the difference between the final dose determinations at the two institutions. The International Atomic Agency has published a dosimetry protocol for heavy-ion beams (IAEA 2000), which is based on chambers calibrated in absorbed dose to water and has been shown to be very similar to the German dosimetry protocol (Jäkel et al. 2003b). In spite of the agreement between the centres, the overall uncertainty in heavy-ion dosimetry due to a lack of data on  $W$ -values and stopping-power ratios is around 3%. There is agreement that cylindrical ionisation chambers (see Chapter 15) are the most suitable types for the dosimetry of carbon ions following international protocols such as TRS-398 (IAEA 2000).

It is mandatory that radiobiological modelling of the depth-dose modulation be included in the treatment planning process, in order to account for the variation of RBE and thus to achieve a homogeneous biological effect in the tumour. The RBE is dependent on the spectrum of secondary particles (which varies with depth), the absorbed dose, the fractionation scheme, the endpoint under consideration (e.g. cell killing) and the type of cells in the irradiated tissue. For a *broad beam* technique such as that used at HIMAC, the dependence of RBE on the depth-dose determines the shape of the depth modulators, which are defined for a particular fractionation regime. If a beam-scanning technique is used, with variable depth-dose modulation, the composition of the radiation field at every point has to be known to be able to model the biological effectiveness for the patient. In Figure 49.4, some examples of the varying depth modulation for a carbon ion beam are shown, as applied to the treatment of chondrosarcoma patients at GSI. The basis of the underlying biological modelling of these depth-dose curves is described in Krämer (2000). The clinical treatment planning aspects are discussed in Jäkel et al. (2001).

### 49.3.3 ACCELERATORS, BEAM-DELIVERY SYSTEMS, AND PET MONITORING

Due to the high energies needed for the treatment of deep-seated tumours using beams of heavy ions, synchrotrons are the usual choice for accelerators in a clinical facility.

At Berkeley, a heavy-ion linear accelerator (SUPERHILAC) served as an injector to a synchrotron (BEVATRON) in the Bevalac facility. This was primarily a research facility and the clinical program initiated in 1977 continued until the shutdown of the facility in 1992 using beams of helium, carbon, neon, argon, and silicon ions (Alonso 1994). Two treatment rooms with horizontal beams were available (Chu 1993). The majority of the patients were treated in a sitting position. For treatment planning, a CT scanner was modified to scan seated patients i.e. in horizontal planes.

The modulation of the depth-dose was performed using a fixed accelerator energy and *passive range modulators*, such as ridge filters and patient-specific compensators (or bolus on the skin surface). The beam was broadened using a double-scattering system which was upgraded to a *beam-wobbling* system in the 1980s. Patient-specific field collimators were used to confine the beam to the target volume. Just before the facility was shut down, a 2D magnetic beam scanning system together with a passive range modulator was installed, but this was used for the treatment of a single patient only.

Based on the experience in Berkeley, the first hospital-based ion facility, HIMAC, in Chiba, Japan became operational in 1994, offering ion beams from helium to argon, with a maximum range of 30 cm in tissue (energies up to 800 MeV/u\*), a dose rate of 5 Gy/min (beam intensities of  $2 \times 10^9$  particles/s), a field size of 22 cm, and vertical and horizontal beams (Kanai et al. 1999).

The accelerator complex consists of two different ion sources, followed by a radiofrequency (RFQ) and an Alvarez linac and a pair of superposed synchrotrons of about 40 m in diameter with a *flat top* intensity per pulse (20% duty factor) and a repetition rate of 0.5 Hz. The beams are fed to horizontal or vertical beam lines, in three different treatment rooms, a biological irradiation room and physical experimentation rooms. Patients can be treated either lying down or seated. At HIMAC the activation of tissue is measured *off-line* with a conventional PET scanner.

The beam delivery system is passive, as the Berkeley system was. It is based on a combination of wobbling magnets and scattering foils for beam spreading, *ridge* filters (instead of modulators) to spread out the Bragg peak, absorbers, a steel multileaf collimator and compensators.

At the research laboratory Gesellschaft für Schwerionenforschung (GSI) in Darmstadt, a therapy unit began clinical operation in 1997 (Kraft 2000). Only one treatment room is available, equipped with a horizontal beam line and a treatment couch. A treatment chair has also been installed.

The GSI synchrotron, Schwerionen-Synchrotron (SIS), can produce ion beams from protons through to uranium. However, only carbon ions are used for therapy. Energies up to several GeV/u are available, while the maximum energy used for therapy is 450 MeV/u.

The beam delivery system is dynamically controlled and allows 3D scanning of arbitrarily shaped volumes with a high spatial resolution (Haberer et al. 1993). Using a magnetic deflection system, the intensity-controlled raster scanner can deliver a monoenergetic pencil beam over an arbitrarily shaped area. To do so, a beam of 6 mm to 10 mm (full-width at half-maximum) is scanned over a regular grid of points with typically 2 mm to 3 mm spacing. After completion of a scan, the accelerator energy can be switched from pulse to pulse and

---

\* u is the *unified atomic mass* or atomic mass unit, or Dalton (Da), which is the unit of mass used to express atomic masses and molecular masses. It is defined to be 1/12 of the mass of one atom of  $^{12}\text{C}$ . Accordingly:  $1\text{u} = 1/N_A \text{ gram} = 1/(1000N_A) \text{ kg}$  (where  $N_A$  is Avogadro's number)  $\approx 1.66053886 \times 10^{-27} \text{ kg}$

another scan can be performed with a different radiological depth. In total, 256 accelerator energies are available. The intensity control moves the beam to the next beam spot when a predefined number of particles has been reached. An on-line monitoring of the beam position and a feedback loop to the scanner is used to keep the beam stable at each scan spot.

In summary, the system allows a very high degree of dose conformation and, at the same time, makes any patient-specific beam-shaping hardware unnecessary. Furthermore a dedicated PET scanner is installed in the treatment room which enables the induced activity in the patient to be monitored *on-line* during the irradiation (Enghardt et al. 1999). An example of the capability of this PET camera is shown in Figure 49.6.

A second hospital-based ion therapy facility came into operation in Japan in 2001. For the first time, both proton and ion beams are available in the same centre. The Hyogo Ion Beam Medical Center (HIBMC) at Harima Science Garden City began operation with protons in 2001 and with carbon ions in 2002 (Kagawa et al. 2002; Itano et al. 2003). Six therapy rooms are available with seven treatment ports. Three rooms are dedicated to carbon ion beams: one with a vertical beam line, one with a horizontal one and one with a 45° oblique beam line. Two proton treatment rooms are equipped with commercially designed gantries. The beam delivery system is based on the HIMAC system.

#### 49.3.4 CLINICAL PROGRAMS

The first experiences with the clinical application of ion beams were between 1977 and 1992 at the Lawrence Berkeley Laboratory (LBL). Treatments of skull-base tumours such as chordoma, low-grade chondrosarcoma and meningioma were performed, as well as tumours of the paranasal sinus, nasopharynx, bone, and soft-tissue sarcomas and prostate cancer (Castro 1994). The results of the clinical phase-I/II study at LBL have to be regarded in the light of the fact that there was at the time almost no clinical information available about the biological effectiveness of ion beams for the different types of tumour and normal tissues. The studies were defined as *dose-finding* studies. The majority of patients were treated with helium ions, which are very similar to protons in terms of biological effectiveness. Four hundred and thirty-three patients were treated with ions heavier than helium, the majority with neon ions, but carbon, argon and silicon ions were also used.

At the HIMAC in Chiba well over 2000 patients were treated with carbon ions during the first eleven years of operation. These were mainly tumours of the head and neck, lung, prostate, liver, bone and soft-tissue sarcoma, uterus, and esophagus (Tsujii et al. 2004).

Dose-finding studies for carbon-ion radiotherapy for prostate cancer, non-small-cell lung cancer (NSCLC) and soft tissue sarcomas (Tsujii et al. 2004) are ongoing at NIRS in Chiba, Japan. In two phase I/II trials for Stage I NSCLC, using different fractionation schemes (18 fractions in 6 weeks and 9 fractions in 3 weeks), a dose-escalation study was performed (Miyamoto et al. 2003). For unresectable bone and soft tissue sarcomas, a further phase-I/II trial was performed (Kamada et al. 2002), using 16 fractions over four weeks. These trials all show very promising results.

Between 1997 and the end of 2005, nearly 300 patients were treated with carbon-ion radiotherapy at GSI. The majority of patients were treated for chordoma and low-grade chondrosarcoma of the skull base using a dose of 60 GyE\* in 20 fractions of 3.0 GyE. For these tumours carbon-ion radiotherapy is offered as a routine treatment to patients. Clinical phase I/II trials for the treatment of sacral and spinal chordoma as well as for adenoidcystic carcinoma are ongoing. For these treatments carbon ions are applied as a boost treatment (using six fractions of 3.0 GyE) after an intensity modulated radiation therapy (IMRT) treatment using photons. Although follow-up time is still limited, the control rates are

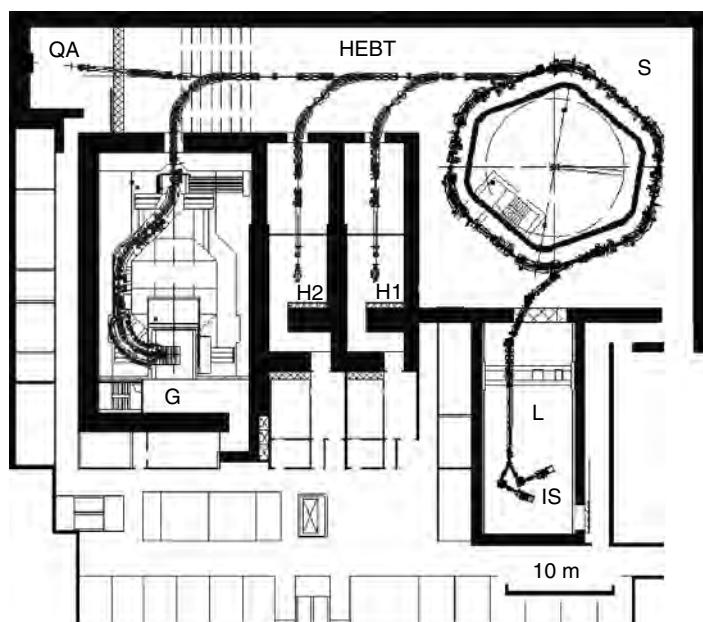

\* GyE=cobalt gray equivalent.

very encouraging (Schulz-Ertner et al. 2004). Furthermore, no severe radiation-induced side effects (neither acute nor late) have been observed (Schulz-Ertner et al. 2002).

#### 49.3.5 ECONOMIC ASPECTS, FUTURE DEVELOPMENTS AND CONCLUSIONS

Although there are promising preliminary results from the clinical trials at HIMAC and GSI, the number of patients as well as the follow-up time is still limited. The clinical value of heavy-ion beams especially as compared to modern photon IMRT techniques (see [Chapter 43](#) and [Chapter 44](#)) and proton radiotherapy ([Chapter 46](#)) has not yet been evaluated. To do so, hospital-based facilities must be established which enable randomised trials between heavy ions, photon IMRT and proton radiotherapy to be carried out for various indications, using similar levels of sophistication in treatment planning and beam delivery.

There are several facilities currently planned in Europe (Sisterson 2003a,b) that may serve this purpose. One is already under construction at the Heidelberg university hospital (Figure 49.7). The facility will feature a dedicated heavy-ion synchrotron, which will be a downsized version of the GSI synchrotron (Eickhoff et al. 2000; Bär et al. 2001). For the first time the facility will provide an isocentric gantry system (Spiller et al. 2000) as well as two fixed, horizontal beam lines. All treatment rooms will be equipped with the same beam-scanning method as is currently performed at GSI. The integration of beam scanning into the isocentric gantry is a technological highlight of the facility (Heeg et al. 2004). Furthermore, not only carbon ions but also protons, helium and oxygen ions will be available for radiotherapy. The facility is scheduled to be finished in 2006 and to start clinical operation in 2007,

**FIGURE 49.7**

Layout of the clinical ion facility in Heidelberg, showing the two ion sources (IS) and Linac injector (L), synchrotron (S), high energy transfer beam line (HEBT), an irradiation room for dosimetry and quality assurance (QA), two treatment rooms with a fixed horizontal beam line (H1, H2) and the isocentric gantry (G) in the third treatment room. The shielding walls of concrete are also shown. In front of the entrance door to each treatment room, the patient changing rooms are shown. Offices are on the first floor of the building with all other technical equipment one floor lower. The size of the building is approximately 70 m × 70 m. It is connected to the radiotherapy department of the university hospital, where all diagnostic services are located. (Courtesy of Architects Nickl & Partners, Munich.)

the final capacity being 1000 patients treated per year. The projected capital investment in the facility is €72 M.

It is clear that the enormous capital investment and technical complications for a hospital-based ion facility make tumour therapy with ion beams more expensive as compared to conventional therapy (the treatment cost reimbursed currently for fully fractionated carbon-ion therapy at GSI is €20,000). However, if ion therapy for certain specific tumour types is proven to be superior to conventional therapy in terms of clinical outcome, it may come to be considered as a cost-effective therapy. This is due to the high costs associated with the treatment of recurrent tumours (Land et al. 2005).

Another clinical facility for protons and carbon ions is under construction in Pavia near Milan. It will feature a proton gantry but only fixed horizontal beam lines for carbon ions. The facility is planned to be operational in 2008. A great deal of effort has also been expended in the design and planning of some other European ion-beam centres, such as the MedAustron project in Wiener Neustadt (Austria), the Etoile project in Lyon (France) and the Nordic Light-Ion facility in Stockholm (Brahme 2004; Svensson et al. 2004).

When the first of these new hospital-based facilities comes into clinical operation, a number of questions have to be addressed: what tumour indications can be treated most effectively with ions? Which tumours are more effectively treated with IMRT or protons? Which type of ion is best suited for which tumour? Is ion therapy cost effective? It will certainly take many years of clinical, radiobiological and physical research to answer these questions and thus determine the role of ion beams in tumour therapy.

## INTRODUCTION

This Part deals with all forms of sealed source brachytherapy. [Chapter 50](#) provides a clinical introduction. This leads to a discussion of the sources available for brachytherapy ([Chapter 51](#)), and methods of afterloading are then considered ([Chapter 52](#)). Brachytherapy treatment planning can be carried out both manually and with a computer, and both aspects are considered in [Chapter 53](#) and [Chapter 54](#), respectively. Finally, in [Chapter 55](#) there is a section on the radiobiology of brachytherapy that has a number of considerations that are peculiar to this form of treatment. Brachytherapy can be time consuming for the Radiation Oncologist and for this reason its use had declined. However, with the availability of afterloading systems that allow optimisation of the dose distribution by the use of stepping sources (see Chapter 52) interest is growing again (Mazeron 2005, Hoskin and Bownes 2006, Guedea et al. 2007). Bentzen et al. (2005) identified the need for more work to be done on the requirements for brachytherapy and this was the motivation for the patterns of care study reported by Guedea et al. (2007), which identified the need for more brachytherapy resources. Brachytherapy is the ultimate in conformal therapy especially with the possibilities for optimisation that are increasingly becoming available. However, no optimisation technique can overcome the problem of an implant that misses the intended target geometrically and it is important that physicists involved in brachytherapy have a firm grounding in the experience of the more traditional techniques so that the hazards of stepping outside the traditional framework are fully understood.

## 50.1 HISTORY AND RATIONALE FOR BRACHYTHERAPY

The term brachytherapy refers to treating tumours from a short distance, in contrast to teletherapy, where tumours are treated at a long distance from the radiation source. Brachytherapy is usually achieved by placing radioactive sources on or in the tissue to be irradiated. In teletherapy, tissue absorption largely governs dose distribution, whereas the inverse square law is most responsible in brachytherapy. Whereas teletherapy is designed to produce a homogenous dose distribution in most cases, brachytherapy uses the

inhomogeneous dose distributions found around sources to create a high dose in tumours, whilst producing a low dose in normal tissue.

Brachytherapy can use sources that are loaded within body cavities (intracavitary), sources that are implanted into tissues (interstitial), trains of sources within the lumen of organs, such as the bronchus or oesophagus (intraluminal), or sources supported in a mould over a tumour (superficial brachytherapy). The prime example of intracavitary brachytherapy is the use of radioactive sources within applicators in the uterus and vagina, whilst the best example of interstitial brachytherapy would be the use of radioactive needles in the treatment of carcinoma of the tongue. Intraluminal brachytherapy is a relatively new technique made possible by high dose rate micro-sources, which need only remain within the lumen for a few minutes, thus avoiding the problems of obstruction. Superficial brachytherapy has largely been replaced by the use of high energy electrons for tumours of the skin, but may still have a place in the treatment of tumours in the upper airways and oropharynx. It is also occasionally used in the treatment of vaginal and vulval cancers.

Historically, brachytherapy developed because of the inadequacy of external radiotherapy in treating deep-seated tumours. The gynaecological organs were particularly suitable for treatment by brachytherapy because of their accessibility through the vagina. Similarly, the treatment of head and neck cancer relied heavily on interstitial brachytherapy because of the ease of access through the mouth and nose. As a consequence, systems were developed for both intracavitary and interstitial therapy in several major radiotherapy centres, particularly Paris\*, Stockholm and Manchester. In the first half of the 20th century, all of these centres used radium, which had the advantage of a long half-life, making recalibration and replacement of sources unnecessary. Radium produces a high energy emission that is not preferentially absorbed in bone by the photoelectric effect. Therefore, it can be used to deliver large doses to tumours adjacent to bone that would be at risk of osteonecrosis if treated with low-energy orthovoltage x-rays. This latter advantage became less important as high energy external-beam therapy improved in the 1950s and 1960s and, as the daughter product of radium was radon gas, radium was phased out of use and replaced with caesium, which has solid decay products. Various applicator designs were created to allow live-source implantation techniques to be replaced by either manual or remote after-loading, whereby the radioactive source was only introduced into the applicators after the applicators were correctly positioned, be they intracavitary or interstitial applicators. Today, newly developed systems allow radioactive sources to be remotely after-loaded by either cable-driven or pneumatic techniques, enabling the activity of the radioactive sources to be increased to allow low-, medium-, and high-dose-rate brachytherapy with complete staff protection.

## 50.1.1 INTRACAVITARY BRACHYTHERAPY

### 50.1.1.1 *Cervix*

Intracavitary brachytherapy has largely been developed for the treatment of gynaecological cancers. Cervical cancer was one of the first tumours to be treated by brachytherapy and, in its early stages, can be treated extremely successfully. A tube is passed through the cervix into the uterus, where radioactive sources are loaded. In addition, further sources placed at the top of the vagina can increase the dose rate delivered to the cervix in relation to the dose rate to sensitive, normal tissues, such as the rectum and bladder. In this way, a tumouricidal dose can be delivered to a small volume without risking damage to the bowel and bladder. The techniques based on specifically designed applicators (see [Figure 52.1](#) through [Figure 52.3](#)) developed in Paris, Stockholm, Manchester and subsequently, in Houston by Gilbert

---

\* In French-speaking countries, brachytherapy is named “curiethérapie” after the name of Pierre and Marie Curie who discovered radium in 1898.

Fletcher, all rely on creating a three dimensional dose distribution using multiple sources in the uterus and vagina to create a high dose volume around the cervix, whilst sparing normal tissues. However, developments in micro-processor controlled, high-dose-rate after-loading now allow complex isodose patterns to be built up with a smaller number of applicators, or indeed, a single-line applicator. While such a system cannot produce as complex a dose distribution as multiple applicators, being constrained by the requirement to limit the high dose region close to the source, there may be circumstances in which the simplicity of treatment makes it an attractive option.

### 50.1.1.2 Endometrium

The treatment of choice for endometrial carcinoma confined to the body of the uterus is total hysterectomy, followed by adjuvant pelvic radiotherapy and vaginal brachytherapy, depending on histological prognostic factors. Vaginal brachytherapy can be achieved easily with either a line source or two *Manchester* style vaginal applicators. However, occasionally hysterectomy is not possible and the uterus remains *in situ*. Heyman developed a system of filling the uterus with small applicators, each containing a radium source (Heyman's capsules). These applicators were active and were removed by pulling on an attached string. Skill was needed to position these applicators in a configuration that would produce an even and tumouricidal dose to the tumour, as well as not entangle while being withdrawn from the uterus. This is a prime example of a skill virtually lost in brachytherapy, as there are very few clinicians who now have any expertise in this technique. Where the technique is still used, both low-and high-dose-rate after-loading systems have been developed.

However, with microprocessor-controlled high-dose-rate systems and CT-compatible applicators, isodose patterns can be created to match those of the classical Heyman system, delivering a homogeneous dose to the uterine wall.

### 50.1.1.3 Vagina

An obturator can treat the vagina by irradiating the mucosa evenly from a central line source or, in some circumstances, by producing higher doses in specific areas of the vaginal wall, using one or more peripherally loaded sources. Shields can be incorporated into vaginal obturators, although in general, they must be used with great caution if the tumour is not to be shielded unintentionally.

### 50.1.1.4 Other Sites

Occasionally, there is a role for intracavitary therapy in treating the nasopharynx, and techniques have been developed particularly for the postnasal space, whereby sources can be introduced into applicators via the nostrils. Similarly, in the treatment of antral tumours, an intracavitary applicator introduced into the maxillary antrum may be useful or, indeed, a mould may be used. However, as external-beam techniques have developed and as high energy electrons have become available, this is less commonly used. Intracavitary therapy may be of use in low rectal tumours with a rectal obturator, although again, this technique has largely been rendered obsolete by conformal external-beam techniques.

## 50.1.2 INTERSTITIAL THERAPY

### 50.1.2.1 Head and Neck

In head and neck cancer, interstitial therapy played a very large part in improving cure rates in early tumours, due to the problems of delivering a tumouricidal dose to a volume without causing bone necrosis. However, the placing of these interstitial applicators, which usually take

the form of active or manually after-loaded needles or hairpins, requires considerable expertise. This expertise has become quite scarce in many centres, as external-beam techniques have improved, decreasing the use of brachytherapy. Nevertheless, in centres with a tradition of brachytherapy, such as those in France, techniques have developed to replace manually after-loaded sources with remote after-loading sources using flexible plastic tubes. The tubes are introduced into the tumour volume and then brought out through the skin to be connected to the after-loading machine. This allows fractionated high-dose-rate regimens to be used, simplifying patient care during treatment.

As with gynaecological cancer treatments, brachytherapy alone can be an effective treatment for early stage disease of the head and neck, but is more commonly used as a boost following external-beam therapy to the primary tumour and draining lymph nodes. As such, it can be used for more advanced cancers that have undergone regression with the first phase of external-beam treatment. Equally, brachytherapy has a post-operative role when it is thought that the tumour bed may not be free of disease. An after-loading technique using plastic tubes laid into the tissues of the neck after node dissection is one of the most frequent uses of brachytherapy in head and neck cancer. Clinical guidelines for head and neck brachytherapy have been developed by the American Brachytherapy Society (Nag et al. 2001).

### 50.1.2.2 Breast

Following lumpectomy for breast cancer, interstitial implantation of the tumour bed may be used after external-beam therapy as the second phase of treatment. However, the wider availability of high energy electrons to provide a boost to this area and the difficulty in accurately delineating the tumour bed several weeks postoperatively, has meant that this technique has declined in the U.K. and elsewhere. However, it is still widely used in France, the U.S. and Italy. The use of an interstitial implant as the sole treatment in conservative treatment of early breast cancer is also being evaluated. This technique uses an inflatable balloon catheter to allow treatment of the tumour bed after mastectomy (Keisch et al. 2003).

### 50.1.2.3 Prostate Gland

Prostate gland work is an expanding area, in that early cancer of the prostate, with no evidence of spread beyond the capsule of the gland, may now be irradiated using permanently implanted  $^{125}\text{I}$  seeds (Hilaris 1997; Vicini 1999; Maurer 2002). The technique requires that the seeds are distributed evenly throughout the entire gland using ultrasound-guided needles. The positioning of these seeds may be *pre-planned* using CT scans or controlled with real-time computer planning on the basis of a predefined loading pattern. There is considerable skill needed in obtaining a satisfactory dose distribution within the prostate gland without causing morbidity to the urethra. Nevertheless, this is one of the few areas of brachytherapy that is expanding rapidly at the present time.

## 50.1.3 INTRALUMINAL THERAPY: BRONCHUS AND OESOPHAGUS

Intraluminal therapy was largely not possible in the past because of the size of applicators and the need for them to remain in place for many hours or days when using low dose rates. Obstruction to the bronchus or oesophagus could not be tolerated for long enough to deliver an effective dose. However, as after-loading techniques have improved and sources are produced of higher activity and smaller size, the intraluminal applicators now need only be in place for a matter of minutes. This allows high doses of radiation to be delivered to the superficial tissues of the bronchus and oesophagus and early results from centres using this for both radical (with external-beam radiotherapy) and palliative treatment are encouraging. The integration of brachytherapy with endoscopic laser resection is problematic and there is some evidence that if both techniques are used, the risk of subsequent catastrophic bleeding,

particularly in the bronchus, is much increased. The recommendations of the American Brachytherapy Society can be found in Gaspar et al. (1997).

### 50.1.4 SUPERFICIAL BRACHYTHERAPY

Superficial brachytherapy is little used these days, but has the potential for development with high dose rate, after-loading systems. The advantage of superficial brachytherapy in this situation is that high energy radiation can be delivered to superficial tumours with a very rapid fall-off within the tissue beneath, due to the inverse-square law. Although electrons may be more suitable for irradiating deeply invasive tumours to a depth of a few centimetres, brachytherapy is an attractive option for treating to depths of only a few millimetres. As such, it may well have a use in the treatment of vulval intra-epithelial neoplasia and other very superficial skin tumours. Occasionally, there are sites where it may be used internally, as in the vagina or oropharynx, when a custom-made mould is used. Treatment of ocular tumours using an applicator placed in contact with the sclera, with either a  $\beta$ -emitter (e.g. ruthenium-106) or with the low energy x-rays from iodine-125 seeds, is another area where superficial brachytherapy is still widely applied.

### 50.1.5 INTEGRATION OF BRACHYTHERAPY WITH EXTERNAL-BEAM THERAPY

In the early days, brachytherapy was prescribed on an entirely empirical basis, relating to the total number of milligrams of radium and the number of hours they remained in place. Prescriptions were therefore in milligram-hours. Accurate dose calculation in small volumes was not possible until relatively recently and, largely, dose distribution has been calculated retrospectively to empirically-derived treatment regimens and tolerance doses, rather than regimens having been derived from dosimetric principles. As a result, there was no easy way to integrate the dose from external-beam therapy and that from brachytherapy. In addition, the radio-biological processes that take place in high-dose-rate external-beam therapy are very different from those in low dose rate brachytherapy. Consequently, the biological effect on malignant and normal tissue is not directly related to the numerical sum of the external-beam and brachytherapy doses. However, mathematical models have been developed (see [Section 55.8](#)), which reflect the biological effectiveness of both external-beam and brachytherapy treatment regimens and the iso-effect curves of these treatments can then be summated. As of yet, this is not a standard method of either prescribing or recording brachytherapy treatments in association with external-beam therapy, but may well be the way forward.

ICRU Report 38 (ICRU 1985) recommends a system of reporting gynaecological brachytherapy in terms of the prescription, dose rate and doses to specific points. In addition, an estimate is made of the volume irradiated to a total dose of 60 Gy. However, when dose rates other than those achieved with radium systems of brachytherapy are used, an assumed equivalent dose has to be stated. This introduces a major problem in reporting therapy using ICRU 38, as there is no agreed equivalence of doses at different dose rates.

#### 50.1.5.1 *Practical Considerations*

In the early days of combined external-beam and brachytherapy regimens for the treatment of gynaecological cancer, central shielding was used in the external phase with the intention that central tissues largely treated by brachytherapy and peripheral tissues at the pelvic side wall were largely treated with external-beam radiotherapy. However, there is a degree of uncertainty as to the combined dose around the edge of the shields, particularly if the brachytherapy

applicators are not symmetrically placed in relation to the shield. As a consequence, there is a swing away from this philosophy towards using external-beam therapy first, with open fields, followed by brachytherapy. *Hot* and *cold* spots can be avoided this way. Some of the potential benefits of a very high dose that can be achieved around a brachytherapy source may be lost, however. Unfortunately, differences in technique of delivering external-beam radiotherapy and brachytherapy and in the sequencing and overall time of these treatments, make it virtually impossible to tease out an ideal treatment from historical data, in terms of tumour control and the avoidance of normal tissue damage. However, it is now clear that the overall treatment time of both the external-beam and brachytherapy contributions should not be excessively prolonged, due to the danger of accelerated tumour-cell re-population during treatment. Therefore, the advice for cancer of the cervix is that treatment is completed within a total of eight weeks.

### 50.1.6 DOSE-RATE EFFECTS IN BRACHYTHERAPY

#### 50.1.6.1 *Medium- and High-Dose-Rate Brachytherapy*

During low-dose-rate brachytherapy, there is repair of sub-lethal damage and, in general, this is more effective in normal tissues than in malignant tissues. There is less time for this repair to take place as brachytherapy dose-rates increase and, as a consequence, the treatment has to be fractionated to allow repair between fractions. In addition, it has been found that the total dose delivered to tissue also needs to be reduced. There are complex mathematical models dictating the size of these reductions. However, most centres use empirically derived regimens whereby, in changing from low-dose-rate therapy to higher dose rates, there is an overall reduction in total dose and a maximum tolerated fraction size.

Increasing the dose rate in gynaecological brachytherapy from  $0.5 \text{ cGy h}^{-1}$  to  $1.75 \text{ Gy h}^{-1}$ , it has been found that a total dose reduction of 10% to 15% is needed in order to achieve an effect on tumour and normal tissues that is similar to classical radium systems. With the use of high-dose-rate brachytherapy with iridium or cobalt sources, where dose rates can exceed  $1 \text{ Gy min}^{-1}$  to point A, the total dose reduction appears to be of the order of 35% to 45% and the maximum tolerated fraction size at point A is 8 Gy (see [Section 54.2.2](#) for the definition of point A). There have been few randomised trials in this area but those that have taken place, and those historical series that have been analysed, would seem to indicate the accuracy of this approach.

#### 50.1.6.2 *Pulsed Dose-Rate Brachytherapy*

Because of the concerns relating to radio-biology of high-dose-rate brachytherapy, systems using pulsed brachytherapy have been developed. A high dose rate is delivered for a very short time in many fractions over the same total length of time that a low-dose-rate insertion would have taken. Typically, a treatment fraction may last a few minutes and be delivered hourly for between 5 and 6 days. Theoretically, this allows the normal tissues to undergo repair, yet has the advantage of segregating the patient for irradiation for only a small proportion of the total treatment time. However, the disadvantages are that the potential for high throughput of patients on treatment machines is lost with pulsed-dose-rate therapy as each patient requires a machine of their own for several days, and that the numerous source positionings in a course of pulsed-dose-rate therapy increase the risk of a malfunction. Nevertheless, pulsed-dose-rate brachytherapy is particularly attractive in interstitial treatment. In gynaecological brachytherapy, the geometrical stability of high-dose-rate applicators outweighs the radio-biological disadvantages, whereby one would expect to see a higher incidence of late effects for a lower incidence of tumour cure. However, in interstitial therapy the positioning of the sources in relation to sensitive normal tissues is such that distances are much shorter and this geometrical advantage is lost. Therefore, pulsed- dose- rate therapy may have a place in

mimicking low-dose-rate brachytherapy in sites suitable for interstitial therapy, but is unlikely to be of benefit in gynaecological intracavitary treatment\*.

### 50.1.7 CURRENT WEAKNESSES AND POTENTIAL DEVELOPMENTS

At present the main weakness in brachytherapy is the lack of agreement on the optimum technique, dose and dose-rate for most brachytherapy treatments at most sites. Differences have arisen because of the wide variety of radioactive isotopes, applicators, and after-loading systems used, and these differences are, if anything, growing wider. In addition, there is still little consistency in dose prescription or dose reporting, or in the integrated dosimetry with external-beam radiotherapy. These areas are being addressed, but documents such as ICRU 38 (ICRU 1985) became outmoded almost concurrently with their production, because of the development of high-dose-rate brachytherapy. Also, the technology is, in many cases, moving ahead more quickly than clinical practice can accommodate.

The use of *iso-effect dosimetry* is very attractive and should move forward over the next few years, but requires a consensus on the validity of mathematical modelling and the wider availability of sophisticated computing systems. A National Cancer Institute review of brachytherapy research (Cumberlin and Coleman 2002) identified a number of areas for development. These included improved understanding of the radiation biology, improved imaging including the use of MR compatible gynaecological applicators and standardization of reporting. The challenge of dealing with the shape and relative position changes that occur both during brachytherapy and between brachytherapy and external-beam treatment was also identified.

For expertise to be maintained in the multidisciplinary team involved in brachytherapy, both for the delivery of a sound service and for teaching and research, it is likely that brachytherapy services will have to become concentrated in a small number of cancer centres. These centres could then have access to a wide variety of brachytherapy techniques to allow treatment to be tailor-made for the patients' needs. A smaller number of centres are also more likely to have a consensus view on conjectural areas.

\* Editors note: This is controversial. PDR brachytherapy for gynaecological treatments is more widely used in Continental Europe, especially in France, than in the U.K. Those radiation oncologists who prefer it, take the view that the radiobiological disadvantages of high-dose-rate brachytherapy are the determining factor.

## 51.1 INTRODUCTION

Brachytherapy developed largely through the use of sealed radium and radon sources. In the 1950s, alternative artificially produced nuclides became available, and gradually radium and radon were replaced with  $^{137}\text{Cs}$ ,  $^{192}\text{Ir}$ ,  $^{60}\text{Co}$ ,  $^{198}\text{Au}$ , and  $^{125}\text{I}$  sources (Trott 1987; Godden 1988). Although radium and radon are no longer used, many of the techniques that are used currently are based on the clinical experience gained with those sources over more than sixty years. Table M.4 in Part M gives data for a number of brachytherapy sources in current use.

---

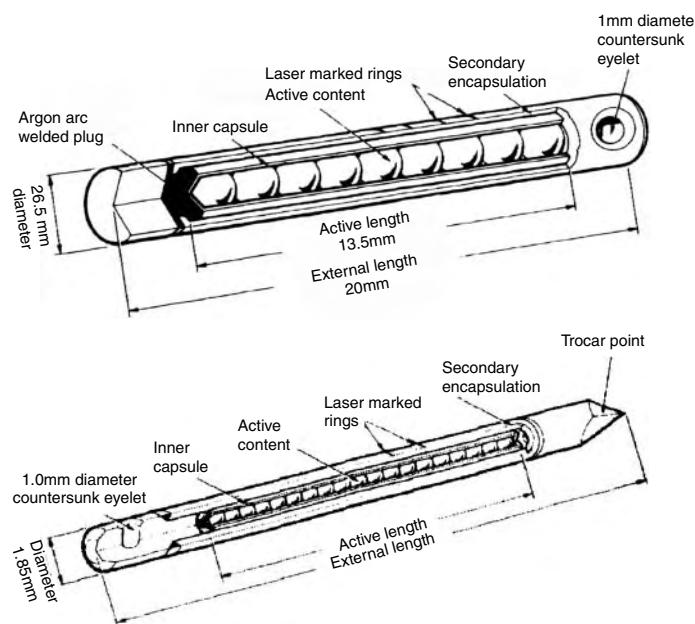

## 51.2 PARTICULAR SOURCES

### 51.2.1 RADIUM-226

Latterly, therapeutic sources of  $^{226}\text{Ra}$  consisted of dried radium sulphate powder doubly encapsulated in hermetically sealed containers made of platinum–iridium alloy. An inert filler was used to facilitate the uniform distribution of the radioactive nuclide in the source container. The 1620-year half-life of radium corresponds to a decay of approximately 1% in 17 years, so the useful life of a radium source was, in practice, determined by its mechanical properties, rather than by its rate of radioactive decay. The spectrum of emission is complex, with the emission of  $\alpha$ ,  $\beta$ , and  $\gamma$  radiation. Many of the  $\beta$ -particles emitted by radium and its decay products present in a sealed source are of high energy. Heavy filtration (typically 0.5 mm or 1 mm of Pt) is therefore necessary for sources intended for brachytherapy, so that the practical minimum diameter of such a source is about 2 mm. A filtration thickness of 0.5 mm Pt reduces the dose contributed by  $\beta$ -particles to about 1% of that contributed by the  $\gamma$ -radiation.  $^{226}\text{Ra}$  itself and several of its decay products, including  $^{222}\text{Ra}$ , are  $\alpha$ -emitters. Although  $\alpha$ -radiation is absorbed by a small amount of filtration, rupture of a radium source implanted within a patient's body could result in radium being deposited in bone, and radon gas, which is soluble in tissue and of high toxicity, irradiating local cells to a high radiation dose. Another disadvantage of radium is that the radiation from a sealed source from  $^{214}\text{Pb}$  (RaB) and  $^{214}\text{Bi}$  (RaC) is of high energy, so that a relatively large thickness of lead, or other protective material, would be needed for radiation protection purposes. For these reasons, and also because the maximum concentration of radium is relatively low, high activity sources are not available for afterloading techniques, and radium has been replaced by less hazardous nuclides.

### 51.2.2 RADON-222

Radon shares many of the properties of radium, the emission in each case being from the same decay products in radioactive equilibrium. The practical maximum activity per unit volume is about 70 times greater than that for radium, and geometrically small radon sources of high activity are therefore possible. The half-life of radon is 3.825 days. Traditionally, radon sources were fabricated as seeds or as linear sources, usually in gold capillary tubing of 0.5 mm wall thickness with crimped ends.

**FIGURE 51.1**  
Typical construction of  $^{137}\text{Cs}$  needle and tube.

### 51.2.3 CAESIUM-137

Up until the commercial availability and development of automatic afterloading equipment,  $^{137}\text{Cs}$  sources of similar shape and equivalent activity were often used as a direct replacement for radium in conventional intracavitary and interstitial therapy. Figure 51.1 illustrates the construction of a typical  $^{137}\text{Cs}$  tube and needle.  $^{137}\text{Cs}$  is a product of nuclear fission and is produced as a by-product of nuclear fuel reprocessing. It emits  $\beta$ -rays and 0.662 MeV  $\gamma$ -rays and has a half-life of 30.17 years, long enough to allow clinical sources to be used for 10 years or so; a 2% annual reduction in source activity occurs. Caesium is a toxic alkali metal of low melting point; earlier sources were made from caesium chloride or caesium sulphate, which are soluble in water. Sources were originally doubly encapsulated in platinum-iridium and, latterly, in stainless steel. In the case of point sources or small capsule sources, the caesium is incorporated as a constituent in a glass or ceramic; in this form the caesium is relatively insoluble.  $^{137}\text{Cs}$  glass has a maximum specific activity of about  $450 \text{ GBq g}^{-1}$  and an activity concentration of  $1.2 \text{ GBq mm}^{-3}$ , so that this form can be used for high-activity brachytherapy sources.  $^{137}\text{Cs}$  incorporated into zirconium phosphate has a lower maximum concentration of about  $180 \text{ MBq mm}^{-3}$ ; this is the form sometimes used in needles and tubes for interstitial therapy. Trace quantities of  $^{134}\text{Cs}$  (usually less than 1%) emit  $\beta$ -particles, and sources require a filter equivalent to 0.1 mm of platinum.

Caesium seeds have also been used. Typical seeds are 5 mm long and have an external diameter of 0.5 mm. The active element is an extruded gold wire 3 mm long and 0.3 mm in diameter, within which the  $^{137}\text{Cs}$  is uniformly distributed, and which is surrounded by a 0.076 mm Pt filter and a 0.1 mm stainless steel wall.

### 51.2.4 IRIDIUM-192

$^{192}\text{Ir}$  has a half-life of 73.8 days and emits  $\gamma$  photons with energies ranging from 9 keV to 884.5 keV, but the weighted average energy of a  $^{192}\text{Ir}$  brachytherapy source is 397 keV (Goetsch et al. 1991). With a high maximum-activity concentration of  $330 \text{ GBq mm}^{-3}$ ,  $^{192}\text{Ir}$  is suitable for high-activity afterloading sources; it is also available in the form of seeds

and flexible wires. In wire form it is produced by reactor irradiation of a 75%/25% iridium/platinum alloy, which is usually provided as wire, clad with 0.1 mm of pure platinum. Pure iridium is very hard and brittle, and is difficult to fabricate. The iridium/platinum wire is available with 0.3 mm and 0.6 mm overall diameter. European manufacturers also produce wires with a 0.5 mm diameter. The wire should be cut to the required length by means of special cutters which are designed to minimise particulate contamination. For clinical use, wires are often sheathed in plastic tubing. Hairpin wires and single pins cut to length before or after activation are used for implantation directly into tissue with the aid of removable stainless steel guides.

In the U.S.,  $^{192}\text{Ir}$  seeds are used in place of wire sources. There are two types of  $^{192}\text{Ir}$  seed sources available commercially, both having a physical length of about 3 mm—the primary difference being that of encapsulation. The first type has a 0.3 mm diameter core of 90% Pt/10% Ir with 0.1 mm Pt encapsulation giving an external diameter of 0.5 mm. The second type has a 0.1 mm diameter core of 70% Pt/30% Ir and is doubly encapsulated with two stainless steel sheaths, each 0.1 mm thick with an external diameter of 0.5 mm.

### 51.2.5 COBALT-60

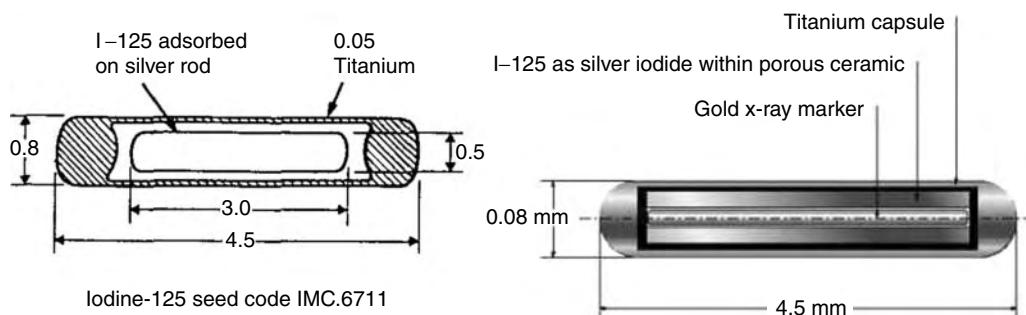

This nuclide is used in some high-dose-rate remote-loading machines since activity concentrations of up to 130 GBq  $\text{mm}^{-3}$  are available;  $^{60}\text{Co}$  emits 0.318 MeV  $\beta$ -rays, 1.17 MeV and 1.33 MeV  $\gamma$ -rays and has a half-life of 5.27 years. Because cobalt tends to be corrosive, it is usually nickel plated; encapsulation with 0.1 mm to 0.2 mm platinum-equivalent is necessary to filter the  $\beta$ -particles.

### 51.2.6 GOLD-198

This nuclide is produced by reactor irradiation of pure gold: activity concentrations of 7.4 GBq  $\text{mm}^{-3}$  can be readily produced. The active material is typically 0.5 mm in diameter and is sheathed in platinum of 0.1 mm to 0.2 mm wall thickness, which acts as an effective  $\beta$  filter.  $^{198}\text{Au}$  emits  $\beta$ -rays and 412 keV  $\gamma$ -rays; it decays with a half-life of 2.7 days. Sources are available as grains, seeds and wires. Grains are usually 2.5 mm long and are supplied in magazines which fit directly into commercially available implantation guns. Gold wire has also been used in intracavitary treatments of the oesophagus.

### 51.2.7 IODINE-125

This nuclide has a photon energy of 0.03 MeV and has a 59.4-day half-life. The initial decay is by electron capture, which produces a 35.5 keV gamma, but this is followed by de-excitation from the K and L shells resulting in a principal energy of 27.4 keV (from the K shell). The spectrum is further complicated by characteristic x-rays from the encapsulation materials. The isotope is produced by the reactor irradiation of  $^{124}\text{Xe}$ ; activity concentrations as high as 3.7 GBq  $\text{mm}^{-3}$  can be obtained by encapsulating an iodide-activated ion exchange bead. Sealed sources of  $^{125}\text{I}$  are being used as temporary or permanent implant sources in the management of prostatic, intra-ocular, and head-and-neck malignancies. Many designs of encapsulated sources are available, including the type 6711 (Amersham, now GE Healthcare) and Symmetra S06 (Bebig) seeds shown in [Figure 51.2](#). The model 6711 seed consists of  $^{125}\text{I}$  adsorbed onto the surface of a radio-opaque silver rod, which is encapsulated within titanium tubing. (The other widely used source from Amersham, the 6702, has now been discontinued.) The Bebig seed uses a gold marker and has a slightly higher effective energy (30 keV compared to 27.4 keV) as a result. In view of the low photon energy of  $^{125}\text{I}$  emissions and

**FIGURE 51.2**  
Construction of the 6711 (Amersham) and Symmetra S06 (Bebig)  $^{125}\text{I}$  seeds.

the different source types that are available, the dosimetry of  $^{125}\text{I}$  seeds has attracted much attention. Experimental studies (Burns and Raeside 1988; Nath et al. 1993) and Monte Carlo calculations (Burns and Raeside 1987) show that the transverse axial dose distributions of seed models are almost identical, but that the longitudinal axis dose distributions are significantly different. Details of all the  $^{125}\text{I}$  seeds in common use in the U.S.A can be found at the web site <http://adcl.mdanderson.org/rpc/BrachySeeds/SourceCharacteristics.htm> together with references to treatment planning data for them. Further discussion of the dosimetry of  $^{125}\text{I}$  seeds can be found in Section 53.4.2.

### 51.2.8 BETA SOURCES: STRONTIUM-90, YTTRIUM-90, AND RUTHENIUM-106

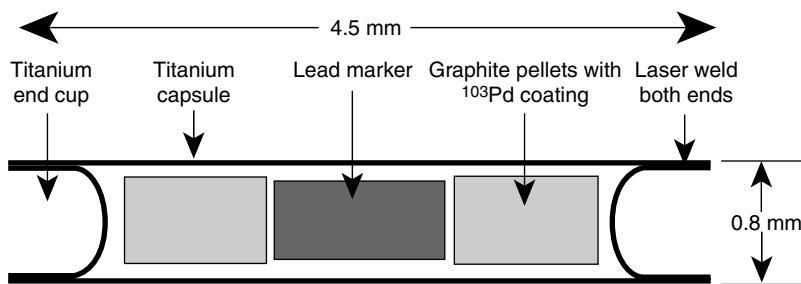

Although  $^{90}\text{Sr}$  has a relatively low  $\beta$  energy of 546 keV maximum, it is in radioactive equilibrium with its daughter element,  $^{90}\text{Y}$ , which has a maximum  $\beta$  energy of 2.27 MeV. This means that even though the half-life of  $^{90}\text{Y}$  is only 64 h, the more energetic  $\beta$ -rays are present for the 29-year half-life of  $^{90}\text{Sr}$ . It has been used in specially fabricated ophthalmic applicators designed to fit over the cornea of the eye (Jones and Dermentzoglou 1971). The applicators contain a  $^{90}\text{Sr}$  refractory compound in rolled silver sheet embedded into an inactive silver shell. Depending on the design, the active discs allow radiation from either the front or back of the applicator, the thickness of silver used for screening the low-energy  $\beta$ -rays being 0.1 mm.

$^{106}\text{Ru}$  is used in a form similar to  $^{90}\text{Sr}$  applicators, but the 3.54 MeV  $\beta$ -particles are more penetrating and have a maximum range in tissue of 18 mm compared to those of  $^{90}\text{Sr}$  which have a range of 12 mm. The applicators are designed for the treatment of intraocular tumours and treatment of ciliar body melanoma (Davelaar et al. 1992). A thin film of  $^{106}\text{Ru}$  is contained within a sheet of pure silver 1 mm thick. The applicators are hemi-spherically shaped with a radius of 7.5 mm or 10 mm.  $^{106}\text{Ru}$  has a half-life of 368 days.

$^{90}\text{Y}$  can be formed by nuclear fission and has been used in the form of rods for pituitary ablation (Jones et al. 1963). The source consists of yttrium oxide, pressed and sintered into rod form 1 mm to 2 mm diameter, 4 mm to 5 mm long. Typically, two or three rods of 150 MBq activity are implanted permanently into the pituitary.

### 51.2.9 OTHER SOURCES

A number of other sources have been used or are being introduced which are described below. These sources are not widely used outside the U.S.

**FIGURE 51.3**  
Theragenics model 200  $^{103}\text{Pd}$  seed.

### 51.2.9.1 Palladium-103

This nuclide has an average energy of 20.9 keV and a 17 day half-life, and is available in the form of seeds with strengths up to 110 MBq. The encapsulation consists of a titanium tube 0.8 mm in diameter and 4.5 mm long (0.06 mm wall), with laser welded end caps. The  $^{103}\text{Pd}$  is contained in a palladium layer electroplated on the surfaces of two graphite pellets, one on either side of a central lead marker pellet (see Figure 51.3). Absorption of incident photons by the titanium wall and the lead marker, and the self-shielding by palladium, result in an anisotropic emission pattern with an axial fluence much lower than the fluence along the transverse axis (Chiu-Tsao and Anderson 1991). Nath et al. (1992) review some of the considerations in using  $^{103}\text{Pd}$  compared to  $^{125}\text{I}$ .

### 51.2.9.2 Samarium-145

$^{145}\text{Sm}$  is produced by neutron irradiation of  $^{144}\text{Sm}$  (96.5% enriched); decay is by electron capture with 140 keV x-rays per 100 disintegrations in the energy region 38 keV to 45 keV plus 13  $\gamma$ -rays at 61 keV. The half-life is 340 days.

Fairchild et al. (1987) report the successful production of sources encapsulated in titanium tubes, 0.8 mm  $\times$  4.5 mm, with strengths up to 111 MBq. Interest in the development of  $^{145}\text{Sm}$  sources is due in part to the possibility of providing a source of low-energy photons with energies appropriate for maximising possible radiation enhancement with the thymidine analogue, iodinated deoxyuridine. By stimulating Auger cascades with photons above the K-absorption edge of iodine (33.2 keV), it is hoped to augment the effects of sensitisation. It is thought that such a technique might be especially effective in treating brain tumours, as the supporting normal brain tissue does not synthesise DNA.

### 51.2.9.3 Americium-241

Sealed sources of  $^{241}\text{Am}$  emit primarily 60 keV  $\gamma$ -rays. For photons with energies less than 30 keV, the attenuation in water is much greater than the build-up of dose due to scatter, and the absorbed dose decreases with depth faster than expected from the inverse-square law. However, for  $^{241}\text{Am}$  photons in water the multiple Compton scattering events compete effectively with the photoelectric effect. The Compton interactions produce a scattered photon with essentially the same energy as the incident photon (see Section 4.3.2) so that multiple photon scattering within the medium occurs, which produces a build up of energy absorption with depth, leading to the observed similarity of dose distributions in water to those produced by  $^{137}\text{Cs}$  sources. However, the  $^{241}\text{Am}$   $\gamma$ -rays interact with high-atomic-number materials such as lead, principally through the photoelectric effect. The half-value thickness (HVT) of  $^{241}\text{Am}$  is only 1/8 mm of lead, so shielding of sources can be achieved more easily than in the case of  $^{137}\text{Cs}$  or  $^{60}\text{Co}$  sources. The interest in  $^{241}\text{Am}$  sources is based mainly on the fact that it could lead to more effective shielding of critical normal tissues at risk in intracavitary irradiation; it is

suggested that in vivo shielding of bladder and rectum may also be possible by using high-atomic-number materials such as Hypaque solution and barium sulphate. However,  $^{241}\text{Am}$  also decays by alpha emission with a half-life of 432.2 years, its exposure rate constant for photons is low, and self-absorption of photons in the source material and encapsulation is high. Nevertheless, experimental sources of  $^{241}\text{Am}$  in the chemical form of  $\text{AmO}_2$  mixed with aluminium powder encapsulated in titanium have been developed and investigated for clinical use (Nath et al. 1987).

#### *51.2.9.4 Ytterbium-169*

$^{169}\text{Yb}$  has been introduced as a brachytherapy source (Mason et al. 1992); this nuclide is a lanthanide (rare earth) with a half-life of 32 days and a photon energy spectrum ranging from 49.8 keV to 307.7 keV with an average energy of 93 keV. The nuclide is produced by neutron activation of ytterbium oxide ( $\text{Yb}_2\text{O}_3$ ) and very high concentrations—comparable to those of  $^{192}\text{Ir}$ —may be produced. The only contaminant radionuclide present in any significant concentration is  $^{175}\text{Yb}$ , which has a relatively short half-life of 4.2 days. These properties are appropriate for both high activity sources for high-dose-rate after-loading procedures, and permanently implantable interstitial sources. Furthermore, the photon energy is such that in multiple-source implants, due to its uniform dose build-up characteristics, the expected dose homogeneity in an ytterbium implant is likely to be superior to that obtainable with nuclides of either higher or lower energy. In comparison with  $^{125}\text{I}$ , the  $^{169}\text{Yb}$  photons are more penetrating, and the radiation distribution around the source has a less pronounced anisotropic effect. Since the half-life of  $^{169}\text{Yb}$  is shorter than that of  $^{125}\text{I}$ , the initial dose rates for a  $^{169}\text{Yb}$  implant will be relatively higher. This may be clinically advantageous, since there is evidence that in some tumours, lower dose rates may impair disease control.

#### *51.2.9.5 Californium-252*

This is a man-made isotope produced by bombarding  $^{239}\text{Pu}$  with neutrons in a high-flux reactor. The radionuclide decays by  $\alpha$  emission with a half-life of 2.64 years and emits neutrons by spontaneous fission with a half-life of 85 years. It is the alpha emission that dictates the practical life of the source, but it is the neutron emission which makes the nuclide of such interest. The fission spectrum of neutrons has an average energy of about 2 MeV with a modal energy of 1 MeV. The associated  $\gamma$ -rays are within 0.5 MeV to 1 MeV.  $^{252}\text{Cf}$  seeds have been used in preloaded plastic tubes with a 10 mm spacing between seeds. The seeds themselves have a 0.25 mm thickness of 10% iridium platinum alloy on their walls, which produces a strong angular dependence in the absorbed dose distribution for the  $\beta$ - and  $\gamma$ -rays. Monte Carlo calculation techniques and experimental measurements have been made to establish the neutron dose delivered to tissue from point and linear sources (Krishnaswamy 1972).

#### *51.2.9.6 Caesium-131*

$^{131}\text{Cs}$  is a low energy x-ray emitter, with the most prominent peaks in the 29 keV to 34 keV region and has a half-life of 9.7 days. Brachytherapy seed sources (typically 4.5 mm long  $\times$  0.8 mm diameter) have been developed principally for prostate implantation. The shorter half-life is thought to offer advantages in biological effectiveness over  $^{125}\text{I}$  and  $^{103}\text{Pd}$  seed sources (Murphy et al. 2004).

---

### **51.3 SPECIFICATION OF BRACHYTHERAPY SOURCE STRENGTH**

Historically, the strength of sealed radioactive sources was specified in terms of activity (in mCi or MBq) or equivalent mass of radium (mg RaEq). Radium tubes and needles were

originally specified in terms of the actual mass of  $^{226}\text{Ra}$  they contained, and sources utilising radium substitutes such as  $^{137}\text{Cs}$  and  $^{192}\text{Ir}$  have been specified in terms of equivalent mass of radium, to give the same dose rate at 10 mm from the source. The quantity *apparent* or *effective* activity has also been widely used. However, these methods of activity definition can be confusing when encapsulated sources are considered.

In 1973 Wambersie et al. (1973) proposed that source strength should be specified in terms of the quantity of radiation emitted. This would avoid errors due to uncertainty in the relationship between the source activity and the radiation emitted, and reduce uncertainties in corrections for filtration in sheathing material and absorption in the source material itself. To this end, various national and international bodies have recommended the use of air kerma to specify source strength (CFMRI 1983; BCRU 1984; ICRU 1985).

The recommended quantity is the *Reference Air Kerma Rate* (RAKR), defined by the ICRU (1985) as “the kerma rate to air, in air, at a reference distance of 1 m, corrected for air attenuation and scattering”. For needles, tubes, wires and other rigid sources, the direction from the source centre to the reference point shall be at right angles to the long axis of the source. In the case of wire sources, it is recommended that the RAKR is specified for a 1 mm length of wire (BIR 1993). The SI unit of RAKR is  $\text{Gy s}^{-1}$  at 1 m, but for the purpose of source specification it is more convenient to use  $\mu\text{Gy h}^{-1}$  at 1 m for LDR sources and  $\mu\text{Gy s}^{-1}$  at 1 m and  $\text{mGy h}^{-1}$  at 1 m for HDR applications.

The American Association of Physicists in Medicine Task Group 32 (AAPM 1987) have recommended a slightly different quantity *air kerma strength*,  $S_k$ . This is defined as “the product of air kerma rate in free space and the square of the distance to the calibration point”. It is specified that the calibration measurement must be performed with the distance between detector and source large enough that the source can be treated as a point source and the detector as a point detector. Generally, this condition is fulfilled if the distance from source to chamber is at least ten times the length of the source. The AAPM recommend that air kerma strength be expressed in units of  $\mu\text{Gy m}^2 \text{h}^{-1}$  (or the numerically identical  $\text{cGy cm}^2 \text{h}^{-1}$ ), which they denote by the symbol  $U$ . In practice, the air kerma strength and the RAKR are numerically identical although dimensionally different (Rivard et al. 2004)\*. In this book, RAKR will be used.

The RAKR,  $\dot{K}_R$ , is related numerically to the activity,  $A$  in Bq, of the source as follows:

$$\dot{K}_R = \Gamma_\delta A / d_{\text{ref}}^2 \quad (51.1)$$

where  $\Gamma_\delta$  is the air kerma rate constant ( $\mu\text{Gy h}^{-1} \text{Bq}^{-1} \text{m}^2$ ) for the specific radionuclide.  $d_{\text{ref}}$  (=1) in the denominator is required as described in the footnote\*.  $\Gamma_\delta$  and its (now obsolete) counterpart, the exposure rate constant, are difficult to measure precisely, due to the uncertainty in the determination of the activity, and their use should be avoided whenever possible. The RAKR can be related to the exposure rate  $\dot{X}_R$  at a distance of 1 m:

$$\dot{K}_R = \dot{X}_R \frac{W_{\text{air}}}{e} (1 - g)^{-1} \quad (51.2)$$

\* The identity of RAKR and source strength depends theoretically on the inverse square law being obeyed between the measurement distance and 1 m. However, since the measurement of RAKR is made at a distance from the source large enough to consider it as a point source and includes a correction for air attenuation (IAEA 2002), this condition is fulfilled. There is then the dimensional difference. At present there is an ongoing discussion about the proper definition of reference air kerma rate (IAEA 2002). In the original CFMRI (1983) definition the units for RAKR were  $\mu\text{Gy m}^2 \text{h}^{-1}$ , interpreting the expression “at 1 m” in the definition as meaning that the unit  $\text{m}^2$  must be appended to the air kerma rate unit, but this was dropped in ICRU (1985). When using the RAKR to calculate the kerma rate at a distance different from 1 m, it is necessary to avoid the confusion resulting from the dimensional imbalance, which can be done either by insertion of the factor  $d_{\text{ref}}$  (=1 m) into some of the equations as required or by following the CFMRI interpretation. Although ICRU defines RAKR as being measured at 1 m, we have specifically included this as a reminder.

**TABLE 51.1**

Air Kerma Rate Constants

Nuclide	Air Kerma Rate Constant ( $\mu\text{Gy h}^{-1} \text{MBq}^{-1} \text{m}^2$ )
$^{60}\text{Co}$	0.30 <sub>6</sub>
$^{137}\text{Cs}$	0.077 <sub>2</sub>
$^{192}\text{Ir}$	0.108
$^{125}\text{I}$	0.033 <sub>7</sub>

*Source:* From ICRU (International Commission on Radiation Units and Measurements), Dose and volume specification for reporting interstitial therapy, ICRU Report 58, ICRU, Washington, DC, 1997. With permission.

where  $W_{\text{air}}$  is the average energy to create an ion pair in dry air and  $e$  is the charge of an electron ( $W_{\text{air}}/e$  has the value  $33.97 \text{ J C}^{-1}$ ), and  $g$  is the fraction of the kinetic energy of the secondary charged particles which is converted to bremsstrahlung in air under calibration conditions. The term  $(1-g)$  is taken as 0.997 for  $^{60}\text{Co}$ , 0.999 for  $^{137}\text{Cs}$ , and 1.000 for  $^{192}\text{Ir}$  (NCS 1991).

For compliance with radiation protection requirements it is common to start from a source specification in terms of activity in MBq. For this purpose the RAKR in  $\mu\text{Gy h}^{-1}$  should be divided by the air kerma rate constant as given in Table 51.1.

For some dose calculation methods conversion of the activity to traditional units is required. This is discussed in [Section 53.6](#).

## 51.4 CALIBRATION OF BRACHYTHERAPY SOURCES

The strength of a brachytherapy source is specified in terms of the air kerma rate at a point in free space at a distance of 1 m from the source on the radial plane of symmetry (i.e. the plane which bisects the active length and the cylindrical axis of the source). In the case of a wire source, the output should be specified for a 10 mm length, but specified as the RAKR per mm.

Before being used clinically, sources should be measured by the user. In principle, there are two methods that are frequently used for calibrating sources. A calibrated well-type chamber can be used, and is usually the method of choice. An in-air air kerma measurement can also be made with an ionisation chamber at a known distance from the source. In the latter case, a correction for the chamber volume has to be made; when the source-to-chamber distance is small compared with the size of the chamber, this correction factor can be significant. The preferred measurement device for low-strength sources is a well chamber (i.e. an isotope calibrator) (IAEA 2002). The calibration of the well chamber should be traceable to a National Standards Laboratory and checked regularly with a source of known strength. For low-strength sources this is best achieved with the aid of one or more radioactive sources calibrated at a National Standards Laboratory. Air kerma rate calibration of small sources of  $^{60}\text{Co}$ ,  $^{137}\text{Cs}$ ,  $^{226}\text{Ra}$ , and  $^{192}\text{Ir}$  at the National Physical Laboratory, U.K., has been described by Rossiter et al. (1991). The overall estimated uncertainty (95% confidence level) was found to be  $\pm 1.4\%$  for  $^{60}\text{Co}$ ,  $^{137}\text{Cs}$ , and  $^{226}\text{Ra}$  and  $\pm 1.5\%$  for  $^{192}\text{Ir}$ . In the U.S., the National Institute of Standards and Technology (NIST), formerly the National Bureau of Standards (NBS), has been instrumental in developing a wide range of traceable standards including those for  $^{192}\text{Ir}$ ,  $^{125}\text{I}$ , and  $^{103}\text{Pd}$  seeds.

The well chamber used for calibrating sources should respond linearly throughout its measuring range; its energy response must be known, and care must be taken to ensure that there is no drop in sensitivity when measuring high activities. Before use, the dependence of the

chamber sensitivity on the position of the source within the chamber should be determined experimentally. Usually, the chamber sensitivity increases gradually with distance from the bottom of the well to a maximum where the response is relatively uniform, and then drops as the source approaches the chamber entrance\*. A characteristic response of this form will require measurements to be made to ascertain how the chamber responds to sources of different lengths. A polymethyl methacrylate (PMMA, known as Perspex or Lucite) source holder should be used to ensure that sources are measured at the same position in the chamber; it is usual for the source to be positioned in the region of greatest sensitivity, and where change in response with source displacement is minimal. Ideally, the well chamber should be used in a location at least 300 mm from adjacent objects that might cause radiation scatter. The user should be aware that the response of the chamber is also dependent upon the source filtration and encapsulation (Williamson et al. 1982).

The calibration method will depend on the radionuclide and its activity. It might be necessary to have one or more long-half-life sources available for checking the reproducibility of the chamber. Chamber calibration checks with sources of known strength should be made every six months. If the well chamber is open to the atmosphere, temperature and pressure corrections must be made. Measurements made at the IAEA (2002) over a two-year period showed that the reproducibility of the well chamber response used with a calibrated  $^{137}\text{Cs}$  source was generally within 0.5%.

Calibration measurements can also be made in air with an ion chamber. Although the RAKR is a quantity specified at 1 m, it is not always practical to make a measurement at this distance. The RAKR,  $\dot{K}_R$ , may be determined from measurements made in air using the equation:

$$\dot{K}_R = N_K (M_u/t) k_{\text{air}} k_{\text{scatt}} k_n (d/d_{\text{ref}})^2 \quad (51.3)$$

where  $N_K$  is the air kerma calibration factor of the ionisation chamber at the actual photon energy;  $M_u$  is the measured charge collected during the time  $t$  and corrected for ambient temperature and pressure, recombination losses and transit effects during source transfer (in the case of remote afterloading systems);  $k_{\text{air}}$  is the correction for attenuation in air of the primary photons between the source and the chamber;  $k_{\text{scatt}}$  is the correction for the scattered radiation from the walls, floor, measurement set-up, air, etc.;  $k_n$  is the nonuniformity correction;  $d$  is the measurement distance, i.e. the distance between the centre of the source and the centre of the ionisation chamber; and  $d_{\text{ref}}$  is the reference distance of 1 m.

Methods of determining these factors and typical values are given in IAEA Technical Document 1274 (IAEA 2002). The document provides descriptions of methods for determining room scatter and data from investigations by Kondo and Randolph (1960) and Bielajew (1990) about chamber correction factors for ionisation chambers in point-source photon beams. The distance from source to chamber will depend upon source strength and the sensitivity of the ionisation chamber, but is typically between 5 cm and 20 cm for chambers up to  $30 \text{ cm}^3$ . For low dose-rate sources, large-volume ionisation chambers ( $30 \text{ cm}^3$  to  $100 \text{ cm}^3$ ) are required to obtain an adequate signal. Leakage currents must be measured and allowed for if these are greater than 0.1% of the signal. The uncertainty of the non-uniformity correction factor for very large chambers is often large, and can limit their use.

In the case of high-dose-rate sources, ionisation chambers of about  $1 \text{ cm}^3$  can be used (e.g. Farmer-type chambers of  $0.6 \text{ cm}^3$ ). For  $^{60}\text{Co}$  and  $^{137}\text{Cs}$  calibrations, chamber factors are usually available, but this is not so for  $^{192}\text{Ir}$ . Until such time as calibration laboratories are able to supply users with a factor for  $^{192}\text{Ir}$  (as the UK National Physical Laboratory (NPL) is now able to do), the principle for determining the air kerma calibration for  $^{192}\text{Ir}$  is to calibrate it at

---

\* For some chambers, where the bottom part of the well is also collecting the ionisation, the maximum of response could be found there.

an appropriate x-ray quality (such as 250 kV) and at  $^{137}\text{Cs}$  or  $^{60}\text{Co}$ . With knowledge of the air kerma calibration factors at these energies, the air kerma calibration factor for  $^{192}\text{Ir}$  is obtained by interpolation.

Air kerma rates (and/or source activity) should be measured and compared with the RAKR in the manufacturer's test report. Discrepancies greater than the accuracy limits specified by the manufacturer should be explored further. The most appropriate method of measuring individual sources will depend largely on the type of source. Some typical examples are described in the following subsections. For sources with shorter half-lives, such as  $^{192}\text{Ir}$ , it is important to include a correction for source decay when calculating the required treatment time.

#### 51.4.1 LONG HALF-LIFE SOURCES OF LOW ACTIVITY ( $^{226}\text{Ra}$ , $^{137}\text{Cs}$ , AND $^{60}\text{Co}$ )

Ideally, the user should have calibrated standard sources for each radionuclide to be measured, and for each type of source. This is rarely possible, and if the user has only one calibrated source, correction factors have to be used to allow for the energy response of the well chamber, variation in source geometry, and any differences in source encapsulation. The appropriate standard should be used to calibrate all other similar sources. This is best achieved by sequential placement of the standard source and the source to be calibrated in the same position in the well chamber, and can be achieved with the aid of a PMMA holder to locate the source centrally. It should be possible to determine the dose rate from individual sources (e.g.  $^{137}\text{Cs}$ ) within 5%. Corrections for radioactive decay should be made at suitably frequent intervals: the frequency recommended is every month for  $^{60}\text{Co}$  sources and twice a year for  $^{137}\text{Cs}$  sources.

#### 51.4.2 SOURCES USED IN AUTOMATIC AFTERLOADING SYSTEMS ( $^{137}\text{Cs}$ , $^{192}\text{Ir}$ , AND $^{60}\text{Co}$ )

For automatic afterloading systems (see [Section 52.3](#) and [Section 52.4](#)), transfer of the source into the measurement position will, during transit, irradiate the well chamber or ion chamber. If the measuring system does not employ an externally triggered electrometer to collect charge after the source has stopped moving, then a correction must be made to account for the dose delivered to the detector during the transit of the source to and from its measurement position. This is simply done by subtracting two readings taken for different intervals to eliminate the transit charge common to both.

There are typically four types of problem:

1. *Preloaded source trains (such as the  $^{137}\text{Cs}$  Curietron type sources).* Ideally, the user should calibrate these sources before they are loaded into the flexible source holders. If this is not possible, the manufacturer should guarantee that the output of each source loaded into the source train is not different by more than 5% from that stated. When possible, the user should confirm the position of individual sources in a source train by means of autoradiography and radiography, and check the isodose pattern for each train using film, thermoluminescent dosimeters, or radiochromic dosimetric film. The location and relative activity of individual sources along a source train can also be recorded by means of a device employing a highly collimated detector.
2. *Multiple medium activity sources such as  $^{137}\text{Cs}$  sources used in the LDR/MDR Selectron.* Upon receipt from the source supplier, the variation in activity between individual sources should be measured with a well chamber. The variation in source strength between sources in a batch should preferably be less than 3.5%. The user should

request a certificate of the homogeneity of the source activities from the manufacturer and confirm that the measured data agree with the manufacturer's data within acceptable limits. For dose distribution calculations, the weighted-mean air kerma rate should be determined.

3. *Single high-activity sources such as the  $^{192}\text{Ir}$  source used in HDR remote afterloading equipment such as the HDR or PDR microSelectron, the GammaMed, and the Varian HDR afterloading machines.* High-activity sources can be measured in a calibrated well chamber or by measuring the source output at a known distance with a Farmer type ionisation chamber. If a calibrated well chamber designed to measure high-strength sources is available, the calibration process is straightforward. However, care should be taken to ensure that the HDR source does not cause a temperature increase inside the chamber (Goetsch et al. 1992). The response of the chamber should be checked at regular intervals using a source with a long half-life. The reproducibility of such measurements should be on the order of 0.5%.

When measurements are made with an ionisation chamber, corrections have to be made for room scatter, air attenuation, and the finite size of the chamber. It is also probable that the user will have to experimentally determine a calibration factor for the Farmer type chamber. This can be done in the following way:

Goetsch et al. (1991) showed that for  $^{192}\text{Ir}$ , which emits  $\gamma$  photons with a mean weighted energy of 397 keV, a total wall thickness of  $0.36 \text{ g cm}^{-2}$  was required for build-up, and also to eliminate the effect of secondary electrons from the source and its capsule. If a total-chamber-wall thickness of  $0.36 \text{ g cm}^{-2}$  is not available, a  $^{60}\text{Co}$  build-up cap can be used instead. Source output measurements are made with ion chamber (and build-up cap) at 250 kV. The chamber calibration factor  $N_{\text{K},\text{Ir}}$  for  $^{192}\text{Ir}$  is then

$$N_{\text{K},\text{Ir}} = (0.8 A_{\text{W},250 \text{ kV}} N_{\text{K},250 \text{ kV}} + 0.2 A_{\text{W},\text{Co}} N_{\text{K},\text{Co}})/A_{\text{W},\text{Ir}} \quad (51.4)$$

where  $A_{\text{W}}$  is the  $A$ -wall factor, which is a correction factor for all energies determined by applying the linear attenuation curves measured with different cap materials and thicknesses for each beam.

The response of the chamber alone is

$$N_{\text{chamber}} = N_{\text{K}} A_{\text{W}} \quad (51.5)$$

The values correspond to the thickness of the chamber wall plus build-up caps of various thicknesses. If  $A_{\text{W}}$  is not available for the chamber in use, then  $A_{\text{W}}$  can be set to unity for each energy in the equation 51.4 and the calibration factor is determined from

$$N_{\text{K},\text{Ir}} = 0.8N_{\text{K},250 \text{ kV}} + 0.2N_{\text{K},\text{Co}} \quad (51.6)$$

With the use of this equation, the uncertainty in the air kerma factor for Ir increases by approximately 0.5%. It is now possible to obtain a direct calibration for a thimble chamber or a well chamber from the NPL.

The values for  $A_{\text{W}}$  for a number of different chambers are given in IAEA Technical Document 1274 (IAEA 2002). The source chamber distance is typically 10 cm to 20 cm. [Table 51.2](#) lists typical factors for calibration in air.

Whatever methods are used for calibrating HDR sources, before being used clinically, new sources should be calibrated from two independent sets of measurements. The dose rate of an HDR source in clinical use should be checked at least every month, and preferably more often. A well chamber is a convenient method of making daily QA checks.

**TABLE 51.2**Typical Factors for In-Air Calibration of  $^{192}\text{Ir}$  HDR Sources

Typical A-Wall Factors	$A_{W,250\text{kV}}$	$A_{W,\text{Ir}}$	$A_{W,\text{Co}}$

4. *Multiple high activity sources such as  $^{60}\text{Co}$  sources used in the HDR  $^{60}\text{Co}$  Selectron.* Techniques similar to those described in (3) can be used to determine the strength of individual sources and to determine a weighted-mean air kerma rate for dose distribution calculations.

### 51.4.3 SHORT HALF-LIFE SOURCES OF LOW ACTIVITY SUCH AS $^{198}\text{Au}$ , $^{192}\text{Ir}$ , AND $^{125}\text{I}$ SOURCES

A suitable long-half-life source should be selected as a reference source. Then a calibrated standard source of the appropriate short-half-life isotope should be obtained and compared with the reference source by sequential placement within the well chamber using the same chamber settings. In this way, it is possible to determine the relative sensitivity of the system to the two sources. The chamber can then be calibrated for the particular radionuclide and the long-lived reference source used to verify that the chamber is operating properly after the short-half-life source has decayed away.

If a short half-life nuclide is not available as a standard, it might be necessary to measure the source strength by measuring the air kerma rate of a typical source. Generally, the air kerma rate will be too low for high precision measurements and it will be necessary to measure the air kerma rate at a distance from multiple sources; the relative output from each source can be determined with the aid of the well chamber.

\* The more recent publication (IAEA 2002) omits the values for the 0.2 cm<sup>3</sup> Farmer chamber, but other values are the same. Factors are also given for a number of other chambers based on the Monte Carlo calculations of Ferreira et al. (1999).

The reference source should be measured every time the chamber is used to calibrate the short-half-life sources. When appropriate, the measurement should be corrected for decay of the reference source.

When several small sources such as  $^{125}\text{I}$  or  $^{192}\text{Ir}$  seeds are used for an implant, the total activity of the batch should be known within 5% and the activity of individual sources should not differ by more than 15%. Well chamber checks of Rapid Strand  $^{125}\text{I}$  seeds usually measure 5 seeds at a time (Butler et al. 1998). However the well chamber must be calibrated precisely for this geometry and for this type of source since, for the low energy radiation emitted from  $^{125}\text{I}$ , the chamber response is very sensitive to any spectral change.

Wire sources should be checked to ensure that the linear activity is uniform with  $\pm 5\%$ . If the wire is bent during use it can cause small areas of low linear activity.

#### 51.4.4 OPHTHALMIC APPLICATORS

The calibration of ophthalmic applicators is problematic because of the extremely rapid fall-off in dose rate. Soares et al. (2001) showed in an international calibration that there are differences in calibration for  $\beta$ -emitting plaques of the order of 14% and the uncertainty quoted by standards laboratories is higher than for other measurements. Kollaard et al. (2006) recommend that the calibration should be specified at a distance of 2 mm from the source surface. Methods available include alanine, radiochromic film, scintillation detectors and TLD. It is recommended that verification of the activity for ophthalmic applicators should be possible within 10% (Kollaard et al. 2006).

---

### 51.5 QUALITY ASSURANCE OF SEALED SOURCES

Quality assurance in brachytherapy includes procedures and tests to ensure source security (including systems to identify sources uniquely), maintain source integrity, and also provide patient dosimetry within clinically acceptable limits. The storage and use of radioactive sources must provide maximum patient and personnel safety. Whereas all of these matters are important, this section addresses only those aspects that are relevant to the calibration of individual sources. These include checks for leakage and contamination, and measurements to ascertain the distribution of radioactivity in the source. Quality assurance checks associated with the storage, manipulation, cleaning, and sterilisation of sources are not described, nor are the procedures related to the clinical dosimetry of multiple sources.

#### 51.5.1 LEAKAGE AND CONTAMINATION CHECKS

These tests are to confirm that the source does not leak radioactivity, and that the surface of the source is not contaminated with free radioactivity. All sealed sources such as caesium tubes and needles must conform to BS 5288 (BSI 1976). Sources obtained from manufacturers are issued with leakage test certificates which describe the immersion and wipe tests that have been carried out. The upper limit of the safety level is 200 Bq. New encapsulated sources should be wiped with a swab or tissue moistened with water or ethanol, and measured with a Geiger-Müller or scintillation counter capable of detecting 200 Bq. The leakage from a sealed non-gaseous source or leak-proof container may be estimated by multiplying the total activity measured in a wipe test by a factor of ten. If the tests indicate that there is a free activity of 2 kBq, the source must be regarded as leaking, and must be sealed immediately in an airtight container and returned to the manufacturer. For encapsulated long-life sources, the maximum time between leakage tests should be 2 years, even though the sources might not be in clinical use; annual tests should be made on old sources that have been in use for several years.

Low-activity sealed sources used in automatic afterloading systems should be swab tested annually or, if this is not possible, source catheters should be checked regularly for contamination. It is difficult to swab test high-activity afterloading sources, and reliance must be placed upon catheter monitoring.

Iridium ( $^{192}\text{Ir}$ ) and gold ( $^{198}\text{Au}$ ) wires and seeds are not classified as sealed radiation sources because their cladding remains slightly radioactive. The principal hazards are those caused by scoring of the surface and particulate fragmentation when the wire is manipulated or cut with inappropriate equipment. Handling tools and cutting equipment should be monitored and decontaminated regularly. Only cutting equipment designed to cut cleanly should be used.

### 51.5.2 RADIOGRAPHY AND AUTORADIOGRAPHY

These tests provide information about the distribution of radioactive material within its container, and positional data about individual sources in radioactive source trains and applicators. Autoradiography is also useful for checking the uniformity of radioactive wires and ribbons of radioactive seeds. Although manufacturers often provide autoradiographs of sealed sources, users should carry out autoradiography on all new sources before clinical use. Autoradiographs should be evaluated to confirm that the source activity is distributed uniformly (within  $\pm 5\%$ ) throughout the inner cell. Needle sources might have two or more cells; the source activity and distribution in each cell should be the same (within 10%) unless one or more of the cells is deliberately loaded differentially.

Radiography and autoradiography should be used to check the configuration of single and multiple sources in pre-loaded source trains. In the case of afterloading machines whose source configuration can be programmed, autoradiographic checks should be carried out at commissioning, and after machine service or catheter replacement (see [Section 52.5.1](#) and [Figure 52.8](#)).

## 52.1 INTRODUCTION

Afterloading for brachytherapy was introduced in order to reduce the radiation dose to some radiotherapy staff groups, such as the radiotherapist performing the brachytherapy and the theatre staff attending the insertion. The first methods used manual afterloading, in which the inactive applicators or needles were positioned and checked before the active sources were introduced. With the advent of remote afterloading techniques, the radiation dose to other

staff, such as nurses, source curators and technical staff preparing radioactive source trains, was reduced. The different techniques and their clinical applications will be discussed in the following sections.

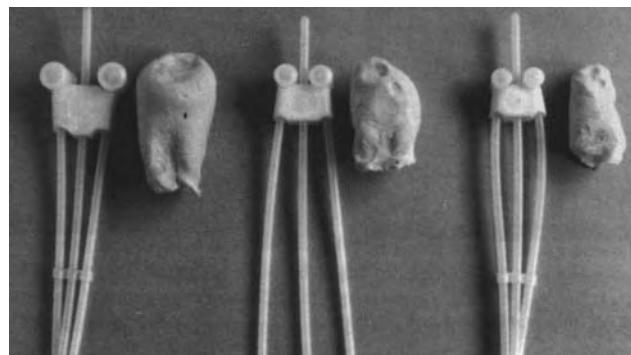

## 52.2 MANUAL AFTERLOADING

### 52.2.1 INTRACAVITARY TECHNIQUES

Although manual afterloading has been used in various techniques since the very earliest days of brachytherapy, the method became popular principally after technical innovations by Henschke et al. (1963) and the introduction of miniature caesium sources (Horwitz et al. 1964) for intracavitary radiotherapy.

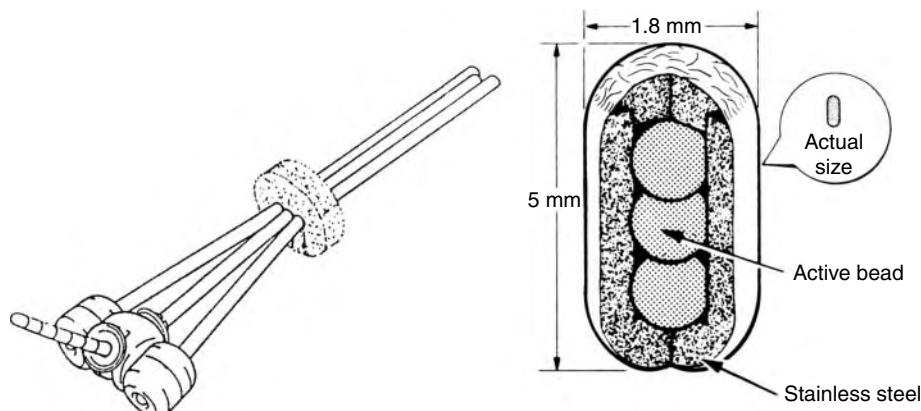

Afterloading can be used for all types of brachytherapy, including interstitial, intracavitary and mould-type treatments. The design constraints on interstitial afterloading devices are obviously greater than those for intracavitary techniques, in which applicators of relatively large volume can be accommodated in many of the body's cavities. Interstitial afterloading consists of inserting either needles or catheters (of small diameter) into the tumour volume; these are then loaded with radioactive wires or seeds. In the case of intracavitary therapy, especially in techniques for treating carcinoma of the cervix, applicator design has varied widely. Chassagne and Pierquin (1966), at the Institut Gustave Roussy, described a technique using a moulded plastic vaginal applicator as shown in Figure 52.1, which could then be afterloaded with  $^{192}\text{Ir}$  wires or  $^{137}\text{Cs}$  sources. This involves fabricating an acrylic mould for individual patients. Flexible source trains are inserted into the mould via flexible plastic tubes. The mould is such a good fit that patients may be allowed to get out of bed for exercise during treatment; local hygiene is assured by daily vaginal irrigation via a special additional tube. Figure 52.1 shows also a series of *Delouche* applicators. Unlike the moulds which are individualized, the Delouche applicators are manufactured as standard sizes (Delouche and Gest 1974). They are disposable. Both types of applicators may be afterloaded manually but they may also be connected to a remote-controlled system (see [Section 52.3](#)). In these methods, the dose fractionation is based essentially on the Paris low-dose-rate system.

[Figure 52.2](#) illustrates another intracavitary method using a disposable manually afterloaded system together with a flexible spring container developed commercially by Amersham International (now GE Healthcare). The uterine and ovoid tubes are made of

**FIGURE 52.1**

Different sizes of *Chassagne* vaginal moulds used at the Institut Gustave Roussy shown side by side together with the disposable *Delouche* applicators which are designed to fit different sizes of vaginal cavities using cylindrical plastic ovoids of 3 different diameters offering 6 possibilities for interspacing. The flexible plastic tubes which guide the sources up to the moulds are not shown. They are similar to the *Delouche* central tube (uterine catheter) or could be thinner if  $^{192}\text{Ir}$  is being used.

**FIGURE 52.2**

Amersham disposable manual afterloading system with detail of sources.

flexible polyvinyl tubing and the ovoids, spacers and washers are made of high-impact polystyrene. The applicators, which are impregnated with barium, separate into sections that can be held together by a polystyrene disc through which the sections pass. Although the device is based on the Manchester system, in practice the principal axis of the ovoid sources lies at a different angle from that of the Manchester ovoids and allowance must be made for this difference when dose calculations are made.

### 52.2.2 INTERSTITIAL TECHNIQUES

Tumours of the oral cavity lend themselves to interstitial brachytherapy. If they are early stage, they can be treated with brachytherapy alone; otherwise, a combined external beam and interstitial approach can be used.

Small tongue tumours can be treated using the hairpin technique and the Paris system of dosimetry. Stainless steel slotted hairpin guides are inserted into the patient under general anaesthetic. The position of these guides is optimised whilst still inactive and x-ray films or fluoroscopic images are frequently acquired at this stage to assist in the positional optimisation. Separation between the hairpins is ideally between 12 mm and 15 mm. The active hairpins are prepared in the radioactive source preparation laboratory and transported to the theatre for insertion. The radiation oncologist inserts the sources and removes the hairpin guides at the same time. Each hairpin is sutured in place to ensure stability for the duration of the implant. Imaging in the form of orthogonal x-rays or CT scans is performed afterwards for the purposes of dose calculation.

If the target volume is too thick for a hairpin-type implant, then the *plastic loop* technique (using iridium wire) can be employed. Stainless steel needles are inserted through the skin in as parallel a fashion as possible, and run through the tumour before exiting through the skin. Nylon cord is then passed through the needle and plastic tube (of the same diameter as the needle) is pulled through into the channel made by the needle as the needle is removed. The skin surface is identified by radio-opaque washers which also act as anchorage for the plastic tubes. Dummy marker wires are then fed into the plastic tubes to act as rulers for the determination of active-wire length and position. Images are taken for dosimetric purposes and the active-wire lengths are cut and heat-sealed into small-diameter plastic tubes. The active wires are then loaded into the patient, anchored by lead washers and remain in situ for the calculated duration of the implant.

These techniques are particularly applicable to buccal mucosal tumours, lower alveoli, neck node recurrences and breast implantation (Pierquin and Marinello 1997).

## 52.3 REMOTE-CONTROLLED AFTERLOADING: LOW AND MEDIUM DOSE RATES

There are several commercially available remote-controlled afterloading systems. Sources can be driven by cable or by pneumatic transfer. The source can be in the form of a single capsule or a series of capsules in a flexible spring container attached to a cable or multiple spherical sources that are blown pneumatically into the patient. Table 52.1 compares the source characteristics and mechanisms for some of the equipment that is available.

There are several methods of achieving low dose-rate afterloading, each using a different applicator system and method of source transfer. Some of these methods are illustrated by reference to commercially available systems, all of which have the following features in common:

- The shielding of the machine head conforms to IEC (1989), which specifies an air kerma rate  $1 \mu\text{Gy h}^{-1}$  at 1 m and  $10 \mu\text{Gy h}^{-1}$  at 50 mm.
- The positioning of the source(s) within the applicator (or catheter) is reproducible within 1 mm.
- In the event of machine failure, source retraction takes place automatically.
- Treatment exposure is controlled and documented.

The *Curietron* system uses a number of preloaded source trains whose composition is specified at the time of purchase. They are made up of  $^{137}\text{Cs}$  sealed sources, which are individually 1.65 mm diameter and 5.3 mm long, with an active length of 3.6 mm. The reference air kerma rate for these sources is between 30 and  $100 \mu\text{Gy h}^{-1} \text{cm}^{-1}$  at 1 m. A number of these sources, together with an appropriate number of spherical spacers, are loaded into a stainless steel spring which is 3 mm in diameter and 250 mm long. The end of this spring distal to the source train is sealed with a hook, which serves as identification of the source train and provides the means of connection to a drive cable. Up to 20 of these preloaded source trains may be stored in the source safe. For treatment, a selection of up to four source trains is transferred from the source safe (using the drive cable and a transfer sleeve) into the Curietron source projector. *Delouche* applicators or *Chassagne* moulds\* are inserted into the patient and connected using connecting sleeves to the projector so that the sources can be remotely inserted into the applicators using the drive cables.

The original *Buchler* system is also driven by cable, but makes use of a single radioactive source, which is made to move linearly by means of a cam device. Variously shaped cams are available, so that the movement of the source along the applicator can be selected according to treatment requirements. During treatment, the position of the source is controlled by the cam (called a *programme disc*), which moves the source with constant frequency within the applicator over a path length of up to 200 mm. For gynaecological work, a three-channel system is available: one channel provides an oscillating source for the uterine tube and two channels with fixed source positions are used for loading of the ovoids. Machine design is such that different nuclides can be used. For example, the oscillating source could be  $^{137}\text{Cs}$ ,  $^{192}\text{Ir}$ , or  $^{60}\text{Co}$ , depending upon the source activity: sources used for irradiating the vagina are usually  $^{137}\text{Cs}$ .

In the *Nucletron LDR/MDR Selectron* machine, the sources are in the form of 2.5 mm diameter spherical pellets. Source trains can be made up of a combination of 48 spacers and sources. The number of sources and their positions in each source train is independently programmable. Nucletron manufactured a three-channel and a six-channel LDR/MDR caesium-137 machine. The six-channel machine can be used to treat two patients

---

\* *Fletcher-type* applicators can also be used with a slightly different type of source train and connector.

**TABLE 52.1**

Details of Sources Used in Remote Afterloading Equipment

Nuclide	Activity	Number of Sources	Type of Source	Source Diameter	Dose Rate	Transfer Mechanism
$^{137}\text{Cs}$	0.5–1.5 GBq	48	Pellet	2.5 mm	LDR/MDR	Pneumatic
$^{137}\text{Cs}$	0.75 GBq	variable	Capsules	1.7 mm	LDR	Cable
$^{137}\text{Cs}$	30–250 MBq/cm	15	Ribbon	< 2.3 mm	LDR/MDR	Pneumatic; Cable
$^{192}\text{Ir}$	400 GBq	1	Cylinder	1.1( $\times$ 5) mm	HDR	Cable
$^{192}\text{Ir}$	20–40 GBq	1	Cylinder	1.1( $\times$ 5) mm	PDR	Cable

simultaneously. As the radioactive sources are  $^{137}\text{Cs}$ , they are usually replaced every 10 years. This is not due to the reduction in dose rate but because with multiple source transfers it is possible that the sources have become distorted and could be damaged or stick in the applicator tubes. The height of the source stack is measured regularly to check the distortion of the sources and pellets.

The sources are sorted magnetically and transferred pneumatically into the patient via stainless steel applicators that fit onto the end of pneumatic flexible tubing. The position of the source is continuously monitored and maintained at the programmed position by a pneumatic air check. A microprocessor controls all the hardware and processing functions of the Selectron. A self-diagnosis function gives appropriate warnings of any faults and sources are automatically withdrawn if a fault occurs.

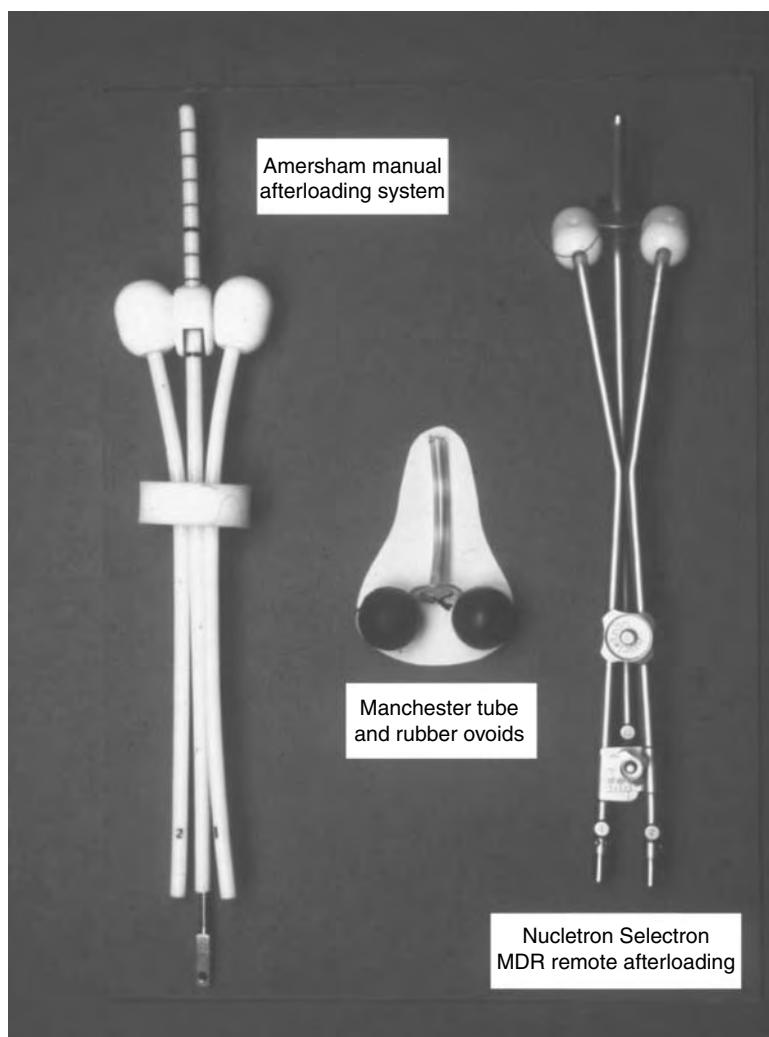

### 52.3.1 APPLICATORS

The applicators for LDR Selectron intracavitory insertions for the treatment of carcinoma of the cervix were developed from the Manchester principles as shown in [Figure 52.3](#).

Approximate source geometry was maintained, although the applicators are now made of stainless steel and can either be anchored together only at the distal end from the patient, or can be made to fix together in reproducible rigid geometry, as shown in [Figure 52.4](#). The applicators are inserted into the patient under general anaesthetic and dummy sources are positioned inside the applicators for identification on x-ray. The dose distribution and treatment time is calculated from the applicator and source co-ordinates; it should be calculated on an individual basis for each patient, as the dose to rectal and bladder points varies from patient to patient. Once the treatment plan has been calculated, the Selectron is programmed with the active source positions and the plastic transfer tubes, into which the sources and dummy pellets are blown, are inserted into the steel applicators. Each applicator is uniquely interlocked to each channel so that it is impossible to place an incorrect catheter into the applicator. Treatment times are of the order of 10 h to 20 h and the patients are treated (often overnight) in a specially protected room on a ward. Nursing staff have a remote control with which to interrupt the treatment; the sources are automatically retracted and nursing procedures can be carried out with no radiation hazard. The machine is fail-safe, as the sources are maintained within the patient by air pressure so that if the power were to fail, pressure would drop and the sources would automatically return to the safe.

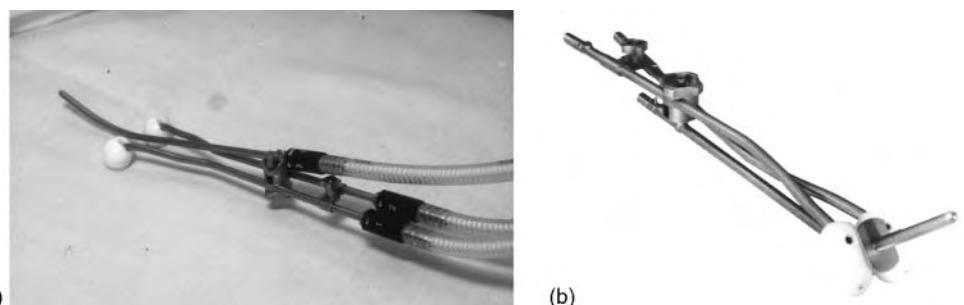

There are many other types of applicator produced for use with the LDR Selectron, but one of the more commonly used for the treatment of carcinoma of the vagina is the straight line source *Dobbie* type applicator, as shown in [Figure 52.5](#).

Sources are loaded into the straight applicator and spacers of different diameters are used as appropriate to best fit the patient's anatomy. Dose is usually prescribed at 0.5 cm from the

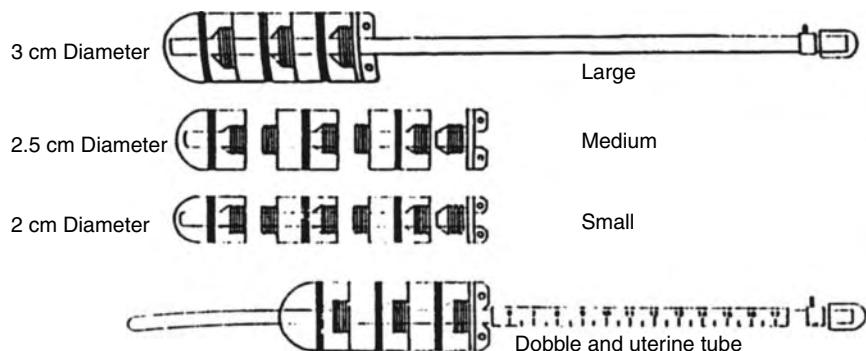

**FIGURE 52.3**  
Amersham and Selectron applicators compared with the Manchester system.

surface of the applicator. Some centres use a uterine tube and Dobbie, differentially loaded, for treatment of carcinoma of the cervix, as illustrated in the lower part of [Figure 52.5](#). This technique also lends itself to customisation in order to keep rectal doses within tolerance. However, care should be taken with the specification of dose calculation points (both for

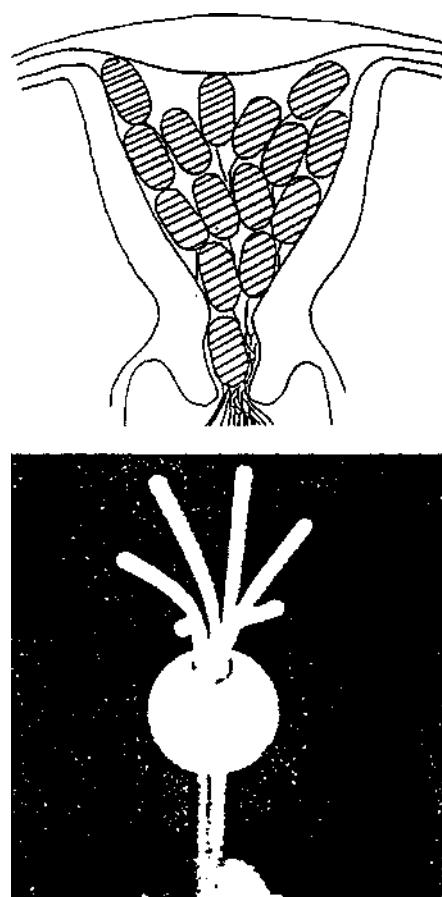

**FIGURE 52.4**  
(a) Rigid Selectron applicators; (b) fixed-geometry applicators.

**FIGURE 52.5**  
*Dobbie type applicators.*

prescription and critical organ dose) to ensure that the correct and safe loading patterns are used.

Carcinoma of the endometrium is difficult to treat, as the uterine wall is of variable thickness and is often considerably distorted. Heyman's capsules (Heyman 1929) were an attempt to produce an even dose distribution to the uterine wall by packing the uterus with

**FIGURE 52.6**  
*AP view of the applicator for clinical use with six afterloading tubes that expand due to the inherent stress of the material.*

many small sources, but it is very difficult to achieve a satisfactory dose distribution. Devices developed for use with afterloading methods usually take the form of two curved tubes that curl into the uterine cavity, although multiple tubes like the ribs of an umbrella have also been used, as shown in [Figure 52.6](#).

In most centres, the standard treatment is total hysterectomy, bilateral salpingo-oophorectomy and adjuvant radiotherapy, which is often given via an intracavitary insertion of two ovoids. The size of ovoid is selected to be the *best fit* in the patient. Doses are prescribed at 5 mm from the surface of the ovoids.

## 52.4 REMOTE-CONTROLLED AFTERLOADING: HIGH DOSE RATES

Historically, the TEM Cathetron was one of the first commercially available high-dose-rate remote afterloading machines. Using  $^{60}\text{Co}$  sources sealed in tubes connected to catheters, treatment times were reduced from hours to minutes. The basic unit comprised a source safe and a set of stainless steel catheters, which could be connected independently to the source safe via flexible tubes. The safe, which was located in the treatment room, housed up to nine separate  $^{60}\text{Co}$  sources, each in a source pencil; each pencil was capable of accommodating individual sources up to a maximum length of 100 mm. Typical source activities were 100 GBq to 200 GBq.

The catheters were connected to the flexible tubes to allow exposure of the source, which was controlled automatically from outside the treatment room by means of electro-mechanically driven cables. Much of the pioneering work in HDR brachytherapy was carried out with the Cathetron (O'Connell et al. 1967; Joslin et al. 1972). The machine was functionally reliable, but one of its limitations was that the source configurations, both in terms of source activity and source distribution, were limited to a choice of nine source pencils.

Liversage et al. (1967) devised source loadings to achieve the same relative contributions to point A (see [Section 54.2.2](#)) from the central tube and ovoids, as in the Manchester system. In producing isodose curves, allowance was made for the effects of oblique screening. Because the Cathetron source pencil comprises a number of short capsules, the  $\gamma$ -ray absorption through the hemispherical ends increases with obliquity rather less than would be the case if the sources were contained in a long steel cylindrical tube.

Santhamma and Das (1978) carried out experiments using TLD to determine the optimum source arrangement to achieve a *Manchester* distribution, although the vaginal colpo-stats are not in the true Manchester orientation with respect to the central uterine tube. The results verified theoretical calculations that took into account the filtration at the ends of the sources, the effective filtration of the  $^{60}\text{Co}$   $\gamma$ -rays in the sheathing of the source capsule, the thickness of the helical steel spring surrounding the source element and the wall of the stainless steel catheter.

In recent years,  $^{60}\text{Co}$  has been replaced by  $^{192}\text{Ir}$  for HDR work. The Nucletron HDR microSelectron and other machines such as the GammaMed 12i and the VariSource make use of a single 370 GBq  $^{192}\text{Ir}$  source (1 mm  $\times$  4 mm long), which is cable-driven into the patient. The source can be programmed to move in step-fashion through one or more catheters. The systems are designed to be used for intraluminal, interstitial, intracavitary and intraoperative brachytherapy. [Table 52.2](#) shows the key features of the three systems mentioned above.

When using an HDR system for brachytherapy, the procedure is to insert the applicators or catheters and then to drive a simulator (dummy) source through them to test the overall source travel distance, and check for obstructions and incorrectly attached applicators, needles or catheters. Only after a successful test run can the  $^{192}\text{Ir}$  source be exposed. The single, small, but highly active source can be programmed to travel consecutively through between 18 and 24 channels (depending on the make of machine) and to stop at up to 60 different dwell

**TABLE 52.2**

Key Features of Afterloading Systems

	GammaMed 12i	VariSource	HDR microSelectron
HDR	✓	✓	✓
PDR	✓	✗	✓
Number of channels	24	20	18
Adjustable height	✓	✓	✓
Stepwidth	1–10 mm	Variable	2.5, 5
Source diameter	0.9 mm	0.6 mm	1.1 mm
Check position	PC controlled with position-control panel	Camera and scale	Hand controllers for dummy source

positions in each channel. Dwell times at each position can be varied up to 999 s. A variety of rigid applicators, needles and flexible catheters from 1 mm outer diameter upward are available and provide means by which a large number of different techniques can be used. The position of the source can be controlled within 1 mm and can be programmed to travel in incremental steps (typically 2.5 mm, 5.0 mm, or 10.0 mm).

The relatively short half-life of  $^{192}\text{Ir}$  leads to regular source replacement, usually every three months: the source exchange can be accomplished without any associated risk to the operator.

Treatments of gynaecological sites with HDR machines are similar to those with the LDR Selectron, but of course the treatment time is about 15 min, compared with 15 h. The dose reduction for the biological effect should be between 50% and 70% of the dose with the conventional Manchester system, and the treatment is given in several fractions. The rigid applicators are inserted in theatre and clamped in position; the clamps are attached to a long bar fixed to the operating table so that the applicators do not move during treatment. The applicators are much smaller in diameter than the LDR Selectron applicators, and can often be used without a general anaesthetic, so that the patient can have treatment as an outpatient.

Rectal retractors or packing are often used to give increased sparing to the rectum. The level of protection of the treatment room for an HDR microSelectron (which is often a protected operating theatre) will depend on the size and location of the room. Although  $^{192}\text{Ir}$  gamma radiation is less penetrating than  $^{137}\text{Cs}$  radiation and treatment times are much shorter, the activity of the HDR  $^{192}\text{Ir}$  source is very much higher than those sources in the LDR Selectron machines. The patient is observed via TV monitors, whilst pulse and respiration are monitored. The source is driven out independently and automatically returns at the end of a pre-set time.

### 52.4.1 ENDOVASCULAR BRACHYTHERAPY

The endovascular application of brachytherapy concerns internal radiation of the wall of a blood vessel, usually an artery, with the aim of reducing a condition termed restenosis, a re-narrowing of a blood vessel (Nath et al. 1999, Pötter et al. 2001a).

There are currently two major sites of interest for endovascular therapy: the femoral and popliteal arteries are being investigated by the PARIS trial (Peripheral Artery Radiation Investigational Study) to demonstrate the safety and efficacy of delivering radiation to these sites; and the coronary arteries are being investigated in the PREVENT study (Proliferation Reduction with Vascular Energy Trial). Both the peripheral and coronary endovascular brachytherapy studies make use of a multiple balloon catheter system, which is introduced into the vessel over a guidewire and positioned, with the array of balloons spanning the target area.

The balloons are then inflated with fluid, which centres the catheter within the lumen of the artery, helping to optimise the dose distribution to the vessel wall. A closed-ended radiation sheath

is inserted and a miniature radioactive source—either an  $^{192}\text{Ir}$  gamma source (Nucletron system) or a pure beta emitter (GammaMed BetaMed)—is advanced, step-wise, through the catheter to the target site, where it remains for a pre-planned period of a few minutes before removal.

A typical system for coronary restenosis comprises three components: the afterloader, a flexible  $\beta$ -emitting  $^{32}\text{P}$  source wire (diameter approximately 0.45 mm) and a centring catheter. The beta emitter and source strength are chosen to allow for treatment in a regularly-shielded cardiac catheterisation laboratory. The source wire can be used in multiple cases because it is protected from blood contact by the centring catheter, which contains a dedicated, dead-end lumen. The normal interventional procedure (angioplasty, stent placement, etc.) is performed and the guide wire is placed in position, followed by the pre-programmed radioactive source. The advantage of remote afterloading is that the procedure can be temporarily interrupted for cardiological procedures to take place; the afterloader automatically records the data relating to any interruptions and calculates the remaining treatment time needed to complete the procedure. This procedure is gradually being replaced by the use of drug-eluting stents.

#### 52.4.2 PDR MICROSELECTRON

The pulsed-dose-rate (PDR) microSelectron is an afterloading machine based on similar mechanical principles to the HDR microSelectron. The machine offers variable, low-dose-rate pulsed brachytherapy: the source activity is in the range 20 GBq to 40 GBq. The pulse length is between 10 and 30 min per hour, according to source activity. This has advantages for the patient in terms of comfort and convenience and there may also be therapeutic advantages (Santhamma and Das 1978; Brenner and Hall 1991). There are a number of reports of the outcome of such treatments (Mangold et al. 2001; Peiffert et al. 2001; Sminia et al. 2001; Harms et al. 2002).

---

### 52.5 ASPECTS OF QUALITY ASSURANCE FOR AFTERLOADING SYSTEMS

There are four important elements that are common to all QA programs. These are:

1. A person experienced in brachytherapy applications of radiation physics should be made responsible for drawing up the quality assurance program and for ensuring compliance with it.
2. A detailed record of the program should be kept, specifying the procedures to be adhered to, the tests to be carried out and the frequency of the tests to be undertaken and recording the results of all tests in a traceable logbook.
3. Radioactive sources should only be used in compliance with local, national and/or international recommendations.
4. Incidents that have, or might have, affected the precision of treatment or the safe use of sources should be noted, so that the program can be modified in the light of experience. The overall program should be reviewed periodically.

Specific areas for quality assurance procedures are discussed in the following sections and are summarised in [Table 52.3](#)

#### 52.5.1 SOURCE POSITIONING

When using afterloading techniques, source positioning and the reproducibility of source positions are very important. Autoradiographs of the sources positioned in the applicators should be compared with radiographs of dummy sources in the same applicators to identify

**TABLE 52.3**

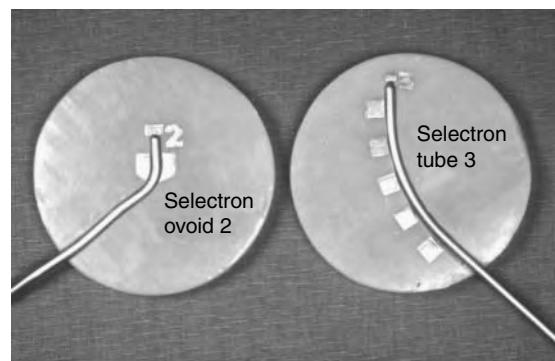

Summary of Recommended Checks

Frequency	Test	Tolerance
Daily	Room safety, door interlocks, alarms	Functional
	Console functions, batteries, switches, printer	Functional
	Visual inspection of applicators	Undamaged
Monthly	Agreement of source and dummy positions	1 mm
	Reproducibility of source positioning	1 mm
	Calibration	3%
Each source change	Timer function	1%
	Position of source in applicators	1 mm
	Mechanical integrity of applicators	Functional
Annually	Source transit time	
	Dose calculation algorithm	3%, 1 mm
	Simulate emergency conditions	Functional
	Digitiser; verification with test phantom	<2 mm
	Review documentation, review procedures	Update when necessary
	Measurement verification vs. planning system	Within 5%

the relationship between the programmed source positions and the dummy markers that are used for treatment planning. Simple wax and Perspex phantoms can be used to check the reproducibility of applicator positioning, as shown in Figure 52.7 and Figure 52.8.

Lead-foil markers can be embedded into the surface of the phantom to provide marks and scales on the film. Once the applicators have been positioned, the film (e.g. Kodak XV2 film) is taped onto the phantom. Secondary electron emission from the lead-foil markers shows up on the autoradiographs, so that the source position reproducibility and source relationship to the applicator surface can be compared and recorded. All applicators to be used clinically should be tested in this way. Autoradiographs should be performed on various clinical source configurations. This should be done routinely after service or maintenance to check the function of the machine.

For high-dose-rate systems when dose rates are too high to allow reasonable exposure times, autoradiographs with film are not as precise, so radiation-sensitive paper such as Detex and Gafchromic material are used. The advantage of these is that they are not significantly light-sensitive, so they can be used in daylight. Exposure time needs to be on the order of 300 s, however, for a 370 GBq source.

**FIGURE 52.7**

Wax phantoms for quality control of the source positions within the applicators.

**FIGURE 52.8**

Autoradiograph of sources (right-hand side) and x-ray of dummy sources (left-hand side).

### 52.5.2 MACHINE FUNCTION

The machine function itself must be regularly checked and the checks documented. These checks will take place at different frequencies, some daily, weekly, or monthly and some three-monthly. These checks should include:

- Couplings and connectors
- Transit tubes and applicators
- Treatment timers—including a measurement of timer errors
- Fail-safe devices during power failure or air pressure failure (e.g. backup storage batteries)
- Limitations of source positions and treatment lengths
- Room and machine interlocks
- Programming and carrying out a simulated treatment
- Measurement of source transit time
- Measurement of radiation exposure levels adjacent to the intermediate and main source safes at the surface and at 1 m.

### 52.5.3 FACILITY CHECKS

Room protection should be sufficient to maintain acceptable dose levels in surrounding areas (see [Section 61.2.1](#)). These dose levels must be checked at commissioning and after structural alterations. Radiation warning signs should be prominently displayed. Independent radiation monitors should be available for regular use inside the treatment room. These should be activated when the source is exposed and tested each time the machine is to be used. There should be a hand-held dose monitor outside the room, which should be tested regularly for use in emergencies.

### 52.5.4 EMERGENCY PROCEDURES

Emergency procedures that will differ between various applications of the afterloading machine should be well documented and posted in a prominent position (see also [Section 61.4.1](#)). These should be tested at regular intervals. Equipment should be available for removal and storage of radioactive sources in the event of a source return failure. A procedure common to most situations is to maintain the integrity of the system (i.e. not to disconnect the applicators unless the exact position of the sources is known).

### 52.5.5 OTHER

Also essential to the safe operation and treatment of afterloading equipment are

- Training of personnel, including written instructions, demonstrations, etc.
- Patient instruction and explanation (including instructions to visitors)
- Comprehensive record keeping of checks performed.

### 53.1 INTRODUCTION

This chapter sets out the methods by which the dose delivered by brachytherapy sources can be calculated. It is important that the physicist has a clear appreciation of the theoretical

basis of these calculations so that, whether applying a manual calculation system or using a computer algorithm, the correction factors that are implicit in the algorithm and those that must be applied explicitly are fully understood. The issue of dose calculation is considered first in a generic way, and then the calculation of dose for specific sources will be considered.

## 53.2 DOSE FROM A POINT SOURCE

The dose rate,  $\dot{D}(r)$ , at a distance  $r$  from a point source can be expressed in terms of the dose rate at  $r_{\text{ref}}$  from the source  $\dot{D}_{\text{ref}}$  by the simple relationship:

$$\dot{D}(r) = \dot{D}_{\text{ref}} \frac{r_{\text{ref}}^2}{r^2} f(r) \quad (53.1)$$

The reference distance,  $r_{\text{ref}}$ , usually considered is 1 m.

$\dot{D}_{\text{ref}}$  is the absorbed dose rate to water\* that would be achieved in vacuo, i.e. with no attenuation and scattering. As explained in [Section 6.4](#), if  $K_R$  is the reference air kerma rate (RAKR) of the source (see [Section 51.3](#)), then

$$\dot{D}_{\text{ref}} = K_R \left( \frac{\mu_{\text{tr}}}{\rho} \right)_{\text{air}}^{\text{water}} (1 - g) \quad (53.2)$$

where  $(\mu_{\text{tr}}/\rho)_{\text{air}}^{\text{water}}$  is the ratio of the mass energy transfer coefficient for water and the mass energy transfer coefficient for air (BIR 1993) and  $(1 - g)$  is the energy loss of secondary electrons to bremsstrahlung in water. The factor  $(1 - g)$  may mostly be ignored (see [Section 51.3](#)) and will therefore be omitted from subsequent equations. Between the energies of 150 keV and 1.5 MeV, the ratio of the mass energy transfer coefficients lies in the range 1.107–1.112, and the BIR working party recommend the use of the value 1.11 for all common energies except  $^{125}\text{I}$ , for which 1.02 is recommended.

The factor  $f(r)$  is a correction factor for attenuation and scattering. Because of attenuation and scattering, the actual dose rate at 1 cm from the source may be either greater (for  $^{192}\text{Ir}$ ) or less (for  $^{125}\text{I}$ ) than that predicted by the straight conversion from air kerma to dose to water. At a specified distance,  $r$ , when this factor is greater than 1, it indicates that scattered radiation makes a significant contribution to the dose. The BIR working party recommended the use of the values of  $f(r)$  given by Sakelliou et al. (1992) as given in [Table 53.1](#). However, these data, like those of Dale (1982), were calculated with the incorrect decay scheme for  $^{192}\text{Ir}$  published in the *Radiochemical Manual 1982* (Wilson 1966). [Figure 53.1](#) shows the data for  $^{192}\text{Ir}$  given in [Table 53.1](#) in a graphical form. All the data have been renormalised to a value of 1.0 at 1 cm<sup>†</sup>.

Combining [Equation 53.1](#) and [Equation 53.2](#) and omitting the bremsstrahlung correction factor we obtain:

$$\dot{D}(r) = K_R \left( \frac{\mu_{\text{tr}}}{\rho} \right)_{\text{air}}^{\text{water}} \left( \frac{100}{r} \right)^2 f(r) \quad (53.3)$$

where  $r$  is in centimetres and  $K_R$  and  $\dot{D}(r)$  have the units  $\mu\text{Gy h}^{-1}$ . (Note that, conveniently, by replacing the term  $(100/r)^2$  by  $(1/r)^2$ —i.e. by dividing both sides of the equation by 10 000—the units of  $\dot{D}(r)$  become  $\text{cGy h}^{-1}$ ). As before,  $(\mu_{\text{tr}}/\rho)_{\text{air}}^{\text{water}}$  is 1.11 for  $^{192}\text{Ir}$  and 1.02 for  $^{125}\text{I}$ .

\* As in external-beam therapy it is usual for reference dosimetry to be based on dose to water. If required the dose to particular tissue types can be calculated instead.

† For a point source, the normalised value of  $f(r)$  is strictly equal to the radial dose function  $g(r)$  used in the TG43 formalism (as in [Equation 53.8](#)).

### 53.3 EXTENSION TO A LINE SOURCE

Consider the activity spread out uniformly over a wire to form a line source. The geometry of this is represented by Figure 53.2, ignoring the attenuation of the wire for the present. The wire may be broken down into elementary lengths ( $dL$ ) and the linear activity of the source in terms of the RAKR per cm must now be considered. Ignoring attenuation and scattering in water (i.e. assuming  $f(r)=1$ ), the elemental dose rate at  $P$ ,  $dD_P$ , is then given by

**FIGURE 53.1**

Graph showing the radial dose function,  $g(r)$ , for  $^{192}\text{Ir}$  as calculated using the data in Table 53.1 (all data are normalised to 1.0 at 1 cm).

**FIGURE 53.2**

Calculation of dose rate due to a line source.  $L$  is the length of the active part of the source and  $t$  is the radius of the source (including its encapsulation).

$$d\dot{D}_P = \left(\frac{\mu_{tr}}{\rho}\right)_{air}^{water} \dot{K}'_R dL \frac{1}{r^2} \quad (53.4)$$

where  $\dot{K}'_R$  is the RAKR per unit length of the source in  $\mu\text{Gy h}^{-1} \text{cm}^{-1}$  at 1 m,  $D_P$  is in  $\text{cGy h}^{-1}$  and  $r$  and  $L$  are in cm. The equation may be rewritten in polar coordinates using the fact that

$$r = x \sec \phi \text{ and } L = x \tan \phi, \quad dL = x (\sec^2 \phi) d\phi;$$

therefore:

$$\dot{D}_P = \left(\frac{\mu_{tr}}{\rho}\right)_{air}^{water} \dot{K}'_R \int_{-L/2}^{+L/2} \frac{1}{r^2} dL = \frac{\left(\frac{\mu_{tr}}{\rho}\right)_{air}^{water} \dot{K}'_R}{x} \int_{\phi_1}^{\phi_2} d\phi = \frac{\left(\frac{\mu_{tr}}{\rho}\right)_{air}^{water} \dot{K}'_R}{x} (\phi_2 - \phi_1) \quad (53.5)$$

where  $\phi$  is in radians and  $x$  in cm. (Note that  $\phi$  has been used here rather than the more usual  $\theta$  to point out the different definitions used in this approach compared to that of TG43 described in [Section 53.4](#).)

Now consider the effect of attenuation in the sheath, but for the time being, continue to ignore attenuation and scattering in the medium. If  $t$  is the radius of the sheath, then this attenuation is  $e^{-\mu t \sec \phi}$ , where  $\mu$  is the linear attenuation coefficient of the material of the sheath (which is assumed to be the same as that of the solid wire). Equation 53.3 then becomes:

$$d\dot{D}_P = \left(\frac{\mu_{tr}}{\rho}\right)_{air}^{water} \dot{K}'_R dL \frac{1}{r^2} \frac{e^{-\mu t \sec \phi}}{e^{-\mu t}} \quad (53.6)$$

Note that it is necessary to divide by  $e^{-\mu t}$  because the definition of RAKR involves a measurement that includes the effect of attenuation in the direction perpendicular to the wire. Converting to polar coordinates gives the result:

$$\dot{D}_P = \frac{\left(\frac{\mu_{tr}}{\rho}\right)_{air}^{water} \dot{K}'_R}{x e^{-\mu t}} \int_{\phi_1}^{\phi_2} e^{-\mu t \sec \phi} d\phi \quad (53.7)$$

The integral term is known as a Sievert integral and can only be solved numerically.

Tabulations of the Sievert integral are available in a number of forms (see [Section 54.1.3](#)), such as the *Manchester system* tables (Paterson and Parker 1967), the French *escargot* curves (Schlienger et al. 1970) and the *Oxford cross-line curves* (Hall et al. 1966; Welsh et al. 1983). As is the case with Equation 53.6, the Manchester and Oxford tables ignore the effect of tissue attenuation and scattering.

With a computer, it is just as easy to divide the source into a number of small segments and treat each one as a point source (but allowing for the self-attenuation of the source) in which case Equation 53.2 can be used together with a correction for oblique filtration.

## 53.4 THE TG43 FORMALISM

In practice, because of the effects of scattering that are ignored, the Sievert integral calculation does not accurately represent the dose from encapsulated sources (Williamson 1996) along the axis of the source, even when  $f(r)$  is included in the calculation. This is especially true for  $^{125}\text{I}$  sources. To improve calculation accuracy, it is desirable to make use of Monte Carlo calculations using real source geometries, etc. To facilitate this, the AAPM (Nath et al. 1995) have proposed that the different components of the dose calculation be divided up into geometry, attenuation and scattering, and anisotropy. They have proposed the formula:

$$\dot{D}(r,\theta) = S_k A \frac{G(r,\theta)}{G(r_0,\theta_0)} g(r) F(r,\theta) \quad (53.8)$$

where  $\dot{D}(r,\theta)$  is the dose rate in water, expressed in  $\text{cGy h}^{-1}$  at a distance  $r$  in cm from a line source and  $\theta$  is defined as in Figure 53.2;  $S_k$  is the air kerma source strength expressed in U (i.e.  $\mu\text{Gy h}^{-1} \text{m}^2$ );  $A$  is the dose rate constant expressed in  $\text{cGy h}^{-1} \text{U}^{-1}$ ;  $G(r,\theta)/G(r_0,\theta_0)$  is the geometry factor;  $r_0$ ,  $\theta_0$ , the reference position, is defined by  $r_0=1 \text{ cm}$  and  $\theta_0=90^\circ$ ,  $g(r)$  is the radial dose function; and  $F(r,\theta)$  is the anisotropy function.

The concept of air kerma strength is discussed in Section 51.3. It is numerically identical to the RAKR. The dose rate constant,  $A$ , is defined as the dose rate to water at the reference position from a unit air kerma strength source. It incorporates the effect of the source dimensions, of the source encapsulation and the effect of scatter. Using the formalism of Equation 53.2, it is equal to  $(\mu_{\text{tr}}/\rho)_{\text{air}}^{\text{water}} \times f(1.0)$  for a point source\*. The geometry factor  $G(r,\theta)$  represents the inverse square law for point sources, whereas for a line source it is the ratio  $(\phi_2 - \phi_1)/(L \times x) = (\phi_2 - \phi_1)/(L \times r \sin \theta)$ , as shown in Equation 53.5. Note that  $G(r,\theta)$  is calculated relative to the value at 1 cm.  $g(r)$  is defined in the central axial plane (i.e. for  $\theta=\theta_0=90^\circ$ ). It includes the effect of water scatter and attenuation but excludes the geometrical factor. For more complex source-activity distributions  $G(r,\theta)$  and  $g(r)$  should be calculated, but the line-source approximation is usually adequate†. In any event, the calculation of  $G(r,\theta)$  is a purely geometric one, excluding any attenuation in the source (or medium). The anisotropy factor,  $F(r,\theta)$ , describes the anisotropy due to attenuation within the source. Anisotropy factors must be derived for each individual type of source—factors for common sources are contained within the report. If anisotropy factors are not available, they may be calculated or measured.

### 53.4.1 APPLICATION OF TG43 TO $^{192}\text{Ir}$ Dosimetry

For  $^{192}\text{Ir}$ , the TG43 report only provided data for a stainless-steel-encapsulated  $^{192}\text{Ir}$  source, and no data were provided for  $^{192}\text{Ir}$  wires or for the high dose-rate sources used in afterloading devices. However, since then a number of authors have applied the TG43 formalism to such sources (Ballester et al. 1997; Lliso et al. 2001, 2003)‡. Ballester et al. provide data for the application of TG43 to 0.3 mm diameter  $^{192}\text{Ir}$  wire of lengths 10 mm and 50 mm.

\* i.e.  $1.11 \times f(1.0)$  for energies between 150 keV and 1.5 MeV and  $1.02 \times f(1.0)$  for  $^{125}\text{I}$ . For  $^{125}\text{I}$ , the situation is complicated by the change in the standards laboratory calibration, as discussed in the next section.

† In the 2004 revision of TG43 (Rivard et al. 2004),  $G(r,\theta)$  and  $g(r)$  are replaced by  $G_L(r,\theta)$  and  $g_L(r)$  to emphasise that the line-source approximation is used for the geometry function.

‡ A further revision of TG43 to deal with  $^{192}\text{Ir}$  is planned.

However, because widely differing lengths of wire are used in practice, it may be best to restrict the use of TG43 use to the calculation of high dose-rate iridium sources. Details and references for a number of <sup>192</sup>Ir sources are given in the ESTRO booklet on brachytherapy quality control (Venselaar and Pérez-Calatayud 2004).

### 53.4.2 APPLICATION OF TG43 TO <sup>125</sup>I DOSIMETRY

The dosimetry of <sup>125</sup>I has always had a higher degree of uncertainty than that of isotopes emitting higher energy radiation. The use of TG43 data involved a decrease of ten percent in the dose calculated at a distance from a seed. This arose mostly from a change in the recommended values for the dose rate constant and the anisotropy factor (or equivalent quantities in older dosimetry protocols) for the Amersham sources which were almost exclusively used at that time (Kubo et al. 1998; Williamson et al. 1999). Bice et al. (1998) recommended that the reference dose for prostate implants be changed from 160 Gy to 144 Gy so as to maintain the same clinical outcome when using the TG53 protocol.

On January 1, 1999, a further complication arose because NIST changed its standard calibration for <sup>125</sup>I by 11.5% (Kubo et al. 1998; Williamson et al. 1999). This was because the earlier standard was affected by 4.5 keV titanium characteristic x-rays, which do not affect the dose in water beyond 1 mm from the source. The AAPM definition of source strength expressly excludes the effect of low-energy x-rays below 5 keV, depending on the application (Rivard et al. 2004). This had two repercussions. First, it was necessary to be certain which version of the standard was used by the supplier when specifying the source strength\*. Second, if the new standard was used, it was necessary to compensate for this change by decreasing by the same amount the values of the dose rate constant to be used for dose calculation. To avoid misinterpretations, these new recommended  $\Lambda$  values were indicated by assigning to the  $\Lambda$  symbol the subscript “99std” (Williamson 1999) or “N99S” (Rivard et al. 2004). The value of  $\Lambda$  should be increased by 1.115 compared to values quoted based on the old standard (Williamson et al. 1999). Rivard et al. provide a set of consistent values. Further refinements of the values for dose rate constants to be used for different source designs have been achieved and the up-to-date recommended values for  $\Lambda$  can be obtained by following the links on the AAPM/RPC website <http://adcl.mdanderson.org/rpc/BrachySeeds/SourceCharacteristics.htm> or from Rivard et al. (2004).

The value of  $\Lambda$  depends on the design of the source, as this can affect the radiation that is actually emitted from the source capsule, resulting in differences in the dose at 10 mm, giving a range of  $\Lambda$  values between 0.94 cGy h<sup>-1</sup> U<sup>-1</sup> and 1.04 cGy h<sup>-1</sup> U<sup>-1</sup> for different source types (Rivard et al. 2004). For a specified source type such as the Amersham 6711 seed, the updated TG53 recommended value is 0.965 cGy h<sup>-1</sup> U<sup>-1</sup> which is consistent with the calculated and experimental values found more recently by Dolan et al. (2006) and well within the 1%–4% uncertainty usually quoted for Monte-Carlo calculated values or 6%–8% quoted for experimental values (Dolan et al. 2006). An analytical approach for a large range of source types and radionuclides is also possible and gives quite accurate results (Chen and Nath 2001).

---

## 53.5 DECAY CORRECTION

In the preceding calculations no mention has been made of radioactive decay (see Section 2.3.2). To correct for decay the formula:

$$\dot{K} = \dot{K}_0 e^{\left(\frac{-0.693t}{T}\right)} \quad (53.9)$$

---

\* By now, all suppliers should be using the new standard.

can be used to calculate the RAKR at the time of treatment, where  $\dot{K}$  is the RAKR  $t$  days after the RAKR  $\dot{K}_0$  was measured (the *activity date*), and  $T$  is the half-life of the isotope (see Table M.4). For an HDR implant the activity time should be the time at which the irradiation takes place—this is normally done automatically within the software. For a manually afterloaded implant the dose rate,  $\dot{D}$ , at the start of the treatment can be calculated. The total dose is then given by:

$$D = \dot{D} \int_0^{t_1} e^{-\frac{0.693t}{T}} dt = \dot{D} \frac{T}{0.693} \left( 1 - e^{-\frac{0.693 t_1}{T}} \right) \quad (53.10)$$

with  $t_1$  being the duration of the implant. For sources used in radiotherapy that have half lives around two months the correction for decay during a one week treatment will be about 4%. If  $T$  is large compared to  $t_1$  the exponential term approximates to  $1 + \frac{0.693 t_1}{T}$  so Equation 53.10 simplifies to  $D = \dot{D} t_1$  as one would expect. In practice it is convenient to make an initial calculation of the duration of the implant based on the RAKR at the time of the implant and to calculate the additional time  $\Delta t$  that will be required using the formula:

$$\Delta t = \frac{-\ln(1 - 0.693 \frac{t_1}{T})}{0.693} T - t_1 \quad (53.11)$$

Tables can be compiled of  $\Delta t$  as a function of  $t_1$ . The  $\Delta t$  correction is greater than 1% as soon as  $t_1$  extends to more than about 2% of  $T$ . For a permanent implant the term in the brackets is 1.0 and the effective duration of the implant is the mean life ( $1.44 T$ ) of the isotope, which is about 87 days for iodine-125 (see Section 2.3.2.2). However, as discussed by Wallner et al. (2002) the effects of such an extended treatment are affected by biological factors as well as the physical dose.

## 53.6 CONVERSION FACTORS FOR OLDER METHODS OF ACTIVITY SPECIFICATION

Brachytherapy was, for many years, exclusively delivered using  $^{226}\text{Ra}$  sources. Because of this, data were widely available to calculate dose rates for radium sources. If source attenuation and scattering are ignored, these data can be used for other isotopes if source activity is specified in terms of milligrams radium equivalent (mg RaEq), and this unit was widely used and reasonably unambiguous. The phasing-out of radium and the need for compliance with radiation protection regulations couched in terms of units of activity led to the specification of activity in MBq or mCi. The almost-universal adoption of air kerma specification reduces the ambiguity in relation to modern dose-calculation methods, but where older computer software or data tables are used, it is necessary to convert RAKR into these older units. It may also be necessary to be familiar with these units in order to be able to understand the historical literature. For this reason, a brief discussion of these earlier units is included here. It is based on the paper by Williamson and Nath (1991), to which the reader is referred for further explanation.

### 53.6.1 THE ROENTGEN

Because many of the tables used for dose calculation were defined to provide the exposure rate in Roentgen, R, it is necessary to convert from values in  $\text{R h}^{-1}$  to air kerma rate and thence to absorbed dose rate. To convert from exposure rate in  $\text{R h}^{-1}$  to air kerma rate in  $\text{cGy h}^{-1}$ , one must multiply by the product of the average energy required to produce one ion pair in air

(divided by the electron charge),  $W_{\text{air}}/e$  and  $(1-g)$  where  $g$  is the fractional energy loss to bremsstrahlung (see Equation 6.9 in [Section 6.3.2](#) and Equation 51.2). The former quantity has the value  $33.97 \text{ J C}^{-1}$  yielding a conversion factor of  $0.876/(1-g) \text{ cGy R}^{-1}$ . Subsequent conversion to dose requires the application of Equation 53.2. This leads to the value  $1.11 \times (1-g) \times 0.876/(1-g) = 0.97 \text{ cGy R}^{-1}$  in water for  $^{192}\text{Ir}$ .

### 53.6.2 RADIUM EQUIVALENCE

Because most early brachytherapy was delivered with  $^{226}\text{Ra}$  and activity of radium was expressed in terms of the mass of radium in the source, the concept of mg RaEq has been widely used. An added complication is that radium was used in different encapsulations—from 0.5 mm Pt filtration up to 2 mm—but it is the former that was the basis for the Manchester system, and hence is what is referred to when defining equivalence. Equivalence is defined in terms of having the same RAKR. Since the exposure rate at 1 cm from 1 mg of  $^{226}\text{Ra}$  filtered with 0.5 mm Pt is  $8.25 \text{ R h}^{-1}$ , the air kerma rate is  $8.25 \times 0.876 = 7.227 \text{ cGy h}^{-1}$  at 1 cm which is an RAKR of  $7.227 \mu\text{Gy h}^{-1}$  at 1 m. So for any isotope, one may convert from mg RaEq to RAKR by multiplying by 7.227.

### 53.6.3 ACTIVITY UNITS

Conversion from activity quoted in MBq or mCi to RAKR is not straightforward, and the conversion factor depends on the isotope. It is, first of all, necessary to examine how the supplier defines activity. This may either be the *contained activity* or the *apparent activity*. The former is the activity that would be measured with any source cladding removed. The apparent activity is defined as the activity of an unfiltered point source of the same isotope which has the same RAKR as the filtered source. If the contained activity is specified, it is necessary to calculate the attenuation due to source filtration and then to multiply by the air kerma rate constant. If, as is more likely, the apparent activity is quoted, then the conversion factor is, in principle, simply the air kerma rate constant. However—for  $^{192}\text{Ir}$  in particular—there is some confusion about the appropriate value of the air kerma rate constant, with values of  $0.1136 \mu\text{Gy h}^{-1} \text{ m}^2 \text{ MBq}^{-1}$  ( $4.80 \text{ R h}^{-1} \text{ m}^2 \text{ mCi}^{-1}$ ) and  $0.1099 \mu\text{Gy h}^{-1} \text{ m}^2 \text{ MBq}^{-1}$  ( $4.64 \text{ R h}^{-1} \text{ m}^2 \text{ mCi}^{-1}$ ) both appearing in the literature. The former was derived from the decay scheme published in the 1982 edition of the *Radiochemical Manual*, whereas the latter is that calculated with the current edition. Although one might suppose that the most appropriate value was the current best estimate, this is not necessarily the case. The manufacturer's calibration of  $^{192}\text{Ir}$  was actually based on an air kerma measurement, and the activity was derived from this using the quoted air kerma rate constant which was, therefore, the factor to use to convert back from activity to RAKR. Furthermore, some commercial software asks for the activity in mCi or MBq and therefore carries out a calculation implicitly or explicitly based on the air kerma rate constant. In this case, when converting to mCi for RAKR, the factor used should be the air kerma rate constant used by the software supplier. The current best estimates of the air kerma rate constant are given in [Table 51.1](#) but they should not be used for dose calculation without checking which coefficients are used by the source supplier or by the software designer to specify the source activity.

---

## 53.7 LIMITATIONS OF BRACHYTHERAPY DOSE CALCULATIONS

Unless a full Monte Carlo calculation is carried out, the accuracy of brachytherapy dose calculations will always involve some limitations. However, because dose values are dominated by the distance to the nearest source and dose gradients are very steep, algorithms based on the

simple dose calculation methods described above are adequate for most practical purposes. However, it is important to bear in mind the factors that may limit accuracy.

### 53.7.1 UNKNOWN SOURCE ORIENTATION

For seed sources that are not contained in a guide tube, the sources are likely to be randomly orientated. A practical solution in this event is to treat them as point sources and to ignore the anisotropy factor. This will inevitably result in a calculated dose that is slightly different from that actually delivered. The TG43 report recommends that this problem be overcome by multiplying the dose rate in the transverse plane by the mean anisotropy factor averaged over all values of  $\theta$ . This is called the *anisotropy constant*. Its value is given by TG43 as 0.98 for  $^{192}\text{Ir}$  seeds, and 0.93 for the model 6711  $^{125}\text{I}$  seed (Nath et al. 1993).

### 53.7.2 SHIELDING BY OTHER SOURCES

None of the standard algorithms take into account shielding of sources by other sources or applicators. Markman et al. (2001) compared Monte Carlo calculations of the dose distribution with and without taking into account the interactions with the applicator and the other sources for the LDR Selectron and found differences around 10%. By pre-calculating the distribution around the entire applicator and its contents and then adding these together, they were able to reduce the error to around 4%.

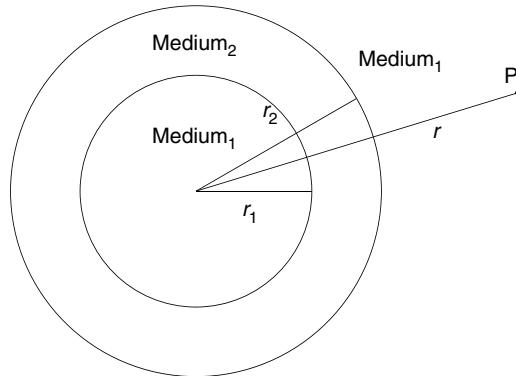

### 53.7.3 APPLICATOR SHIELDING

Gynaecological applicators are usually made of stainless steel. This will attenuate the radiation by a small percentage. Standard source models do not take this into account, but an adequate correction (albeit not considering oblique filtration) may be made by reducing the source activity by a small amount. A factor of 2% has been found appropriate for Selectron  $^{137}\text{Cs}$  sources.

### 53.7.4 INHOMOGENEITY CORRECTIONS

The tables of  $\mathcal{J}(r)$  given in TG43 are based on water-equivalent phantoms. Meigooni and Nath (1992) investigated the effect of a 20-mm-thick polystyrene cavity on the dose rate due to  $^{103}\text{Pd}$ ,  $^{125}\text{I}$ ,  $^{241}\text{Am}$ , and  $^{192}\text{Ir}$ . They found that the cavity made little difference to the dose calculated with an  $^{192}\text{Ir}$  source, but for  $^{103}\text{Pd}$ ,  $^{125}\text{I}$  and  $^{241}\text{Am}$ , the dose beyond the cavity was greater by a factor of 130%, 55% and 10%, respectively. They proposed a simple calculation method that replaces  $\mathcal{J}(r)$  for a homogeneous medium with a corrected value. Consider a point source with an inhomogeneity which begins a distance  $r_1$  from the source and ends at  $r_2$ , as illustrated in [Figure 53.3](#). The value of  $\mathcal{J}(r)$  that is appropriate for use in Equation 53.8 is then:

$$\begin{aligned} \mathcal{J}_{\text{medium}_1}(r) & \quad \text{for } r < r_1 \\ \mathcal{J}_{\text{medium}_2}(r) \frac{\mathcal{J}_{\text{medium}_1}(r_1)}{\mathcal{J}_{\text{medium}_2}(r_1)} & \quad \text{for } r_1 < r < r_2 \\ \mathcal{J}_{\text{medium}_1}(r) \frac{\mathcal{J}_{\text{medium}_2}(r_2) \mathcal{J}_{\text{medium}_1}(r_1)}{\mathcal{J}_{\text{medium}_2}(r_1) \mathcal{J}_{\text{medium}_1}(r_2)} & \quad \text{for } r > r_2 \end{aligned}$$

**FIGURE 53.3**

Calculation of dose at point  $P$  from a point source with an inhomogeneity. Medium<sub>2</sub> represents the inhomogeneity.

The appropriate value of  $g_{\text{medium}}(r)$  can be obtained from the literature (e.g. Dale 1983; Meigooni and Nath 1992) or calculated *de novo*.

Other workers have proposed a method based on the separation of the primary and scatter contribution (Russell and Ahnesjö 1996; Williamson 1996; Anagnostopoulos et al. 2003). Anagnostopoulos et al. propose to replace  $\Lambda g(r)$  in Equation 53.8 by the following formula:

$$\frac{\sum_i n_i E_i \left( \frac{\mu_{\text{en}}(E_i)}{\rho} \right)_{\text{medium}} e^{-\mu_{\text{medium}}(E_i)r} [1 + \text{SPR}_{\text{medium}}(E_i, r)]}{\sum_i n_i E_i \left( \frac{\mu_{\text{en}}(E_i)}{\rho} \right)_{\text{air}}}$$

where  $n_i E_i$  represents the energy spectrum of the isotope and SPR is the scatter-to-primary ratio in the medium, which is the ratio of the scatter dose divided by the primary dose at a distance  $r$  from the source.  $\mu_{\text{medium}}(E_i)$  is the linear attenuation coefficient at the energy in question for the medium, and  $\mu_{\text{en}}(E_i)/\rho$  is the corresponding mass energy-absorption coefficient. Although in principle these values need to be evaluated for each source and medium, the authors have shown that for <sup>192</sup>Ir, the scatter-to-primary ratio scales with density and is given by the equation:

$$\text{SPR}_{\text{medium}}(\rho r) = 0.121(\rho r) + 0.0068(\rho r)^2 \quad (53.12)$$

where  $\rho$  is the density of the medium in  $\text{g cm}^{-3}$  and  $r$  is in cm. The values in Equation 53.12 are strictly the values for water but Anagnostopoulos et al. found that the equation worked well for other media.

## 54.1 INTERSTITIAL IMPLANTS

### 54.1.1 INTRODUCTION

Radiation oncologists use interstitial implant techniques for the treatment of many different sites within the body. An interstitial implant administers a high dose of radiation to the tumour, whilst effectively sparing surrounding normal tissue and nearby critical organs. The dose homogeneity of such an implant will be different from that achievable with external-beam radiotherapy, as there is a very high dose region immediately around the implanted sources. This high dose region is within the target volume and is not clinically significant. In order to ensure adequate tumour coverage and sparing of critical organs, dosimetry systems are usually based on the minimum dose to a volume.

In the 1930s Paterson and Parker (1934, 1938) developed the Manchester System and Edith Quimby developed the Quimby system (Quimby and Castro 1953, Goodwin et al. 1970) for use with radium sources. These two systems had their own unique implantation rules and dose specification, but were completely self-consistent and have been used for many years to calculate dose to tissue. Godden (1988) provides an excellent description of the Manchester system and its distribution rules.

Once other isotopes such as caesium-137, cobalt-60 (Fletcher 1953, 1980) and iridium-192 (Pierquin et al. 1978 and Dutreix et al. 1982) became available, other dosimetry systems with their own implantation rules were developed. The advent of computerised dosimetry and the availability

of multiple-plane isodose distributions provide radiation oncologists with more comprehensive information about the variation of dose within the treatment volume. Three-dimensional dose distributions are now possible, together with volumetric data on doses to critical organs.

Dosimetry systems have been developed for interstitial treatments to ensure reproducibility between implants and adequate coverage of tumour volumes, provided that the rules that have been developed are adhered to as closely as possible. For iridium implants, the system most often used is the Paris system developed by Pierquin et al. (1978).

Afterloading techniques, where inactive applicators can be optimally placed within tumours and loaded with radioactive sources once the dosimetry calculations have been performed, have allowed more flexibility and optimisation of dose distributions. The pioneers of these techniques for interstitial radiotherapy were Henschke in the U.S.A. and Pierquin in Paris.

## 54.1.2 PARIS PREDICTIVE DOSE-PLANNING SYSTEM

The Paris dosimetry system was developed for flexible wire implants, particularly iridium-192, and acts as a basis applicable for standard implants. There are often exceptions where special calculations are necessary, in addition to the standard dosimetry.

### 54.1.2.1 Basic Principles

The basic implantation rules of the Paris system are:

1. Active sources should be straight and parallel.
2. The sources should be placed equidistant from each other.
3. The linear activity of each source should be uniform and identical.
4. Each source should extend beyond the limits of the volume so that the dose calculated as the reference isodose is achieved over all the target volume.
5. The plane through the mid-points of the sources should be at right angles to the axis of each source.
6. In any one implant, sources should be equidistant, but from one implant to the other, the inter-source separation can be varied (between 5 mm and 20 mm)\*.
7. For volume implants the distribution produced in cross-section through the central plane should be either an equilateral triangle or a square.
8. The maximum activity in any implant using iridium should not exceed 5.5 GBq (i.e. a maximum Reference Air Kerma Rate of  $550 \mu\text{Gy h}^{-1}$  at 1 m).

These are the implantation rules, but there are some additional guidelines that have been developed to assist the placement and choice of sources within the tumour volume, derived from clinical experience (Dutreix et al. 1982).

### 54.1.2.2 Single Source

The dose variation around a single source is dependent on its length. Very close to the wire the dose rate is determined by the local activity of the wire and is only marginally dependent on the length. Further away from the wire there is a relatively greater contribution from more distant parts of the wire. Dutreix et al. (1962) suggested that a high dose sleeve ("manchon de surdosage") where the dose rate was twice the treatment dose rate could be tolerated around a

\* The maximum separation between sources is constrained by the requirement to limit the magnitude of the high dose sleeves around the wires (as explained in Section 54.1.2.2) and this limits the separation to about 20 mm. On the other hand, if the sources are too close together it may be difficult to keep the wires sufficiently parallel to each other along their length to avoid hot and cold spots. For single plane implants the separation of the wires determines the thickness of the treated volume (see [Section 54.1.2.3](#)).

wire provided that its diameter did not exceed 10 mm, although 8 mm would be safer. If we restrict this high dose sleeve to 8 mm the diameter of the volume treated by a single source varies from 12 mm for a 1 cm long source to 16 mm for a 10 cm long source. The *useful length* treated is 0.7 times the *radioactive length*.

#### 54.1.2.3 Planar Implants

Varying the spacing between sources from one implant to another is possible in the Paris system, so that greater dose uniformity and optimal tumour coverage can be achieved. In general, the longer the wire, the greater the separation between wires with an upper limit of 2.0 cm. If the separation between the sources is  $s$ , and  $n$  is the number of wires of active length  $L$ ; the dimensions of the treatment volume are length  $\ell$ , thickness  $t$ , width  $w$  and lateral margin  $d$ : the relationships relating  $s$  and  $L$  to  $\ell$ ,  $w$ ,  $t$  and  $d$  are given in Table 54.1, taken from Godden (1988). Figure 54.1 shows the target volume dimensions for single and double plane implants.

#### 54.1.2.4 Nonplanar Implants

It is sometimes necessary to treat a cylindrical volume, such as vagina and rectum with straight and parallel radioactive sources. In these circumstances, the reference isodose curve for dose prescription is often chosen to limit dose to a critical organ in preference to a strict *Paris* type of dosimetry.

#### 54.1.2.5 Dose Specification and Calculation

The *central plane* of an implant is defined as a plane perpendicular to the sources, which is at right angles to the long axis of the sources and is situated mid-way along their length, as shown in Figure 54.2. Dose calculations are based on the distribution of sources across this central plane.

The *basal dose rate* (BDR) provides a measure of the dose rate in the centre of the treated volume and acts as the basis for dosimetry. It is always calculated from the position of the sources in the central plane and is the minimum dose rate between a pair or group of sources. For a single plane implant, the dose minima occur at the midpoints between sources in the central plane. For an implant in two or more planes, triangles may be formed at the intersection of sources with the central plane and the basal dose (BD) points are taken where the bisectors of the triangles intersect. The BDR is then the mean of the dose rates at the midpoints of all component triangles as shown in Figure 54.3a and Figure 54.3b.

When squares are formed by the intersection of wires with the central plane, then the BDR is the mean of the dose rates at the midpoints of the squares as shown in Figure 54.3c and d. The value of the BDR at the different calculation points across the implant should be

**TABLE 54.1**

Relationships for Planar Implants

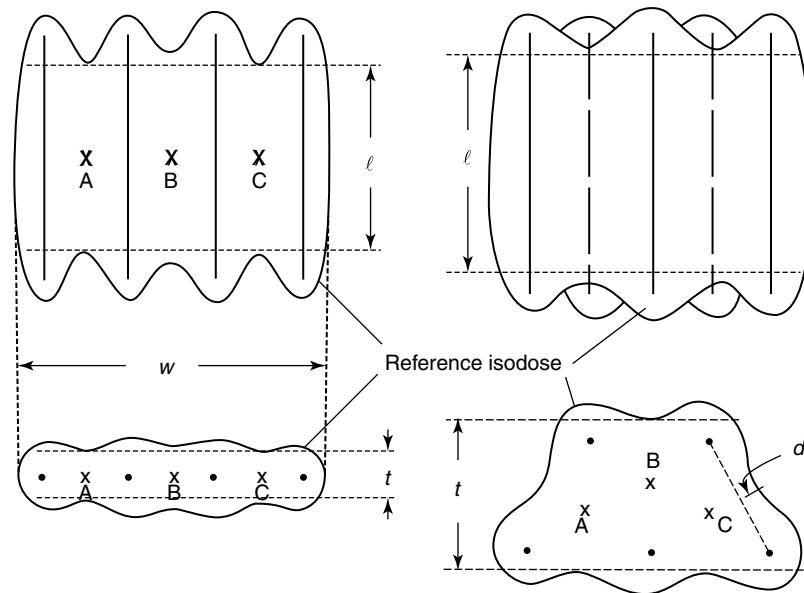

Implant Type	$\ell$	$w$	$t$	$d$
Single plane	0.65L to 0.75L <sup>a</sup>	(n-1)s+0.74s	0.46s to 0.59s <sup>b</sup>	0.34s to 0.37s
Triangular double plane	0.7L	—	1.2s	0.15s
Square double plane	0.7L	(n-1)s+0.74s	1.5s	0.28s

The treatment volume has length  $\ell$ , width  $w$ , thickness  $t$  and the lateral margin is  $d$ .

<sup>a</sup> Variation between 0.65 and 0.75 as the active length,  $L$ , increases from 10 mm to 100 mm.

<sup>b</sup> Variation between 0.46 and 0.59 as the active length,  $L$ , increases from 10 mm to 100 mm.

**FIGURE 54.1**

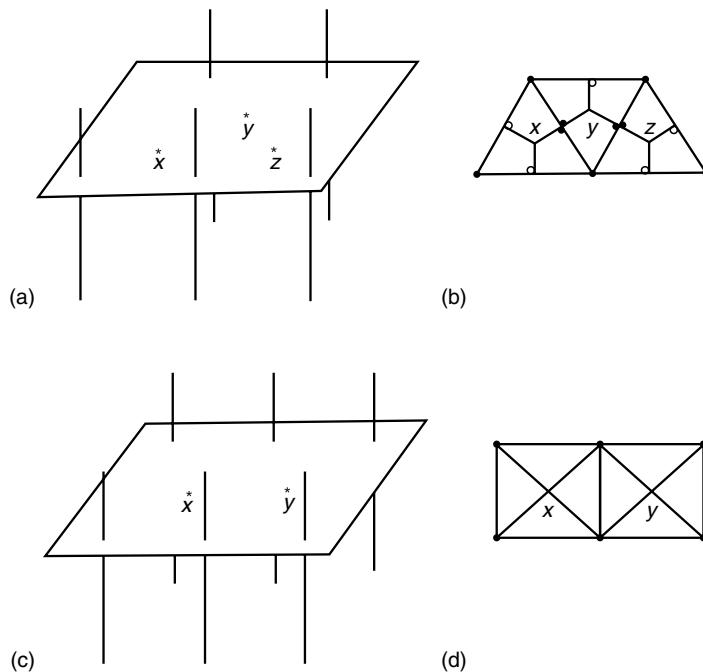

Positions of the basal-dose points (see [Section 54.1.2.5](#)), reference isodose and dimensions of the volume ( $\ell \times w \times t$ ) defined for a single-plane and double-plane  $^{192}\text{Ir}$  wire implant. (A cross indicates a basal-dose calculation point). (From Pierquin, B., Dutreix, A., Paine, C. H., Chassagne, D., Marinello, G., and Ash, D., *Acta Radiol. Oncol. Radiat. Phys. Biol.*, 17, 33–48, 1978.)

within  $\pm 10\%$  of the mean value, for acceptable homogeneity. The BDR depends on the number, activity, and length of sources and their distance from the calculation point.

For hairpins, the value for active length is taken as the leg length as shown in [Figure 54.4](#) in addition to one-half the loop length. This is valid as long as the total length of the hairpin is at

**FIGURE 54.2**

The central plane is correct in (a), where  $XYZ$  is a right angle and not in (b), where this angle is acute. In (b) an incorrect source separation would be employed for calculation of the basal dose rate.

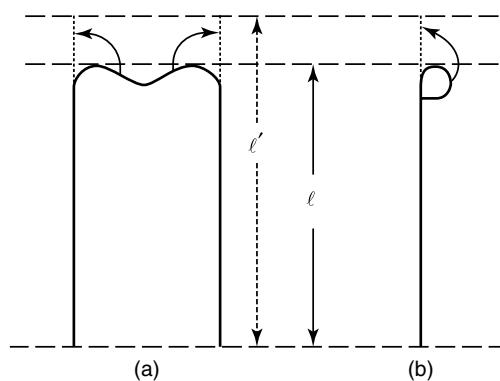

**FIGURE 54.3**

(a, b) Five-line-two-plane implant, where the sources are arranged in triangles. Such triangles should be equilateral. Whether or not they are strictly equilateral, BD is found at points  $x$ ,  $y$  and  $z$ —where the perpendicular bisectors of the sides of the triangles intersect. (c, d) Six-line-two-plane implant where the sources are arranged in squares. BD is found in the centre of each square (at  $x$  and  $y$ ).

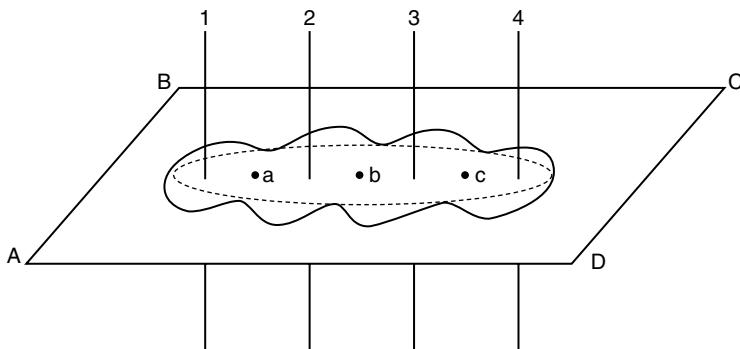

least twice the separation between the legs. For example, if the leg length is 3 cm, the radioactive length for calculation purposes will be 3.6 cm (inter-leg spacing is 1.2 cm).

The *reference dose rate* (RDR) is the dose rate used as the basis for dose prescription and hence for calculating the total time of the implant. It is defined as 85% of the basal dose rate. The reference dose rate should encompass an envelope around the implant. Within the limits of source geometry, 85% leads to an acceptable compromise between too steep a dose gradient in passing from the margin of the treatment envelope towards the basal dose rate in its interior, and too great a ripple of the contour of the treatment envelope (see [Figure 54.5](#)).

The *treatment volume* is defined as the volume enclosed by the 85% reference isodose. The minimum dimensions of the isodose envelope produced should correspond as accurately as

**FIGURE 54.4**

Radioactive length ( $\ell'$ ) of a hairpin, which should be used for calculation purposes.

**FIGURE 54.5**

Four lines (1,2,3,4) transect the central plane (A, B, C, D) on which dose calculation is carried out. The basal dose rate (BDR) is the mean of the dose rates at a, b and c. The reference dose rate (85% BDR) has an irregular contour (wavy solid line) and totally encloses the target volume (dotted line).

possible with those of the target volume, which it must enclose. The width,  $w$ , for a single plane is the maximum width of the reference isodose in the central plane. It is equal to the distance between the most lateral sources plus 37% of the separation between the sources added to each side (see column  $w$  in [Table 54.1](#)). The thickness,  $t$ , of the treatment volume varies with the length and the separation of the sources (see column  $t$  in [Table 54.1](#)).

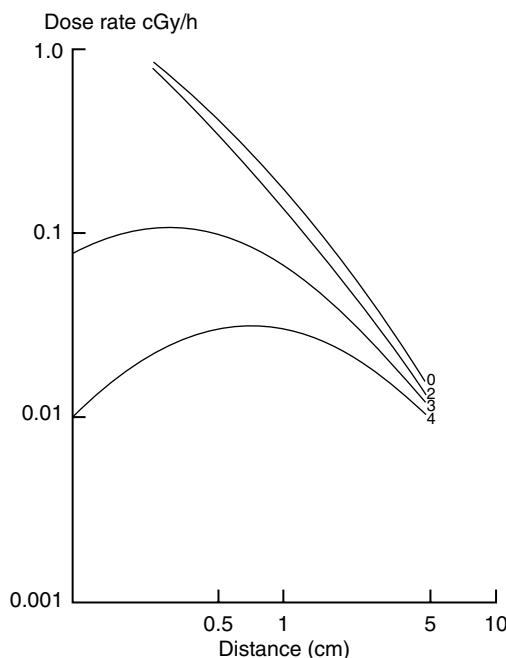

### 54.1.3 DOSE CALCULATION FOR REAL IMPLANTS

Once the source positions within a tumour volume have been defined, whether for a pre-implant calculation or from an actual implant by the use of orthogonal or stereo radiographs, transverse CT, or manual measurement, the basal and reference dose rates can be calculated. It is necessary to know the length of the wire used in each source in addition to the distance between sources. Prior to an implant, a preliminary calculation is made on an *ideal* implant so that iridium wire of the correct source strength can be ordered. This preliminary calculation is often done by hand with the aid of dose data in the form of *crossline graphs* or *escargot curves*, and the source strength selected to give a reference dose rate of approximately 10 Gy per day (42 cGy/hr). The calculation to provide isodose distributions for the actual implant can then be done on a computer by reconstructing the actual source positions and checked using one of the following manual methods or an equivalent computerised lookup table.

#### 54.1.3.1 Crossline Curves

Hall et al. (1966) derived crossline curves, such as those shown in [Figure 54.6](#). The curve shown is for a  $^{192}\text{Ir}$  wire of 5 cm length and shows dose rates at different distances from the axis of a line source. A different graph is necessary for each active length used in 1 cm intervals. Crossline 0 corresponds to the central plane of the Paris system. The curves labeled "2, 3, 4" also refer to dose rates at distance from the axis of the wire, but starting at a point on the wire which is 2 cm, 3 cm and 4 cm away from the central plane (towards the end of the wire), respectively. Data are based on wire of linear activity 1 mg Ra-equivalent per cm (RAKR 7.23  $\mu\text{Gy h}^{-1}$  at 1 m) and the dose rate is given in cGy/h.

The distance from each basal-dose point to each source is calculated, then the dose rates at these distances from each individual source are measured from the crossline graphs and summed for each point. The mean of all the basal dose points is taken and 85% of this mean is the reference dose rate. The prescription dose is assigned to this value.

**FIGURE 54.6**

Crossline curves for a 5 cm source for a source of linear activity of 1 mg-Ra equivalent per cm. The dose rate is given in  $\text{cGy h}^{-1}$  at different distances from the source axis along crosslines at position 0, 2 cm, 3 cm and 4 cm from the source midplane.

The crosslines as provided give the exposure rate in Roentgen ignoring scatter and absorption in tissue and the encapsulation. The dose rate calculated should therefore be multiplied by correction factors as discussed by Welsh et al. (1983).

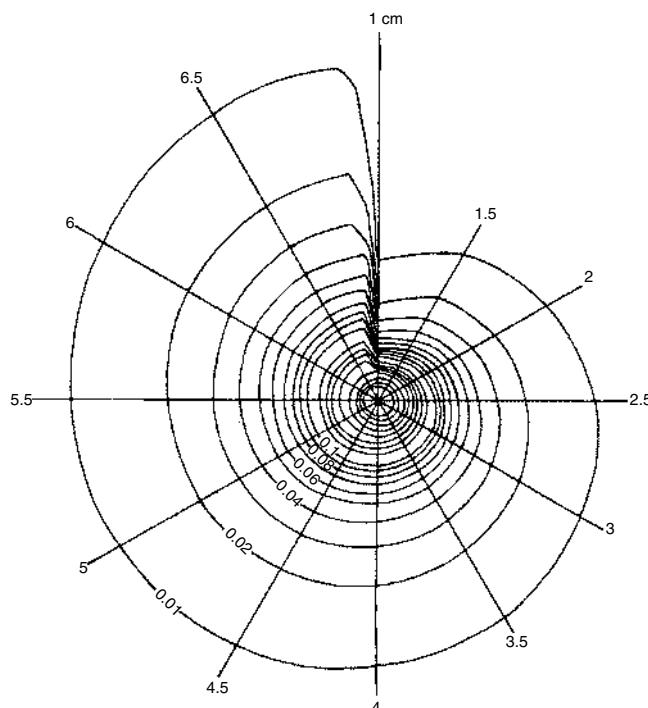

#### 54.1.3.2 Escargot Curves

The method, adopted by Pierquin in Paris, makes use of *escargot*\* curves described by Schlienger et al. (1970). To use these curves it is necessary to reconstruct the source intersections in the central plane. These were originally obtained from conventional radiological tomography acquired in planes perpendicular to the mean source axis. The escargot curves, as shown in Figure 54.7, are constructed with the appropriate magnification factor so that they can be placed directly onto the reconstruction, the centre of the curve being placed on each point where the source intersects the central plane. The graph is then turned so that the line appropriate for the length of the active wire passes through the point at which the dose is required. The dose rate in  $\text{Gy h}^{-1}$  is then read directly from the spiral line. These curves were initially based on linear activity of  $1 \text{ mCi cm}^{-1}$ , although a new method of specifying source activity was adopted in 1974 following the proposal of Dutreix et al. (1982) (see Section 51.3).

#### 54.1.3.3 Calculation of Reference Dose Rate

Once the dose rate to each calculation point has been calculated, the basal dose rate is the mean of the values obtained at all the points of calculation. The actual reference dose rate at the time of application is 85% of the basal dose rate corrected for the actual linear activity of the wire used. The treatment time during which the therapy is given is then determined from

\* The name “escargot” is the French word for snail.

**FIGURE 54.7**

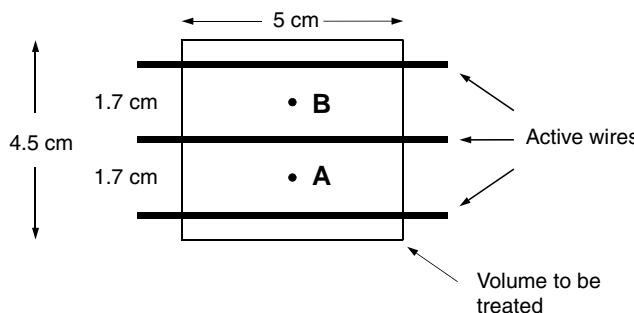

The escargot isodose lines in the central plane of an active wire. The figures on the curved lines give absorbed dose rate in  $\text{Gy h}^{-1}$  for a source linear activity of  $1 \text{ mCi cm}^{-1}$ . This single escargot may be used for wire lengths between 1 cm and 7 cm (shown at the tip of each radial line).

this reference dose rate. It may be necessary to apply a further correction to account for the decay of the source during the implant as discussed in [Section 53.5](#).

There is a paper by Casebow (1985) giving tables for standard iridium-192 wire single- and double-plane implants, together with the dimension of the treatment volume within the 85% dose contour. Various workers, including Kwan et al. (1983), have investigated single- and double-plane implants using different source and plane separations (using iridium seeds). Having established the best variables for different thicknesses of implant, they were able to produce standard tables for square implants. These facilitate a rapid estimation of minimum and maximum target dose rates with rectangular implants being calculated on the basis of the *equivalent square* implant.

In flexible wire interstitial techniques, however, there are usually deviations from the ideal implant and often the implanted wires do not strictly comply with Paris system rules. This may produce increased areas of hot and cold spots if the dose is based solely on the basal dose rate, and therefore production of isodose distributions in multiple planes is essential for evaluation. To overcome the problems associated with nonideal implants, Mayles et al. (1985) developed a dose optimisation method, which achieves a clinically acceptable dose distribution by using sources of different linear activity, or by removing sources of the same linear activity at different times during the implant. For interstitial treatments of vagina and rectum, circular templates are frequently used, where the reference dose rate is often specified in a circular plane at a distance (such as 1 cm) from the sources. The dose is frequently limited by the dose to the critical organ in closest proximity.

The introduction of high-dose rate (HDR) or pulsed-dose rate (PDR) remote afterloading machines with single high activity sources (see [Section 52.3](#) and [Section 52.4](#)) has increased the opportunity for dose optimisation as discussed later in this chapter.

**FIGURE 54.8**

Example of a single-plane source arrangement of the Paris system used to treat a parallelepipedic volume which is 1.5 cm thick. The active length of the wires is 7 cm. The resulting dose distribution is shown in [Figure 54.9](#).

#### 54.1.3.4 Example Iridium Implant Calculation

An example of an iridium implant calculation based on the Paris system follows:

The volume to be treated is illustrated in Figure 54.8 and is 5 cm long and 4.5 cm wide, by 1 cm thick. The Paris system would use a single plane implant with the basal dose calculated at points A and B. From [Table 54.1](#) if the separation of the wires is 1.7 cm and their length is 7 cm:

- The thickness of the treated volume would be:  $0.55 \times 1.7 = 0.94$  cm
- The width of the treated volume would be:  $2 \times 1.7 + 2 \times 0.37 \times 1.7 = 4.7$  cm
- The length of the treated volume would be  $0.72 \times 7 = 5.0$  cm

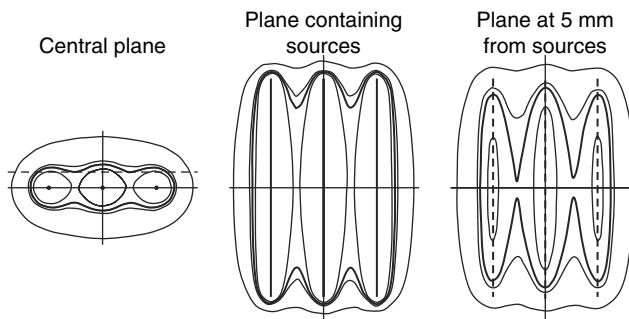

For  $^{192}\text{Ir}$  wire with a linear Reference Air Kerma Rate (RAKR) of  $6.5 \mu\text{Gy h}^{-1} \text{cm}^{-1}$  at 1 m ( $0.9 \text{ mg Ra Eq cm}^{-1}$ ), the total RAKR would be  $137 \mu\text{Gy h}^{-1}$  at 1 m. The basal dose rate is  $21.6 \text{ cGy h}^{-1}$  from the two closer wires and  $5.3 \text{ cGy h}^{-1}$  from the third wire, giving  $48.5 \text{ cGy h}^{-1}$ . The reference dose rate is therefore  $41.2 \text{ cGy h}^{-1}$ . The dose distribution in the central plane and a plane at 0.5 cm from the sources is shown in [Figure 54.9\\*](#).

Interstitial brachytherapy can be given on its own for the treatment of an early stage tumour, e.g. stage-I carcinoma of the tongue, where a typical treatment dose might be 65 Gy in 6.5 days to the 85% isodose. It may also be given as part of a combined radiotherapy approach where the dose delivered by the interstitial brachytherapy would be about 30–35 Gy, depending on the dose already delivered by the external-beam techniques.

#### 54.1.4 ICRU RECOMMENDATIONS ON INTERSTITIAL BRACHYTHERAPY DOSIMETRY

The International Commission on Radiation Units and Measurements (ICRU) published their Report 58 giving recommendations on the reporting of Interstitial Brachytherapy (ICRU 1997). The general concepts are similar to those of the Paris system although expressed in terms of the target volumes defined by ICRU 50 (1993)—see [Section 29.2](#). These recommendations allow implants following different systems to be described in the same terms.

\* A comparison of this implant with a similar volume implanted with sources following Manchester system rules is given in a paper by Gillin et al. (1984).

**FIGURE 54.9**

Dose distributions following the Paris system for the source arrangement shown in Figure 54.8. Dose distributions are shown in the central plane perpendicular to the wires (left), parallel to the wires (centre) and in a plane 5 mm from the source plane and parallel to it (right) - this plane is indicated by the dotted line in the left hand figure. The isodose lines shown are (from the outside in) 50%, 90%, 100% and 120% relative to the reference dose rate (RDR). The 100%, RDR, isodose is bold. The BDR is approximately 120% (actually 117.6%).

#### 54.1.4.1 Description of Volumes

The *planning target volume* (PTV) is considered to be the same as the *clinical target volume* (CTV) in interstitial brachytherapy. It is important that the CTV should be defined prior to the implantation process rather than defining it based on what has actually been implanted. The radiation oncologist will determine an isodose surface, which represents the *minimum target dose* and should ideally encompass the CTV. This isodose surface defines the *treated volume*.

#### 54.1.4.2 Reference Dose

The minimum target dose could potentially be set at any level to ensure that the CTV is covered adequately, but this would risk inappropriately high doses within the implant. In order to provide a more objective reference the *mean central dose* is defined. This is exactly equivalent to the *basal dose rate* of the Paris system. In order to specify the mean central dose it is necessary to identify the central plane of the implant exactly, as in Section 54.1.3. ICRU envisages that there might be a need in a complex implant to divide the implant into two parts and identify the central plane of each part. The mean central dose is defined as the arithmetic mean of the local minima between the sources on the central plane of the implant.

A second approach to ensuring that there is an objective reference is the requirement that the *total reference air kerma* (TRAK) be calculated for the implant. (This concept is discussed in detail in Section 54.2.6.5.)

#### 54.1.4.3 High and Low Dose Volumes

An implant will have high dose regions around the individual sources. Since the size of these high dose regions will influence the toxicity of the implant, it is necessary to measure them. For this purpose, the high dose volume around each wire is defined as the volume encompassed by the isodose corresponding to 150% of the mean central dose around each wire. The maximum dimension of the largest high dose region in all planes should be reported. This will usually be in a direction parallel to the wires.

It is possible also that there may be part of the CTV that does not reach the minimum target dose. Any volume within the CTV, which receives less than 90% of the prescribed dose, is defined as a low dose volume. In a well-constructed implant prescribed to the minimum target dose (i.e. following the Paris system), there would be no low dose volume.

#### 54.1.4.4 Dose Uniformity

The aim of brachytherapy is to deliver a relatively uniform dose to the CTV. However, it is to be accepted that dose rates close to the wires will be significantly higher. In order to express the uniformity of the implant two parameters are recommended:

- The spread in the individual minimum doses used to calculate the mean central dose in the central plane expressed as a percentage of the mean central dose.
- The dose homogeneity index: defined as the ratio of minimum target dose to the mean central dose.

An implant following the Paris system exactly would have a dose homogeneity index of 85%, but the report gives examples of two implants where this index is just over 70%.

#### 54.1.4.5 Implant Duration

The overall time and the temporal pattern of irradiation should be recorded. The irradiation time is the time during which a radioactive source is present in the patient. The overall treatment time is the total time elapsed from the beginning of the first irradiation to the end of the last one. The *instantaneous dose rate* is the *dose per fraction* divided by the *irradiation time* for that fraction. The *average overall treatment dose rate* is the *total dose* divided by the *overall treatment time*.

---

## 54.2 GYNAECOLOGICAL INTRACAVITARY TREATMENTS

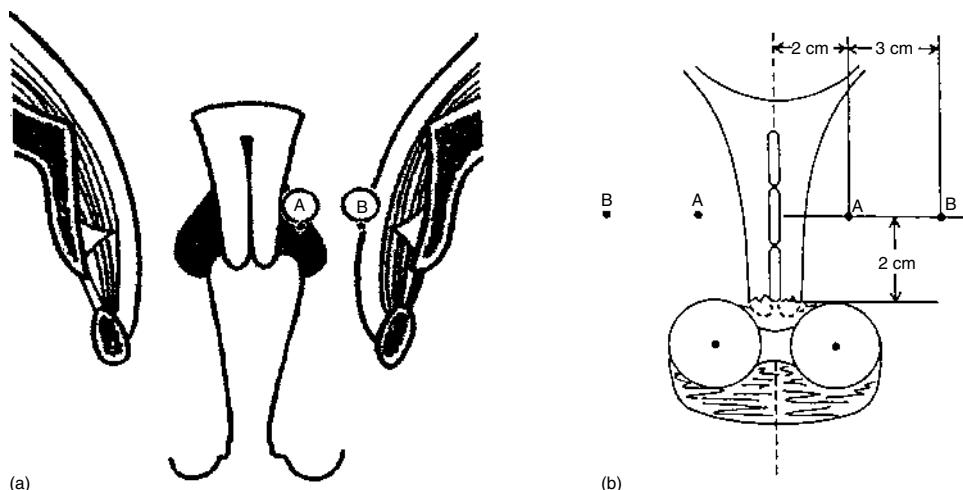

### 54.2.1 INTRODUCTION

Intracavitary brachytherapy involves the insertion of radioactive sources into natural body cavities. Many sites are treated in this way, e.g. rectum, antrum, oesophagus, nasopharynx, etc. The most widespread use of this technique has been in the treatment of gynaecological malignancies. However, this means that for extensive tumours, brachytherapy is only a part of the treatment and external-beam therapy is often given before (or occasionally after) the intracavitary irradiation.

The original brachytherapy techniques (the Stockholm system (Heyman 1929, 1935) and the Paris system (Regaud 1929)) evolved using sealed radium sources for the treatment of uterine cancer. Both methods used radium inserted into the uterine canal and the lateral fornices of the vagina, but there were important differences in terms of the activity, the distribution of radium used and the duration of treatment. The dosimetry systems were based on the concept of milligram hours, which is the total activity (in mg) multiplied by the time in hours. However, when intracavitary and external-beam treatment are combined, it becomes important to calculate the absorbed dose in tissue, taking into account the radiobiological effect of the different dose rates (see [Section 55.4](#)).

### 54.2.2 MANCHESTER RADIUM SYSTEM

The classical Manchester system was the first system to attempt reproducible dosimetry to a specified dose point. Tod and Meredith (1953) began to calculate “dose” in roentgen to various sites in the pelvis. It was decided that the limiting dose was not the dose to the rectum or bladder, but to an area where the uterine vessels cross the ureter, the *paracervical triangle* ([Figure 54.10a](#)). This area is also frequently the site of early infiltration of the disease. This led to the definition of Points A and B.

**FIGURE 54.10**

(a) Anatomical drawing of the pelvic area showing the approximate location of Points A and B; (b) Manchester system showing Points A and B positions and their relationship with the intracavitary sources.

- *Point A*, is defined as a point at 2 cm lateral to the centre of the uterine canal and 2 cm from the mucous membrane of the lateral fornix of the vagina in the plane of the uterus (Figure 54.10b). Point A is a geometric and not an anatomical point, its position can only be defined with respect to the applicators in an idealised, or reference geometry. It allows the treatment to be prescribed in terms of dose rather than milligram hours. The dose to Point A can be regarded as the minimum dose on the surface of a large volume of potentially tumour bearing tissue.
- *Point B* is defined to be 5 cm from the mid-line and 2 cm up from the mucous membrane of the lateral fornix. This gives a good indication of the lateral spread of the effective dose in addition to the dose near the pelvic wall near to the obturator nodes.

Loading rules were produced for the uterus and vaginal sources to enable the same dose to be given to Point A, regardless of the shape and size of the uterus and vagina, and consequently the applicators used.

To achieve a constant dose rate at Point A, the Manchester system defines the number of *units* of radium to be used in each ovoid and tube size. The radium loading in the uterine tubes is (10 + 10 + 15) mg, (10 + 15) mg and 20 mg for long, medium and short tubes. The ovoids are loaded with 22.5 mg, 20 mg and 17.5 mg of radium for large, medium and small ovoids respectively. When a short tube ( $\sim 2$  cm) is used, a dose reduction of at least 13% should be made to the dose prescribed to Point A. This is because the dose rate at Point A will not be representative of a standard insertion owing to the relative dose rates from the ovoids and the uterine tube at this point\*.

The standard “dose” to Point A in the Manchester system was fixed at  $53 \text{ R h}^{-1}$  and the total “dose” for two equal fractions of treatment was 8000 R delivered in 144 h. The dose at Point B is between 25% and 30% of the dose at Point A. Typically the “dose” rate at Point A from the uterine tube was between  $27 \text{ R h}^{-1}$  and  $34 \text{ R h}^{-1}$  and from the ovoids about  $19 \text{ R h}^{-1}$ . These “dose” rates apply for an ideal insertion and often the disease does not allow perfect positioning. Point A is always perpendicular to the uterine canal and 2 cm

\* In this case the most superior part of the uterine tube would be at the same distance from the mucosal surface of the lateral fornix as Point A and the dose distribution would not have the characteristic pear shape shown in Figure 54.12 - so the dose rate would be falling off faster than usual at Point A.

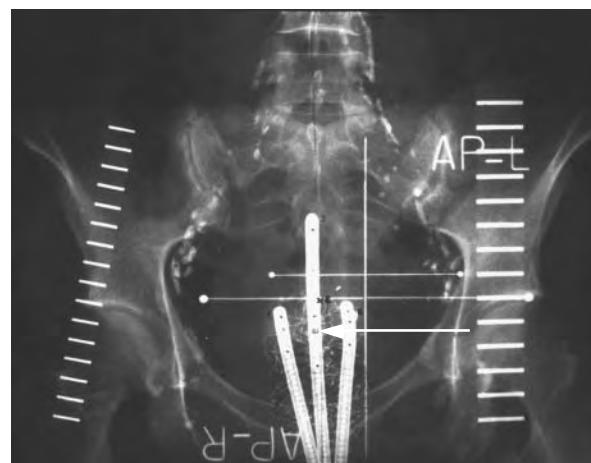

from it, whereas Point B remains constant relative to the midline of the patient. Wilkinson (1983) pointed out that even with displaced sources, the dose rate at Point A calculated for the ideal insertion is what is used to determine the treatment time, even if the perfect geometry is not achieved for that particular insertion.

### 54.2.3 EXTENSION OF THE MANCHESTER SYSTEM TO LOW-DOSE-RATE REMOTE AFTERLOADING

#### 54.2.3.1 Geometrical Considerations

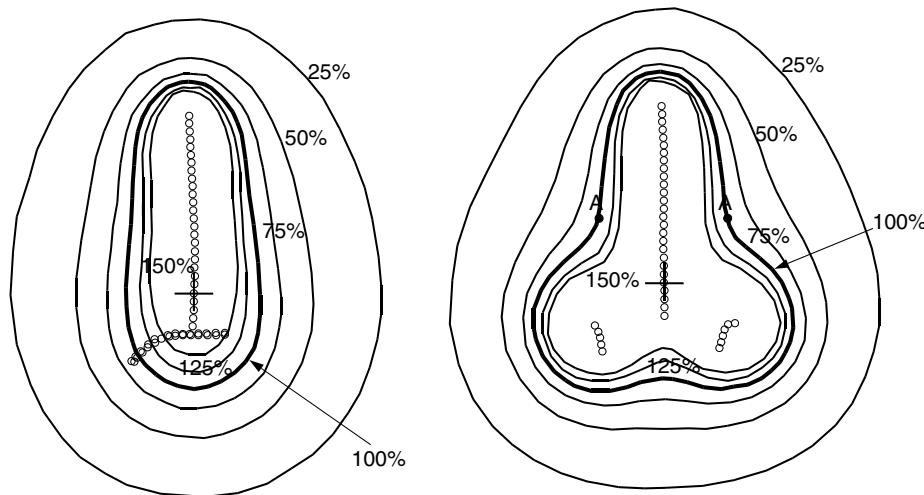

The principles of the Manchester system are still employed when using modern low-dose-rate (LDR), pulsed-dose-rate (PDR), or high-dose-rate (HDR) afterloading systems, though the geometry of the applicators used is more rigid. When one takes x-rays, it is easier to identify the flange on the uterine tube than the mucosal surface of the lateral fornix, as often the plastic *ovoids* cannot be seen on x-ray. These two identification points are not necessarily at the same position in the pelvis so there can be a variation in position of Point A, dependent on which of these points is chosen as the reference origin for Point A. This is particularly true if applicators that do not fit to the same rigid geometry each time are used. Care should be taken to report exactly how Point A has been identified, in addition to the dose prescribed. Figure 54.11 shows an AP x-ray of a typical uterine tube and ovoid application using a rigid LDR applicator system. The black dots on the image show the positions of the reconstruction points of the applicators and the position of the flange.

Point doses to Point A and Point B are usually calculated from orthogonal radiographs of the application. Tables are available of typical dose rates to Point A and Point B from standard (fixed geometry) applicators. However, it is now usual to carry out calculations of dose distributions on an individual patient basis. Most modern brachytherapy planning systems require applicator information, digitised from x-rays or from co-ordinates typed at a keyboard. Orthogonal x-rays are the simplest way to locate the applicators and sources, but sometimes a sufficiently penetrated lateral film is difficult to achieve. It is then necessary either to have another reconstruction method from a different set of films or to use a template of the applicator at the correct magnification and superimpose this on the lateral x-ray. (Different reconstruction techniques are discussed in [Section 54.5.2](#)).

**FIGURE 54.11**

X-ray of typical uterine tube and ovoid application. The black dots which are just distinguishable on the central axis of the applicators show the positions of the points that will be digitised to allow reconstruction of the applicators and the position of the flange - the latter being the most inferior dot on the central tube level with the white arrow.

**FIGURE 54.12**

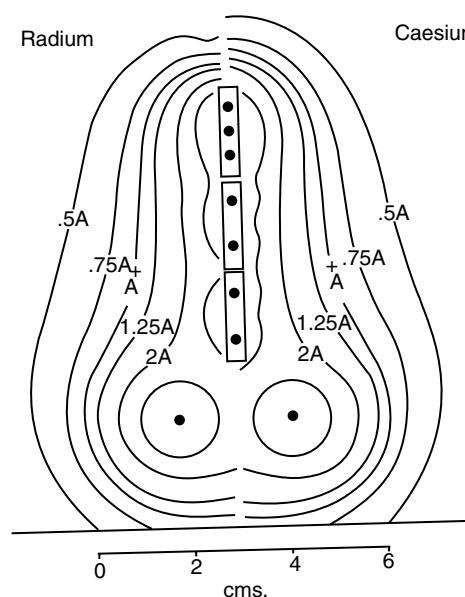

Lateral and AP isodose distributions for an LDR insertion. Isodoses are shown as percentages of the dose to point A.

Once the positions of the applicators have been defined, some computer systems will allow the applicator and patient points to be entered separately. Points A and B can be defined from the position of the applicators and only the patient points have to be digitised separately from the radiographs. Some computer systems will position the sources inside the applicators automatically, once the applicators have been defined and the active sources requested. This also speeds up the time spent on dosimetry, which is often important for HDR calculations where the patient is waiting for dosimetry to be calculated before treatment can commence. If it is necessary to modify the resulting dose distribution (for example, if the rectal dose is too high) then automatic positioning of the sources inside the applicators is a very useful feature which means that the sources do not have to be re-entered into the computer. Automatic source placement also assists in computer optimisation of dose distributions.

Many planning systems allow anatomy to be traced in from radiographs so that dose distributions can be superimposed in the correct position. Distributions can be selected in any plane and plotted at any magnification, to assist with the accurate positioning of shielding if required. Figure 54.12 shows typical AP and lateral isodose distributions, displayed in the plane of the uterine tube. Three dimensional brachytherapy planning is now a feature of some systems, where isodose surfaces and volumes irradiated are displayed. Input of data is often from CT data sets in combination with orthogonal x-rays.

#### *54.2.3.2 Source Loading Pattern*

When the Selectron LDR machine was first introduced, the aim was to reproduce (as closely as possible) the isodose patterns achieved with the traditional Manchester radium system (Wilkinson et al. 1983), by using standard loading patterns and treatment times. The afterloading source patterns that simulate the radium system were achieved by comparing dose distributions for sources arranged in the same reference geometry as is used for the Point A calculation. Similar dose distributions are expected with similarly distributed source activities, so the 10 mg, 15 mg and 20 mg radium tubes were replaced by 2, 3 and 4 caesium pellets. Where the ovoid activity required was 22.5 mg and 17.5 mg radium equivalents, it was not possible to keep exactly the same ratio; consequently, four pellets were used but the treatment times for the ovoid channels were adjusted accordingly. Now a more common practice is to alter the number of ovoid sources to correspond with the variation in ovoid diameter. Mini, small, medium and large ovoids contain 2, 3, 4 and 5 sources respectively, to give similar dose

**FIGURE 54.13**

A comparison of the relative isodose distributions from radium G-type tubes and the corresponding Caesium-137 pellet-loading pattern for the reference geometry. The positions of the active pellets are shown, the intervening spaces being taken up by inactive pellets. Isodoses are shown as multiples of the Point A dose.

rate contributions from the ovoids of all sizes to Point A. This may be preferable to varying the dose rate to Point A during the treatment delivery.

An example of a relative dose distribution comparison for a 6 cm uterine tube and 2 medium ovoids is shown in Figure 54.13. There is no correction for the oblique filtration in the metal applicators or for the shielding effects when the pellets are in line. The errors here will only be significant at the tips of the applicators along the axis where the dose would be reduced by a factor of up to two. Any other small errors are considered insignificant when such steep dose gradients exist. The dose-rate to Point A when using 1.5 GBq (15 mg radium equivalent, RAKR 120  $\mu\text{Gy h}^{-1}$  at 1 m) caesium-137 pellets is about 3.5 times greater than the classical Manchester system so a dose-rate correction for the biological effect is applied as discussed in Section 55.4.3. Typical Selectron source positions for this insertion are given in Table 54.2 compared to the classical Manchester system loading.

#### 54.2.3.3 Optimisation

There is also the possibility of optimising the dose distribution and tailoring it to individual patients using the LDR Selectron. Compared with external-beam treatment there are relatively few options for altering dose distributions in intracavitary therapy. However, some

**TABLE 54.2**  
Equivalent Manchester and Selectron Loadings

	Manchester	Selectron Loading Positions
6-cm uterine tube		
Fundus	15 mg 10 mg 10 mg	3, 5, 7 (45 mg Ra equiv) 11, 15 (30 mg Ra equiv) 19, 23 (30 mg Ra equiv)
Medium Ovoids	2×20 mg	2×3, 4, 5, 6 (60 mg Ra equiv)

modification of the dose distribution to tailor it to the individual patient anatomy can be achieved by varying the number of active pellets and their position in each applicator. For example, if the dose to the rectum is considered to be too high, the ovoid sources can be moved from position 3 to position 4, 5, 6 or 7 (or removed completely), which results in a shift in the isodose curves. Because of the high dose gradients, the dose to the anterior rectal wall could be altered sufficiently by this change, whilst making very little difference to the dose higher in the pelvis. However, dose to the bladder may be increased unacceptably.

If the disease is concentrated around the cervix, the loading of the uterine applicator can be increased in this area. Care should always be taken with optimisation techniques because clinical data has been collected over many years using standard rules for source positioning and dose prescription. These rules no longer apply when dose distributions are tailor-made to fit treatment volumes. However, optimisation is being investigated because the potential gains in local tumour control with a reduction in normal tissue damage could be considerable.

Pulsed-dose-rate (PDR) intracavitary treatments give very similar dose distributions. They offer similar optimisation possibilities based on a single iridium-192 source which moves along the catheters as for the HDR treatments (see Section 54.2.7).

#### 54.2.4 HDR TREATMENT OF GYNAECOLOGICAL CARCINOMAS

Carcinoma of the cervix may be treated on a HDR machine using the narrow uterine tube and ovoids, which have built-in packing (an extra 5 mm of plastic incorporated instead of conventional packing) (Nag et al. 2000b). The applicators lock together in a fixed geometry and are fixed to the table during the treatment. With the narrow tubes, it is possible to use local anaesthetic for the insertion of these applicators although this is technically difficult and not recommended. X-rays are taken before the first treatment, but because the applicators fit together in a standard, reproducible way, an atlas of pre-calculated dose distributions may be used to select the required dosimetry for the first insertion. A typical isodose distribution is shown in [Figure 54.14](#).

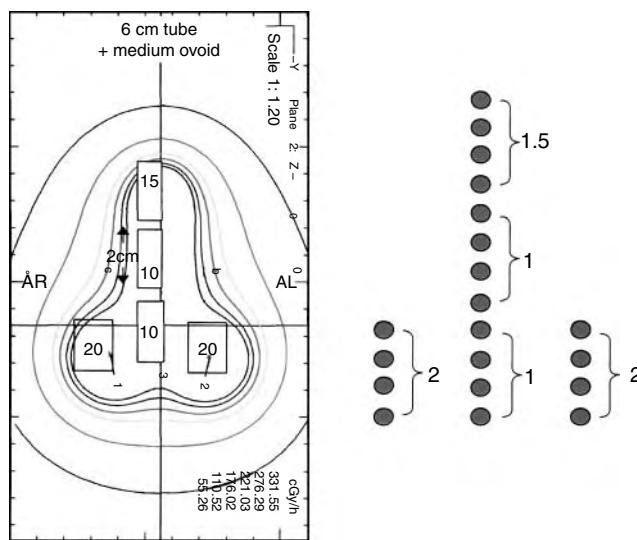

The treatment times are calculated based on the actual activity of the source. Standard dwell positions and times are used (see [Figure 54.14](#)). Dose to a point 5 mm behind the back of the ovoids (which is the ICRU rectal point) is calculated to represent the minimum rectal dose\*. The dwell positions and times are chosen to mimic the classical Manchester pear-shaped dose distribution as closely as possible.

[Table 54.3](#) shows typical dwell positions to reproduce the dose distribution shown in [Figure 54.14](#). Dwell position separation is 2.5 mm, i.e. one active dwell position every 5 mm except in the ovoid applicators.

After the first treatment, the actual dose distribution is calculated for that particular patient, including the dose to the rectum. If any alterations need to be made, these can then be calculated in preparation for the subsequent insertion(s). In order to avoid the second application of a general anaesthetic it is possible to insert a Schmidt sleeve at the first insertion which remains in place until the completion of all fractions.

For the radiotherapy treatment of carcinoma of the endometrium and carcinoma of the vagina, similar techniques may be used as for the LDR Selectron, but owing to the small diameter of the applicators through which the source travels it is possible to give this treatment on an outpatient basis, using only local anaesthetic. Dwell times are calculated from standard tables, which are produced to give a dose rate at the prescription distance from the source, using a specified activity. These tables are based on double-ovoid insertions of known

\* The dwell weightings in the ovoids does sometimes have to be reduced, or a dwell position not used, to bring the rectal dose within tolerance.

**FIGURE 54.14**

(See colour insert following page 590.) HDR source dwell position pattern with relative dwell weights to reproduce typical Manchester loading.

separation, or line-source simulation. The dose rate for each individual insertion is decayed for source activity. Radiographs are taken of every patient as a record of treatment and so that subsequent dosimetry and field matching can be achieved when necessary.

#### 54.2.5 COMBINED INTRACAVITARY AND EXTERNAL-BEAM THERAPY

Intracavitary therapy is often used in combination with external-beam therapy, which is usually given before brachytherapy. When attempting combined dose distributions it is essential to convert the delivered doses into radiobiologically equivalent doses before combining the brachytherapy and external-beam components. When prescribing the intracavitary dose for this technique the dose given can be influenced by the tolerance of the bladder and rectum. It used to be the practice, for some stages of disease, to treat with intracavitary therapy first, followed by external-beam therapy. The external-beam treatment often incorporated shielding and compensation to spare the volume irradiated by the intracavitary treatment. If a wedge filter of some description was used consideration had to be given to the rapid fall-off in the dose from the intracavitary therapy, the maximum dose to Point A, and the desired dose to the rest of the pelvis. The wedge had to be reproducibly positioned with its thickest part over the position occupied by the uterine sources. The use of such wedges has been described by many authors (e.g. Tranter 1959, Jones et al. 1972). When using shaped wedges or shielding blocks

**TABLE 54.3**

Source Positions to Reproduce Manchester Loading Patterns

Manchester	HDR Selectron Dwell Positions and Weights
6-cm uterine tube	
Fundus	15 mg 1, 3, 5, 7 Dwell time weight 1.5 10 mg 9, 11, 13, 15 Dwell time weight 1.0 10 mg 17, 19, 21, 23 Dwell time weight 1.0
Medium Ovoids	2×20 mg 3, 4, 5, 6 Dwell time weight 2.0

there were many difficulties associated with their reproducible positioning and the consequent matching of steep dose gradients.

1. When adding intracavitary to external-beam dose distributions, the pear shaped intracavitary volume is often at an inclined angle within the pelvis so the position of the shielding block must be matched to the projection of this distribution onto a horizontal plane through the patient.
2. For the ideal dose distribution, the uterus must be in the same position with and without the applicator inserted. This is frequently not the case and as the position of the block is defined from the radiographs of the intracavitary insertion, the volume shielded is not necessarily the volume irradiated by the sources, this results in areas of over- and under-dose.
3. If more than one intracavitary treatment is used, the summed dose distributions should be used and the doses to Points B are likely to be different. There are also inaccuracies in the day-to-day set up of external-beam treatments.
4. A more fundamental inaccuracy occurs from the use of radiographic techniques to calculate the true position of the sources. An accuracy of at best  $\pm 3$  mm can be achieved. In addition, the positioning of the block on the lead tray cannot be achieved to better than  $\pm 1$  mm which when magnified can result in a  $\pm 2$  mm uncertainty. This can result in significant areas of under- and over-dose due to the high dose-gradients in this region.

For the above reasons the use of such wedges and shielding devices is not so commonly practised nowadays.

#### 54.2.6 ICRU RECOMMENDATIONS ON GYNAECOLOGICAL BRACHYTHERAPY

Intracavitary therapy is frequently used in conjunction with external-beam therapy for the treatment of gynaecological malignancies. For this reason, the ICRU have published Report 38 (1985)\* on *Dose and volume specification for reporting intracavitary therapy in gynaecology* recommending that similar terminology and definitions be used, to that used in the ICRU Report 29 (1978) and anticipating the more recent ICRU Report 50 (1993) *Prescribing, recording and reporting photon beam therapy*. This is only possible to a limited extent, since the high dose gradients near intracavitary sources make the specification of absorbed dose to specific points within the target volume less meaningful than in external-beam therapy. The necessary modifications are made in the way in which various volumes are defined.

##### 54.2.6.1 Target and Treatment Volumes

The *target volume* is that volume which contains tissues to be irradiated to a specified absorbed dose according to a specified time-dose pattern

The *treatment volume* is the volume enclosed by a reference isodose surface, which encompasses at least the target volume. In intracavitary therapy, the dose cannot be specified in terms of a percentage of the dose at any point within the target volume due to the steep dose gradient. It is therefore necessary firstly to agree upon a reference dose level, secondly to plan the treatment to include the *target volume* within that reference isodose surface and then to determine the dimensions of the *treatment volume*.

The *irradiated volume* is larger than the *treatment volume* and includes tissues irradiated to a significant absorbed dose.

\* The ICRU report 38 does not include the recent possibilities offered by modern imaging techniques. It is currently under review (Pötter et al. 2001b) and will include some of the concepts developed in the recommendations issued by the GEC-ESTRO group (Haie-Meder et al. 2005; Pötter et al. 2006) or by the American Brachytherapy Society (Nag et al. 2004).

Using these definitions, the ICRU recommend that for an insertion of uterine and vaginal sources the specification of the intracavitary application should be in terms of the *treatment volume*, which the ICRU have defined as the volume enclosed by the 60 Gy reference isodose surface for classical low-dose-rate therapy\*. If there is an external-beam component in addition to the brachytherapy, then the brachytherapy isodose must be selected to allow for the external-beam dose (e.g. if the external-beam contribution is 50 Gy, then the brachytherapy *treatment volume* is the volume enclosed by the isodose that is equivalent to 10 Gy at low dose rate).

This reference volume should be defined by the height, width and thickness of the pear-shaped volume enclosed by the 60 Gy absorbed dose level, measured in the oblique-frontal and (oblique-) sagittal planes containing the uterine sources as shown in [Figure 54.15](#), taken from ICRU 38.

The dose delivered to a gynaecological malignancy is limited by the radiation dose that can be tolerated by the bladder and the rectum. The determination and specification of the bladder and rectal doses should either be measured or calculated. The recommended calculation points are shown in [Figure 54.16](#). Chassagne and Horiot (1977) have described methods of determining points of reference for both organs.

#### 54.2.6.2 Dose to the Bladder

A Foley catheter is inserted and partially filled with 7 cm<sup>3</sup> of radio-opaque fluid. The catheter is pulled down to bring the balloon against the urethra. On the AP radiograph, the reference point is taken as the centre of the balloon. On the lateral radiograph, the reference point is taken at the posterior surface of the balloon along an AP line drawn through the centre of the balloon.

#### 54.2.6.3 Dose to the Rectum

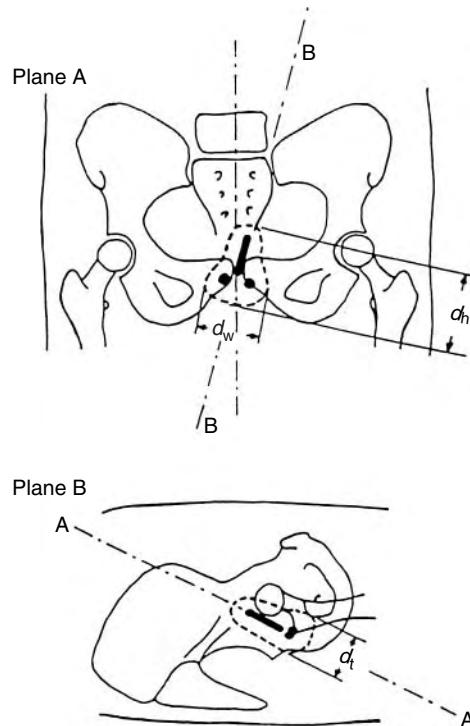

The rectal point is located at 5 mm behind the posterior vaginal wall as shown in [Figure 54.16](#). Knowledge of the dose to the rectum can mean that the sources or applicators need to be repositioned to keep the rectal dose to less than 65% of the dose to point A, and less than 65 Gy in total.

In practice, it is difficult to identify the posterior vaginal wall on the lateral radiograph. The rectal point calculation is therefore usually made at a point 5 mm posterior to the back of the ovoids or 5 mm posterior to the packing if there is any in place.

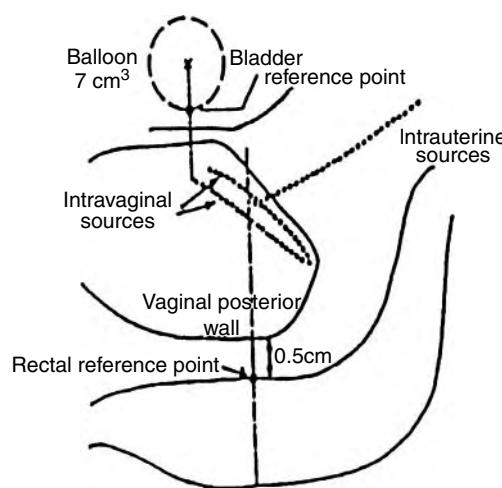

If rectal and bladder measurements are to be made, there are several pitfalls that should be noted:

1. Applicators are normally inserted in the lithotomy position and packing and measurement of dose points is much easier in this position. For low-, pulsed- or medium-dose-rate treatments, the treatment is always given with the patient lying flat so that the critical anatomy is in a different position.
2. When using afterloading systems with high activity sources, microsources have to be used to measure dose points. This means some radiation exposure to staff. Using microsources also means that it is necessary to measure dose rates of the order of 0.05 cGy s<sup>-1</sup> (3 cGy h<sup>-1</sup>) which is technically difficult. If using an ionisation chamber the measuring volume is of the order of 10.6 cm<sup>3</sup>, which is large for clinical use. Other solid state and photovoltaic detectors are often temperature and energy dependent, so have to be used with care. Measurements have been made at various centres using TLD inserted into rectal catheters, which are left in place during the course of an insertion (see [Section 40.2.3.5](#)). However, this gives a retrospective average dose over the whole intracavitary treatment, and is not necessarily the maximum dose received by the anterior rectal wall.

\* For medium- or high-dose-rate techniques the radiation oncologist must indicate the dose level he believes to be equivalent to 60 Gy, delivered at low dose rate.

**FIGURE 54.15**

Geometry for measurement of the size of the pear-shaped 60 Gy isodose surface (broken line) in a typical treatment of cervix carcinoma using one uterine applicator and two vaginal applicators. Plane A is the oblique-frontal plane that contains the intrauterine device. The oblique-frontal plane is obtained by rotation of the frontal plane around a transverse axis. Plane B is the oblique-sagittal plane that contains the intrauterine device. The oblique-sagittal plane is obtained by the rotation of the sagittal plane around the AP axis. The height ( $d_h$ ) and the width ( $d_w$ ) of the reference volume are measured in plane A as the maximal sizes parallel and perpendicular to the uterine applicator, respectively. The thickness ( $d_t$ ) of the reference volume is measured in plane B as the maximal size perpendicular to the uterine applicator. (From ICRU Report 38, 1985.)

**FIGURE 54.16**

Determination of the reference points for bladder and rectum (see text). (From ICRU Report 38, 1985.)

3. When using a straight measuring probe it is very difficult not to distend the anatomy. It is also difficult to be sure that maximum doses are measured.

Some centres acquire CT scans of the patient with the applicators in place to define the maximum bladder and rectal points by superimposing isodose curves on the relevant transverse slices. This is a good method, but practically difficult to achieve and expensive on a routine basis. The use of CT and Magnetic Resonance Imaging (MRI) is increasing in brachytherapy dosimetry and allows volumetric dose calculations for bladder and rectum.

#### 54.2.6.4 Dose to the Pelvic Wall

The points related to bony structures ([Figure 54.17](#) and [Figure 54.18](#)) are the mid-external lymph nodes (R and L EXT), the low para-aortic area (R and L PARA) and the low common iliac lymph nodes (R and L COM). The pelvic wall reference points represent the absorbed dose at the distal part of the parametrium and at the obturator lymph nodes. The evaluation of these doses is useful when intracavitary therapy is combined with external-beam therapy.

Typical doses to the above pelvic points expressed as a percentage of the dose to Point A are shown in [Table 54.4](#).

#### 54.2.6.5 Total Reference Air Kerma

There are steep dose gradients in the region of the sources, so that specifying a treatment in terms of the dose at a point is not recommended. It is proposed that the total intracavitary treatment should be specified in terms of total air kerma. The reference air kerma rate (RAKR) of a source is the kerma rate to air, in air at a reference distance of one metre, corrected for air attenuation and scattering (see [Section 51.3](#)). The *total reference air kerma* (TRAK) is conceptually similar to specifying the number of milligram hours in traditional systems.

For example, a point source containing 1 mg radium with 0.5 mm Pt filtration, producing an exposure rate of  $8.25 \text{ R h}^{-1}$  at 1 cm would have an RAKR of  $7.2 \mu\text{Gy h}^{-1}$  at 1 m. (The conversion factor from exposure to air kerma used is  $0.873 \text{ cGy R}^{-1}$ ).

A typical Manchester type insertion of 75 mg radium with 1 mm Pt filtration (difference in filtration reduces dose-rate by 0.93) would produce an air kerma rate of

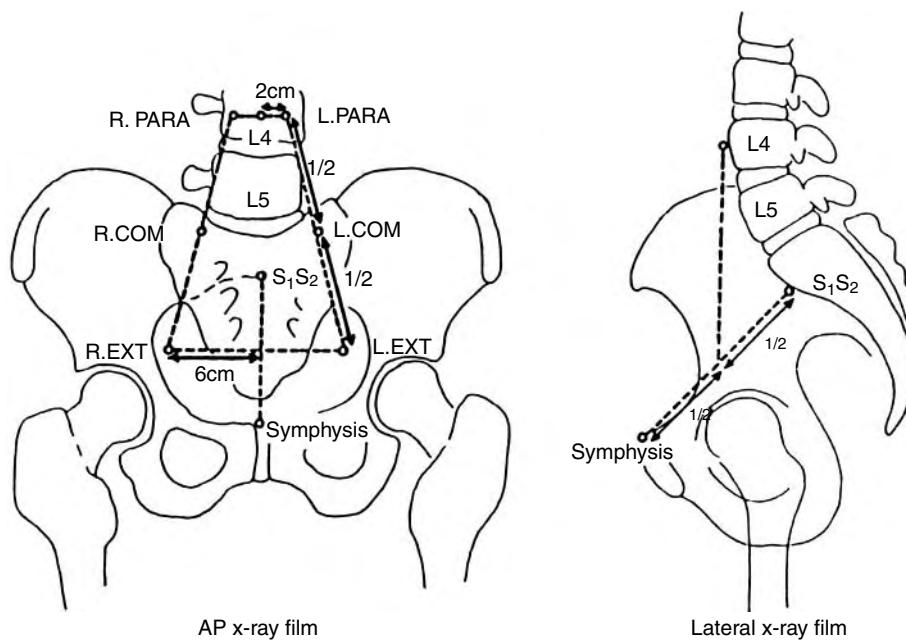

$$75 \times 0.825 \times 0.873 \times 0.93 = 502 \mu\text{Gy h}^{-1} \text{ at 1 m.}$$

The TRAK is the sum of the products of the RAKR and the duration of the application for each source. Assuming the sources are left in position for 72 h, then the TRAK is 3.6 cGy at 1 m for a typical *Manchester* insertion.

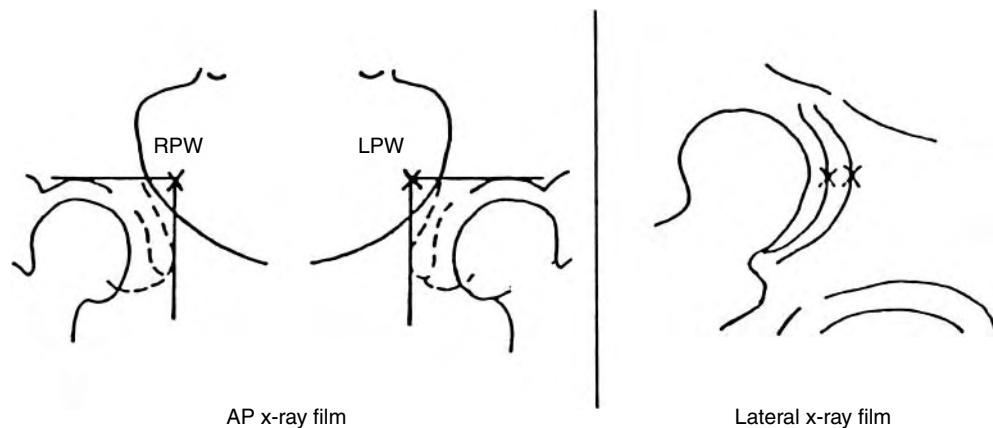

The TRAK is independent of the source geometry and proportional to the integral dose to the patient. It provides a useful quantity to compare treatments within one centre or between different centres and to explain possible differences in the delivered dose or in the treatment volume dimensions. It can also serve as a useful index for radiation protection of personnel. By application of the inverse square law it can be used to evaluate to a reasonable approximation, the total absorbed dose delivered during treatment at distances between 10 cm and 20 cm from the sources (Dutreix et al. 1982). However, it cannot be used to calculate absorbed doses in the tumour or target volume (i.e. close to the sources).

#### 54.2.6.6 Time-Dose Pattern

The prescription method for a particular type of intracavitary system cannot necessarily be extended from one system to another. It is therefore important to record the specific time-dose pattern that has been used. With all intracavitary treatment, whether continuous low dose rate, or fractionated high dose rate the prescription should specify the total radiation dose, the length of

**FIGURE 54.17**

Determination of the lymphatic trapezoid. On the left is an anteroposterior view and on the right a lateral view.

**FIGURE 54.18**

Determination of the right (RPW) and the left (LPW) pelvic wall reference points.

**TABLE 54.4**

Typical Doses Expressed as a Percentage of the Dose to Point A

A	R	BL	RPW LPW	R/L EXT	R/L COM	R/L PARA
100%	65%	60–80%	25%	25%	15%	5%

treatment and the number of times the treatment is to be repeated. Frequently the intracavitary treatment will be a part of a combined approach using external-beam therapy. The external-beam dose must also be recorded. For example, a typical radiotherapy prescription for the treatment of carcinoma of the cervix would be 50 Gy in 28 fractions over 5.5 weeks delivered by external therapy (8 MV or 10 MV x-rays) to the pelvis, using an anterior and two lateral wedged fields. This would be followed by 25 Gy delivered over 12 h to Point A from a uterine tube and two vaginal ovoids remotely afterloaded with caesium.

For a complete description of the treatment a more specific prescription detailing field sizes, wedge compensator and blocks, the length of the uterine tube and size of vaginal ovoids and the distribution of activity within the applicators is necessary.

There is often confusion between low and medium dose rates for caesium-137 Selectron dosimetry. The ICRU definitions of dose rate are as follows:

Low dose rate	$0.4 \text{ Gy h}^{-1}$ to $2 \text{ Gy h}^{-1}$
Medium dose rate	$2 \text{ Gy h}^{-1}$ to $12 \text{ Gy h}^{-1}$
High dose rate	Above $12 \text{ Gy h}^{-1}$

The classical Manchester system gives a dose rate to Point A of  $53 \text{ cGy h}^{-1}$ , which is clearly low-dose-rate therapy. Modern afterloading machines with higher activity caesium-137 sources give dose rates between  $1.5 \text{ Gy h}^{-1}$  and  $2.0 \text{ Gy h}^{-1}$ . This would be termed low dose rate by the ICRU definition, but clinical experience has shown that a dose reduction is needed to maintain the same isoeffect as standard therapy (Roberts et al. 2004). The suggestion is therefore that the definitions should be changed so that dose-rate classification would reflect the requirement for a reduction in dose compared to doses given by standard activity systems (Pötter et al. 2001b). There is a much clearer division between medium and high dose rate systems.

## 54.3 HIGH-DOSE-RATE TECHNIQUES FOR NON GYNAECOLOGICAL SITES

The small physical size of the iridium-192 source lends itself to use in other sites where a small diameter applicator can be used. The use for endovascular brachytherapy has already been described in [Section 52.4.1](#). Other uses are described below.

### 54.3.1 CARCINOMA OF THE BRONCHUS AND OESOPHAGUS

Patients suitable for treatment with HDR brachytherapy are those with localised endobronchial lesions where both the proximal and distal extent of the tumour can be identified bronchoscopically. The treatment is largely palliative and results have shown that it is at least as effective as external-beam palliation, achieving the same relief of haemoptysis, cough and breathlessness but with less associated morbidity. The adverse effects on normal tissue are confined to those tissues within the immediate vicinity of the bronchus. It has the benefit to the patient of requiring fewer hospital visits and less treatment time (as the dose is given in a single fraction), whilst preserving the possibility of more than one fraction. Intraluminal therapy can also be used in combination with external-beam treatment. Many centres use this technique and a large clinical trial has been conducted at the Christie Hospital (Stout et al. 2000). The technique of treatment is usually to perform a bronchoscopy on the patient on the treatment couch (provided that x-ray facilities are available in the treatment room). The patient is screened while the catheter containing the guide wire with dummy sources is placed at the correct site for treatment. The bronchoscope is removed and the patient is re-screened to

check the position of the catheter. The length of the tumour volume to be treated is determined, which includes a treatment margin of (usually) 10 mm at either end. An anterior radiograph and two oblique films may be taken for dosimetry purposes so that clear visualization of the dummy source and catheters are possible. The guide wire is removed and the dosimetry calculated from standard tables decayed for source activity. The procedure for treatment of carcinoma of the oesophagus is similar although the external diameter of the applicator is 10 mm. The dose is usually prescribed at 10 mm from the source.

#### 54.3.2 CARCINOMA OF THE NASOPHARYNX

The small diameter of the flexible catheter and small source size lend themselves to insertion into small orifices. Two catheters are inserted through the nose. This technique has been used to deliver a boost treatment in nasopharyngeal carcinoma in several centres (Gao et al., 1990).

#### 54.3.3 CARCINOMA OF THE BREAST

HDR is very useful for the treatment of breast carcinoma, using templates and rigid introducers. Lumpectomy is performed and before the skin is closed, a single metal introducer is placed along the tumour bed to obtain the correct template orientation. The skin is then closed, leaving the needle in situ. The remaining needles are inserted through the templates and the breast is slightly compressed. The needles are fixed in position. Measurements are taken which enable the active lengths to be calculated. 5 mm skin sparing is usually allowed deep to the skin surface (reproducible positioning is therefore very important). The dwell positions and times are calculated for the treatment, as the HDR has a single high activity source. Linear sources are simulated by stepping the source at 5 mm intervals along the needle. The dose distribution is calculated, based on the Paris system. The treatment is fractionated and treatment time is on the order of a few minutes. Once the machine has been programmed, a test run is performed to check dwell positions and times using film.

#### 54.3.4 SPECIALISED MOULDS AND APPLICATORS

Moulds and applicators can be made for particular applications. Removable applicators, such as moulds for treating hard palate, are particularly useful as the patient can be treated on an outpatient basis. The limiting factor is usually the angle through which the source cable has to turn, although the dummy source is used for checking the travel before the active source is used for treatment. The mould is constructed to place the catheters with a few mm stand-off from the skin in order to increase the relative dose at depth within the patient. Dosimetry is based on either the Manchester or Paris system principles.

---

### 54.4 PROSTATE BRACHYTHERAPY

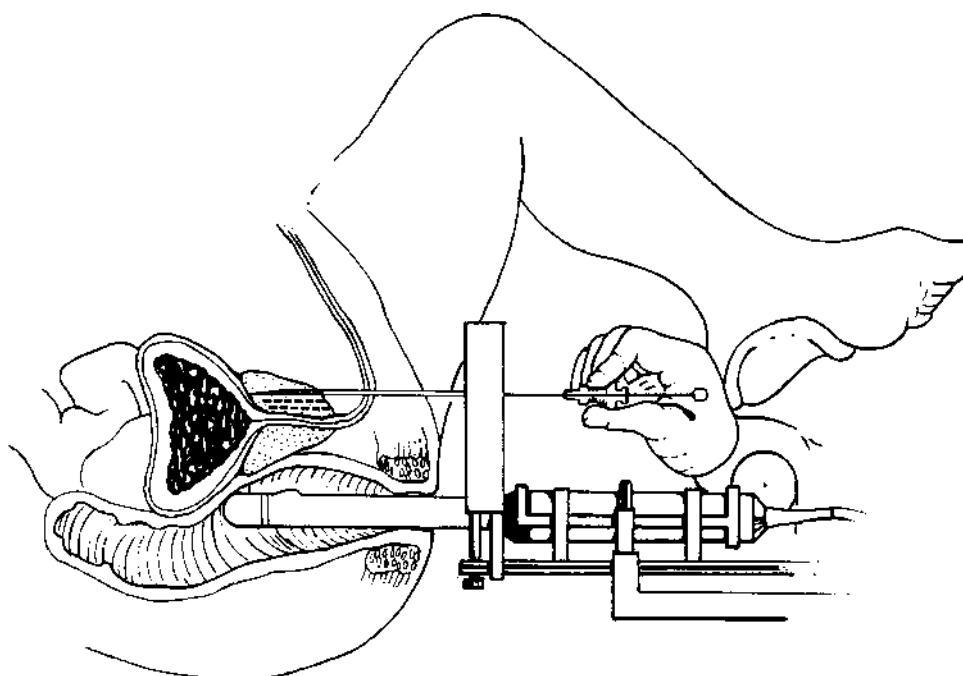

Transperineal source implantation, guided by trans-rectal ultrasound and remote after-loading techniques with HDR, PDR, or low dose rate  $^{125}\text{I}$  or  $^{103}\text{Pd}$  have recently become very popular as one of several methods for treating prostate cancer. These techniques lend themselves to more precise placement of radioactive sources within the prostate, allowing dose to urethra and rectum to be minimised. The advent of high-frequency rectal ultrasound probes has meant that the placing of the applicators or sources can be monitored both in the transverse and longitudinal planes. The planning and dosimetry process is similar whether using afterloading or seed implantation. However, permanent implants, in which iodine or palladium seeds are distributed within the prostate volume and never removed from the patient, are more

widely used. Specific recommendations have been issued both in the United States and in Europe (Nag et al. 1999; Yu et al. 1999; Ash et al. 2000). What follows considers only such permanent implants although the process is similar for afterloading methods (Kovács et al. 2005).

Conduct of prostate implants may be carried out either as a two-stage process involving a planning visit and a treatment visit or as a single session. The two-stage process will be considered first. A volume study of the prostate is performed, several days before the actual implant, using transrectal ultrasound with a stepper to move the ultrasound probe in the longitudinal direction (normally with 5 mm increments). During this study, the prostate and critical organs (especially the urethra) are contoured at several levels. These data are used to determine the prostate volume and hence the optimal position of the needles with the aid of a dedicated treatment planning system. Fixed needle positions on a Cartesian grid (5 mm steps) are used, according to a template mechanically attached to the probe support (see Figure 54.19).

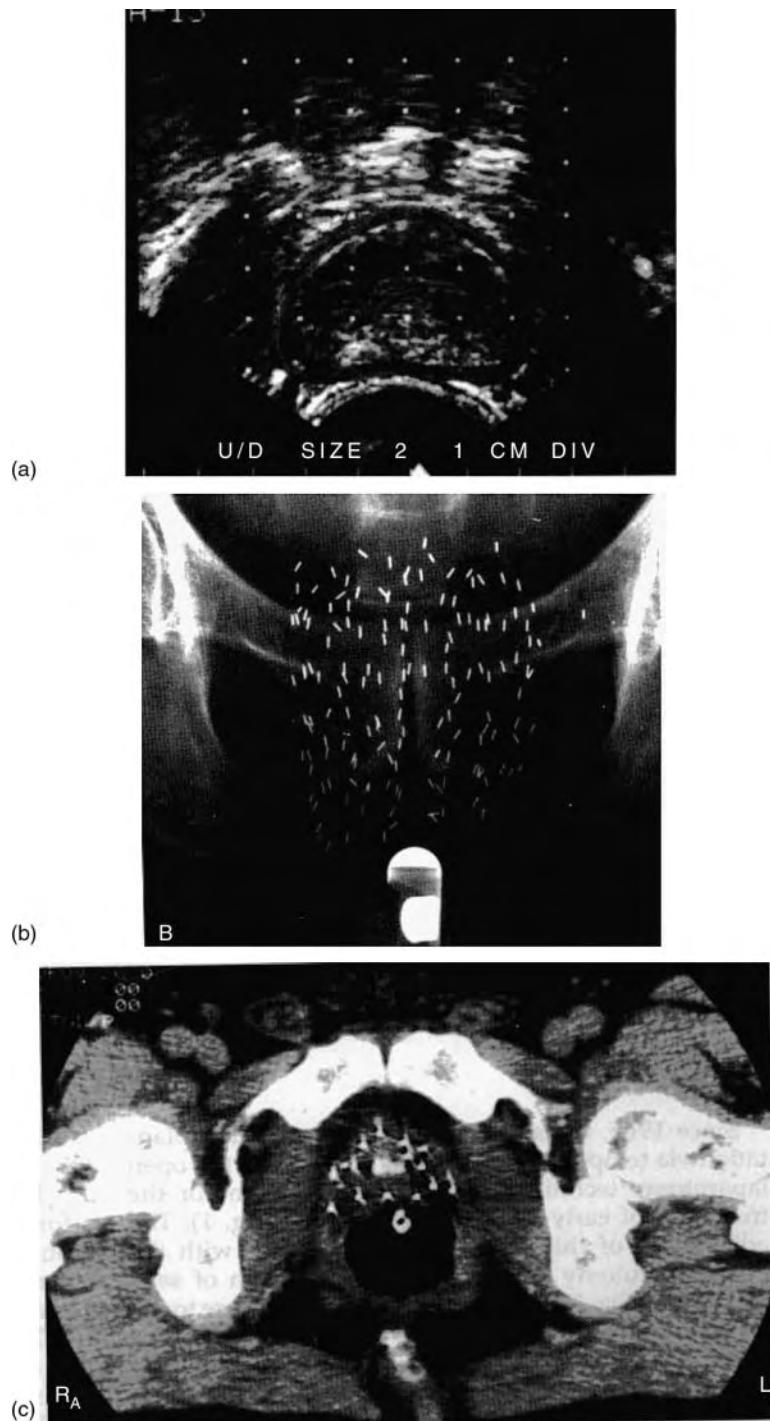

The positions of the active sources are then determined within each needle. Although this is often done without the use of *dosimetry rules* more controlled systems have been evolved. Examples are *peripheral* or *modified peripheral* loading or nomogram based implants, where the total activity is calculated according to the prostate volume and the loading is mostly peripheral with 75% of the activity distributed close to the external surface of the prostate (Stone et al. 1995, Stock et al. 1998). Additional guidelines are as follows:

- It is best to avoid having seeds at the same depth in adjacent needles.
- It is better to have a larger separation between seeds along a more central needle, than a peripheral one, where the prostate contour changes more rapidly.
- It is common practice to avoid placing seeds close to the prostate-rectal interface or close to the urethra.

**FIGURE 54.19**

Typical patient set up for prostate implant. A trans-rectal ultrasound probe gives a real time image of the prostate and of the inserted needles, in either the transverse or sagittal plane. This allows control of the needle position and seed loading within the prostate capsule. The needles are guided by a template with a Cartesian grid of 5 mm spacing. (After Blasko, J. C., Mate, T., Sylvester, J. E., Grimm, P. D., and Cavanagh, W., *Semin. Radiat. Oncol.*, 12, 81–94, 2002.)

**FIGURE 54.20**  
Transverse images of implanted seed using ultrasound, x-ray and CT.

One problem with the pre-implant volumetric study is that it is difficult to set the patient exactly in the same position for the actual implant. In addition, the shape of the prostate changes as the needles are inserted or removed, which causes the pre-planned theoretical seed distribution within the prostate to be difficult to be reproduced precisely. Finally, the

patient has to come to the hospital and be anaesthetised twice. For all these reasons real-time dose planning is becoming more popular. Several approaches are possible but in all cases the treatment planning computer is brought into the operating room and is directly connected to the ultrasound machine so that 2D or 3D real time images of the prostate can be acquired. The basis for source placement is either a seed distribution computed automatically according to some predefined algorithm or predefined rules as indicated above. The dose distribution is calculated in real time as seeds are inserted. The seed insertion could be performed either line by line with preloaded needles which are then removed leaving the seeds retained within the prostate gland, or one after the other with a *Mick applicator* attached successively to each needle which is then retracted step by step.

Typical seed activities used are between 0.3 mCi and 0.4 mCi ( $0.4\text{--}0.5 \mu\text{Gy h}^{-1} \text{m}^2$ ) for  $^{125}\text{I}$  and between 1 mCi and 1.4 mCi ( $1.3\text{--}1.8 \mu\text{Gy h}^{-1} \text{m}^2$ ) for  $^{103}\text{Pd}$ . A typical distance between adjacent seeds is of the order of 1 cm. The details of dose calculation for seed sources are discussed in [Section 53.2](#) and [Section 53.4.2](#). For permanent implants, it is not possible to adjust the treatment time. The total dose is calculated assuming a constant activity and an overall equivalent time of the half-life multiplied by  $\sqrt{2}$ . The isodose distribution produced is then examined and compared with the contours of the prostate. The lowest value isodose that just encompasses the prostate contours on all levels is selected. This is called the *minimum peripheral dose*, which is generally selected to be the *prescribed dose*. When brachytherapy is used as monotherapy, the recommended prescribed dose is usually 145 Gy for  $^{125}\text{I}$  and 125 Gy for  $^{103}\text{Pd}$ . The limits of dose to the urethra and the rectum are not firmly established but it is recommended that the length of urethra receiving more than 200% of the prescribed dose should be limited.

Once the seeds have been implanted it is not possible to alter the outcome for that particular implant, but it is useful to analyse the dose distribution and assess the quality of the implant. Post-implant dosimetry is therefore recommended (Nag et al. 2000a). This is usually done from transverse CT slices performed several weeks after the implant (to allow for stabilisation of the post-implant oedema). Orthogonal x-ray films were originally used for reconstruction. Rosenthal and Nath (1983) developed a method of reconstructing an implant from uncorrelated images and this method was further refined by van der Laarse and Batterman (1984), using the fact that the seeds should appear in the same order along the y-axis on all three films. Films are now mostly used as a check of the overall seed distribution. [Figure 54.20](#) shows typical images from ultrasound, x-ray and CT. Ash et al. (2000) recommend that the following dosimetric indexes should be reported:

- The value of the prescribed dose
- $D_{90}$ , the dose that covers 90% of the prostate volume (which should be at least equal to the prescribed dose)
- $V_{100}$ , the percentage of the prostate volume that has received the prescribed dose
- $V_{150}$ , the volume that receives 50% more than the prescribed dose

---

## 54.5 DOSIMETRY CONSIDERATIONS FOR BRACHYTHERAPY IN GENERAL

### 54.5.1 SEALED SOURCE DOSIMETRY

The dose calculation around a sealed source has become progressively more accurate and more complicated over the years. Originally, a source was considered as a single point source using the specific gamma-ray constant to relate the exposure rate of the source to the specified source activity or strength. The encapsulation and filtration of the source was ignored and the *apparent* source strength used to approximate the effects of filtration and self-absorption. Many

sources in brachytherapy are not actually point sources, but line sources and therefore the exposure rate at a distance from a line source can be calculated by integrating over the total source length. Filtration and self-absorption in the source then become much more significant and should be included in the dose model.

Various authors have attempted to calculate effective absorption coefficients and anisotropy factors required to model linear sources. Sievert (1932) published extensive tables of the integral for values of exposure round a line source and these have been compared with Monte Carlo evaluations by Williamson (1996) for iridium and other sources. Monte Carlo calculations can be used not only to model the source, but also to predict the effects of different tissues on the absorbed dose.

Other calculation methods required the application of a tissue correction factor, such as the polynomial expressions used by Meisberger et al. (1968), Van Kleffens and Star (1979), and Dale (1986). A good review and presentation of the theory of sealed source dosimetry is provided by both Godden (1988) and Williamson et al. (1995) (see [Chapter 53](#)). Much work still has to be done on calculation of dose in different tissues and the effect of air cavities. The increased use of CT scanning for brachytherapy patients will provide improved data.

#### 54.5.2 METHODS OF IMPLANT RECONSTRUCTION

Radiographic techniques are often used to define the spatial positions of the applicators and radioactive sources. The choice of reconstruction techniques is influenced by the availability of isocentric x-ray equipment, the complexity of the source arrangement and the site of the implant in relation to the patient anatomy.

Radiographs can be used to reconstruct three-dimensional models of the applicators and source positions, which in turn are used to produce multiplanar dose distributions.

1. Direct measurement can be used for single plane implants for superficial skin tumours, and when rigid plastic templates or jigs are used with rigid introducers in a standard pattern (e.g. breast implants.)
2. Orthogonal radiographs using views at right angles to each other, preferably parallel and perpendicular to the plane of the implant are the most commonly used method\*. A pair of orthogonal films share one common co-ordinate axis, so the  $x$  and  $y$  dimensions are obtained from one film and the other film gives the  $y$  and  $z$  dimensions<sup>†</sup>. The  $y$ -axis is therefore common to both films. A base line common to both films, which is often a line perpendicular to the intersection of the radiographs and is usually parallel to the edge of the films, must be defined. The magnification of films must be taken into account and there are various devices such as rulers or rings to assist in this calculation. Dummy marker wires can be positioned in plastic tubes and applicators to determine directly the length of active wire to be loaded. They can also be used to define the magnification at the plane of the implant or insertion.

For accurate results from this technique, the two films must be mutually perpendicular; the central ray should be perpendicular to the film and, as for the other methods, the patient must not move between exposures. It may also be necessary to correct for beam divergence.

3. An isocentric (variable angle) technique is useful for separating multiple sources (e.g. iodine seeds in a prostate, multiple catheters in a breast or head and neck implant) and for visualising sources where bone or other structures may obscure them, or where a good lateral film is not possible. A simulator should be used for this technique because the best plane can then be chosen whilst screening, so that all the sources or applicators are clearly visible and do not obscure one another. The highest accuracy with this method is when there is 90 degrees

\* If image planes parallel to the plane of the implant are not easily achieved it is easy to rotate the reconstructed planes within the computer to achieve a more appropriate display.

<sup>†</sup> This is in the co-ordinate system recommended by the International Electrotechnical Commission where  $y$  is the caudo-cranial direction (see [Section 11.5.4](#)).

between the two beams. It is sometimes useful to take three films to assist in source identification, though only two are used for the actual reconstruction process.

4. Semi-orthogonal methods have been developed using a proprietary reconstruction box with markers. They are particularly suited for mobile x-ray systems, which do not have accurate scales or movements. The x-ray beams are approximately AP (or PA) and lateral and the radiographic images of the cross-wire markers on the AP and lateral box faces are used to reconstruct the spatial localisation of the x-ray foci. This method accepts beams whose central axes do not intersect and are not perpendicular to one another, as long as the projections of the cross-wires on the two corresponding box faces are visible on the radiographs. A typical set-up with a localisation box is shown in Figure 54.21.
5. Stereo shift films, which involve taking two AP films at a measured distance between them with a common reference point projected onto both films, may be used for source localisation when there are many sources.
6. To take a tomographic section through the central plane of the implant, either with x-ray tomography or more commonly with CT, is a useful method that gives both the relationship between sources on the central axis and associated anatomical structures, e.g. breast (lung), tongue (spinal cord), intracavitary techniques (bladder and rectum). It is now possible to input source and applicator positions directly from a series of transverse CT scans.

It is easier and safer to perform any of these radiographic techniques whilst afterloading applicators are inactive. When entering source positions into computers it is important to have the orientation of the radiographs correct for the particular computer's dosimetry system and to identify each end of the active sources correctly, in addition to the applicator itself. Dummy sources, consisting of radioopaque markers, inserted precisely where the sources are expected to be, may be used to enable the source positions to be digitised. There are also several computer

**FIGURE 54.21**

(See colour insert following page 590.) X-ray unit and localisation box used to reconstruct the 3D coordinates of sources. With such a box, it is not necessary to have an accurate x-ray set-up since the radioopaque markers of the box can be used to restore an orthogonal coordinate system.

programs which will automatically place active sources in specified positions within applicators once the co-ordinates of the applicator have been defined, and will automatically determine the central dosimetry plane after the sources have been reconstructed from the films.

A tracking technique may be useful to reconstruct dummy source positions on two radiographs, if a correspondence can be established between the points belonging to the same catheter as seen separately on both radiographs and there are sufficient points to allow good reconstruction (Rosenwald 1975).

Some inherent limitations in reconstruction techniques, which lead to inaccuracies, are the accuracy with which the magnification is determined; the limitation of the calculational accuracy obtainable with the equations used for deriving source position and, in the absence of a localisation box, the fact that the radiation beam may not be perpendicular to the films. Greater accuracy can usually be achieved by using radiotherapy simulators for applicator or source visualization. Quality control of the reconstruction methods may be carried out using geometrical phantoms (Roué et al. 2006).

### 54.5.3 COMPUTERISED DOSIMETRY

Dose computation algorithms have evolved over the years to calculate dose distributions around sources in a variety of planes and orientations. Stovall and Shalek (1972) and Shalek and Stovall (1975) described a number of computer techniques available at that time. These have since been extended to include the calculation of source coordinates from radiographs, and the sorting of multiple seeds and wires, particularly useful for prostate implants. Faults in the dose rate formula, including errors in the constants used can also introduce errors into the dose computation, although errors in the source-positional data supplied to the computer program due to inaccurate data entry from the localisation films are usually more significant. Kline et al. (1985) reported a comparison of reference dose point data with dose calculations carried out using a Theraplan computer for iridium wire. This paper highlights some of these pitfalls of brachytherapy dosimetry.

Welsh et al. (1983) have reported that, with their computer dosimetry system, repetition of the dose distribution calculation for the same wire arrangement may show differences of as much as 5% in the doses at individual points although the average discrepancy is much less than this (<3%). The differences have been shown to be due to small variations in the digitised wire position data and the position of the calculation plane. Wire positions should therefore be entered carefully and a representative dose rate chosen for the prescription of the dose to reduce the errors to less than 3%. Rigorous quality assurance checks should be performed on the input and output devices of the treatment planning system, in addition to QA checks on the sources and applicators in an attempt to minimise these errors.

To verify computer calculations a database of individually measured data or appropriate published data must be available. For external-beam treatments, data are usually measured for the individual linear accelerator to be used. However, brachytherapy is different in that experimental determination of dose rates at short, clinically relevant distances around brachytherapy sources is extremely difficult and there can be large uncertainties in the measurements. Several phantoms have been developed to check consistency of dose distributions, but absolute dosimetry is more of a problem. Some errors in computer dosimetry have been found to be because of incorrect input parameters, particularly the use of the correct exposure-rate constant or unit of source strength. It is important to know what internal factors the computer uses, whether tissue correction algorithms are used, if nonlinear sources can be modeled, and if self-absorption in sources, applicators and cables is calculated. There are also many different units associated with brachytherapy and although every book on brachytherapy provides a conversion scheme (see [Section 53.5](#)), the use of the correct units for a particular treatment-planning computer can be crucial. For a particular brachytherapy computer planning system users are constrained by the

concepts in the software development as well as the validity of the calculation algorithms (IAEA 2004; ESTRO 2004). It is important to apply a source calibration methodology that is consistent with the assumptions made by the software designer. There are uncertainties in the value of the specific gamma rate constant but in some senses it is a *dummy variable* when source calibration is specified in terms of reference air kerma rate (see [Section 51.3](#)).

---

## 54.6 OPTIMISATION IN AFTERLOADING BRACHYTHERAPY

The objective of treatment planning for brachytherapy is to obtain an optimum dose distribution to deliver the desired target dose at the desired dose rate, whilst minimising the dose to surrounding normal tissue. In interstitial techniques, it is very rare to achieve an ideal implant, some method of optimisation that can be applied after the needles have been implied would therefore be beneficial.

History shows us that brachytherapy techniques have evolved around available radiation sources. Prominent examples are the Manchester system for radium-226 and the Paris system for iridium-192. We now have available the miniature stepping source and it is appropriate that a dosimetry system should evolve around this type of source.

Brachytherapy has always been a geometrically conformal therapy. The applicators placed within the treatment volume enable the delivery of a high dose of radiation to a small volume of tissue while sparing normal tissues. External-beam therapy in moving to conformal therapy uses imaging based treatment planning together with volume-dose analysis. Should brachytherapy be moving in this direction?

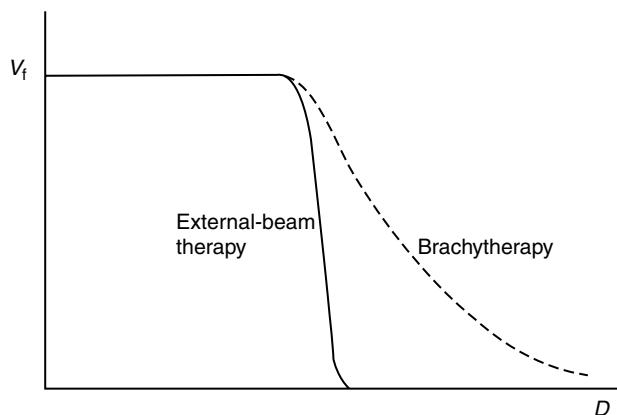

The established dosimetry systems have evolved empirically over a long period. Considerable clinical experience in their application has been accrued. Progress to new dosimetry systems should only proceed with care being taken in comparing the old with the new, using the computational tools currently available.

The miniature stepping sources can be used to mimic traditional source arrangements such as those of the Paris or Manchester systems or they can be used with variable dwell times in each position so producing *optimised* dose distributions. Implants can be optimised to produce as uniform a dose coverage as possible throughout the implanted volume or they can be optimised to encompass a volume outlined on a set of images. In the latter case the dose in the implanted volume may be very non-uniform.

### 54.6.1 IMAGE-BASED PLANNING

Conformal radiotherapy to the prostate can be delivered either by external-beam therapy or by means of a stepping source in implanted needles, as well as by a seed implant (see [Section 54.3](#)). CT can be used to define a target volume and any critical structures such as the rectum. Dose volume histograms (see [Section 35.3](#)) are easy to interpret for external-beam therapy ([Figure 54.22](#)). Deviation from the ideal, with all the target volume receiving the prescribed dose, is immediately apparent. In brachytherapy, the inevitable inverse-square falloff of dose around the sources results in an inherent inhomogeneity. This obscures regions of underdosage or overdosage, which may be present.

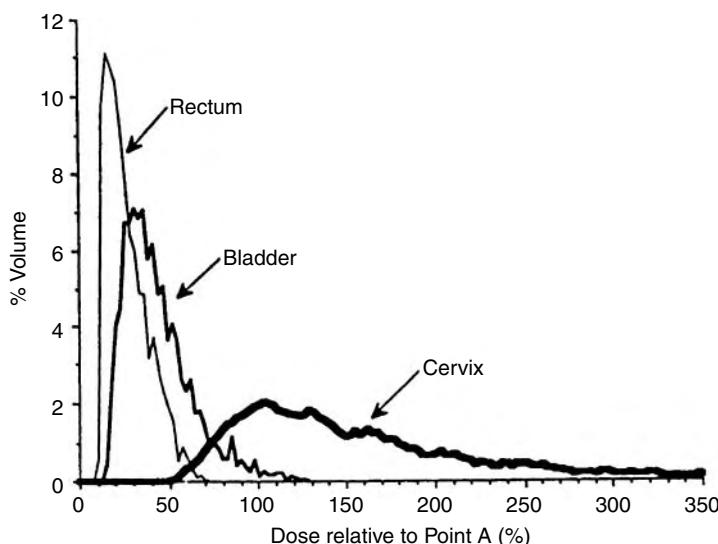

Clinical experience has demonstrated tolerance of significant high dose volumes within implants. The Paris system allows quite a range of needle separations resulting in significantly different high dose volumes (Pierquin et al. 1978). However, these treatments have involved conventional doses of radiation. As dose escalation is the aim of much conformal therapy the tolerance of significant high dose regions may be reduced and the greater uniformity produced

**FIGURE 54.22**  
Representative cumulative dose volume histogram.

by optimised plans may be required. The presence of low dose regions within the target volume is undesirable as it could result in local recurrence. It is clear that dose volume analysis of a more sophisticated nature needs to be applied in considering the brachytherapy target volume.

The issues relating to dose to critical structures in brachytherapy are similar to those in external-beam therapy. In gynaecological brachytherapy, for example, the dose is limited by rectum, bladder and bowel tolerance. Indeed the widely used Manchester point A for dose prescriptions is intended to limit the dose to a normal tissue tolerance point (Paterson and Parker 1967). Most gynaecological applications use standard source loading patterns, planning being performed to determine critical organ doses usually by means of ICRU reference point doses (ICRU 1985) (Figure 54.16). However, more recent image based planning has demonstrated how unrepresentative these points can be of whole organ doses and dose volume analysis could play a useful role (Figure 54.23).

**FIGURE 54.23**  
Representative dose volume histogram.

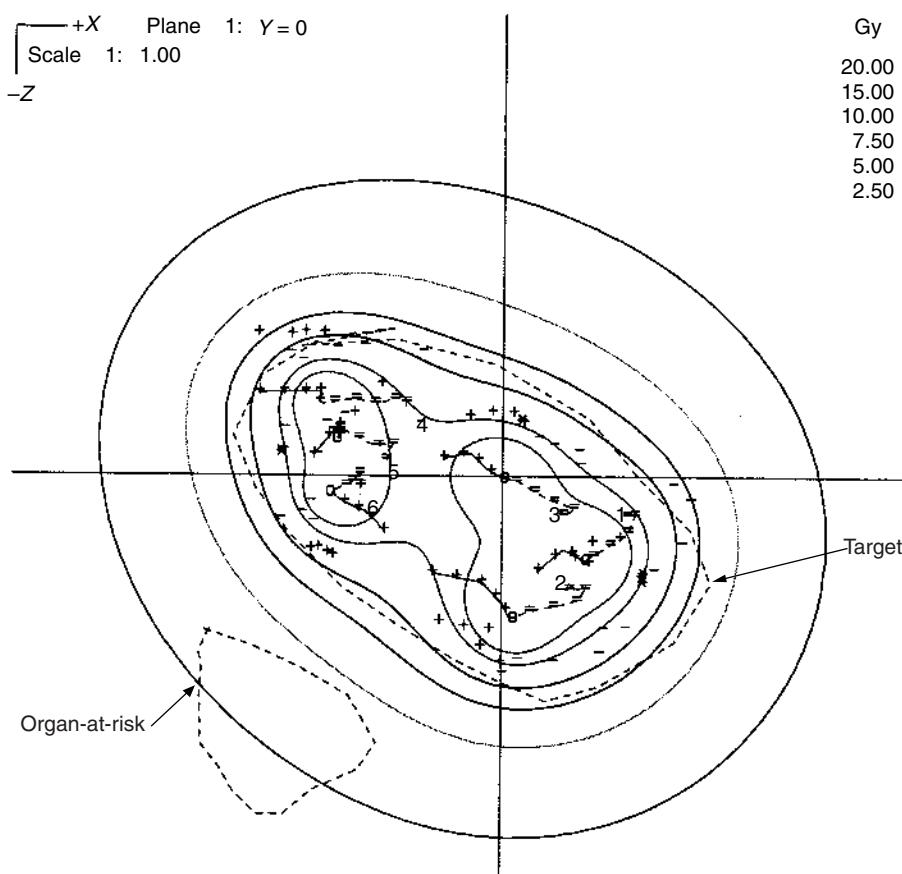

### 54.6.2 APPROACHES TO OPTIMISATION IN BRACHYTHERAPY

Brachytherapy is an inherently conformal therapy due to the applicators being positioned within the treatment volume. This geometric conformality can be improved upon to produce a conformal dose distribution by optimisation of the source dwell positions and times.

The miniature stepping sources employed in modern afterloaders contain iridium-192 in a stainless steel capsule of about 1 mm diameter, the active source length being between 3 mm and 5 mm. The afterloader enables this single source to be stepped through the implanted catheters stopping at programmed positions for variable *dwell* times. Dwell positions have largely been predetermined by applicator placement, so dose optimisation involves varying the dwell times in each position. Optimisation can be performed to produce as uniform a dose as possible in dose points, which may be distributed throughout a volume or across a surface.

### 54.6.3 SURFACE OPTIMISATION

Surface optimisation can be used when an outline of the target volume is available, dose points can then be placed across the surface of the volume. This technique is not directly comparable with any existing dosimetry system.

**FIGURE 54.24**  
The inappropriate use of surface optimisation.

The type of situation where this technique has been employed is in the treatment of small solitary brain lesions. A limited number of catheters are implanted under image guidance. The surface of the treatment volume is defined by a number of points and the dwell times within the catheters optimised to give as uniform a dose as possible to these points and within the volume defined. This method must be applied with caution because depending on the distance from the catheters to the volume surface, some very high-dose regions can exist within the volume. [Figure 54.24](#) demonstrates the inappropriate use of this type of optimisation in an implant to the rectum containing insufficient catheters to encompass the target volume. The dose distribution has been *optimised* to deliver the prescribed dose to the surface of the outlined target volume. This has resulted in massive regions of over dosage within the target volume.

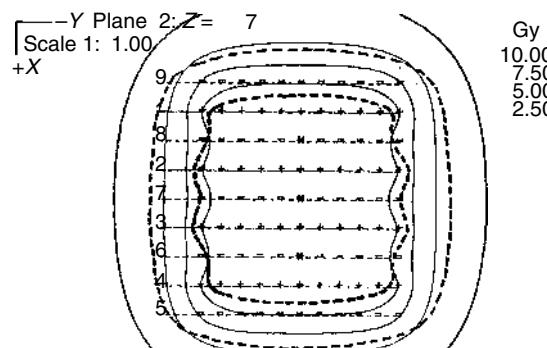

#### 54.6.4 VOLUME OPTIMISATION

If one considers a regular interstitial implant using the Paris system, the basal dose points are in the mid transverse plane only. Consider these points extended throughout the length of the treatment volume with optimisation of dwell times to deliver as uniform a dose as possible to these points. Mathematically this can be treated in the same way as the previous surface point example but the results will be amenable to comparison with the previously used Paris system.

An alternative volume optimisation technique involves using the other dwell positions within the catheters as dose points and optimising dwell times to produce as even a dose as possible within them (Edmundson 1990, 1991). This is a particularly useful technique in situations involving curved flexible catheters where the placement of suitable dose points can be difficult to perform.

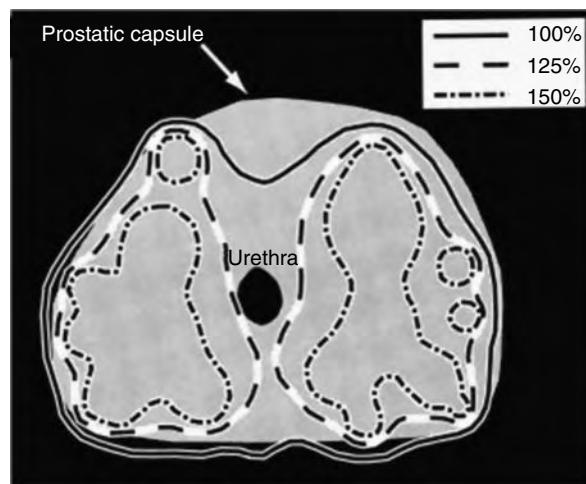

[Figure 54.25](#) compares a Paris-type distribution with an optimised distribution. The solid lines are for the optimised plan using an active source length of 50 mm, the dotted lines are the Paris distribution using an active source length of 60 mm.

One of the main advantages of the optimised distribution lies in not having any active source positions outside the target volume. Care needs to be taken in changing systems, as the distributions are also different in the transverse planes (Van der Laarse 1994). The increased weighting of outer catheters relative to inner catheters in optimised plans results in extended coverage by the reference isodose in the transverse directions. These optimised plans are essentially direct descendants of the Manchester interstitial system, which used more radium around the periphery than in the centre of the implant. They have the added advantage of being applicable in situations where the geometry of the implant deviates from the regular ideal.

**FIGURE 54.25**

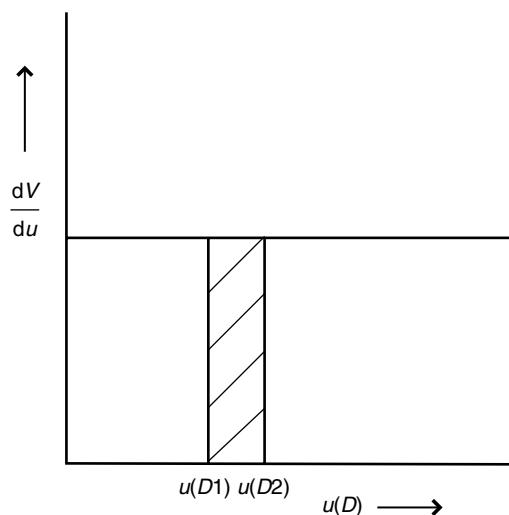

Comparison of Paris system based plan and an optimised plan. The Paris system distribution is represented by dotted lines and uses sources with 60 mm active length, whereas the active length required for the optimised plan is only 50 mm.

**FIGURE 54.26**

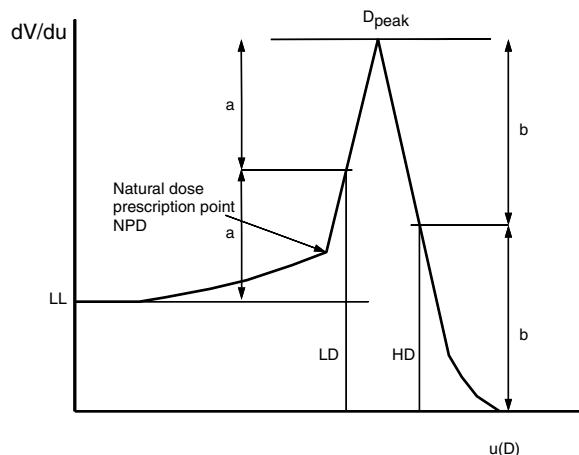

Typical isodose pattern in a plane through the middle of an HDR prostate implant. (From Mate, T. P., Gottesman, J. E., Hatton, J., Gribble, M., and Van Hollebeke, L., High dose-rate afterloading  $^{192}\text{Ir}$ idium prostate brachytherapy: Feasibility report, *Int. J. Radiat. Oncol. Biol. Phys.*, 41, 525–533, 1998.)

The ideal planning situation involves conforming the dose distribution to a target outlined on an image utilising the available optimisation techniques. HDR interstitial implants to the prostate are prime examples (Mate et al. 1998). The treatment catheters are inserted under ultrasound guidance and the planning is performed on these images or on post implant CT scans. The planning aims to deliver a higher dose to the periphery of the gland than to the urethra. Optimisation is used to obtain the best conformation. Figure 54.26 shows a typical mid gland dose distribution.

Optimisation cannot make a technically poor implant good but it can reduce the incidence of too hot or too cold regions within the treatment volume.

**FIGURE 54.27**

Natural dose volume histogram for a point source. The shaded area represents the volume receiving a dose larger than  $D_1$  and smaller than  $D_2$ .  $u(D)$  is defined in Equation 54.1.

**FIGURE 54.28**

Idealised natural dose volume histogram for a multi-source implant. LL (lower limit) represents the value of  $dV/dU$  at a distance from the sources large enough for them to be treated as a single point source. The natural dose prescription point is at the low dose base of the peak and represents the edge of the high dose volume. HD (high dose) and LD (low dose) represent the doses at half the maximum on the high dose and low dose sides of the peak respectively\*.

#### 54.6.5 DOSE VOLUME ANALYSIS

The rapid drop in dose rate around sources (due to the inverse-square law) renders integral dose volume histograms of little value in evaluating the dose distribution within the target volume, although they are important to show whether parts of the target will be underdosed. The presence of hot or cold regions that may be of clinical significance are masked by the inherent inhomogeneity. The use of differential histograms can reduce this problem. The process can be taken further in using *natural dose volume histograms* (Anderson 1986).

The dose distribution around a point source is a series of concentric spheres of equal dose rate varying as the inverse square of the radius. The volume receiving more than a specified dose  $D$  is then proportional to the square root of  $D$  raised to the power of 3. Anderson introduced a new variable,  $u(D)$ , to be used as a replacement for  $D$  on the DVH abscissa axis and defined as:

$$u(D) = D_b^{-3/2} - D^{-3/2} \quad (54.1)$$

where  $D$  can be either dose or dose rate and  $D_b$  is the minimum dose that is of interest. The value chosen for  $D_b$  is not critical. If a dose volume histogram is created using  $u$  by plotting the volume element that receives  $u(D)$  against  $u(D)$ , the differential histogram for a point source will be a horizontal line as shown in Figure 54.27.

Since the point source inverse square distance variation reflects the largest gradients encountered in an implant and is represented as a horizontal line in Figure 54.2, when there are multiple sources there will be areas of uniform dose and these will give rise to a peak in the natural dose volume histogram (as can be seen in Figure 54.31). Figure 54.28 is an idealised representation of this. Outside the implanted volume  $dV/dU$  will decrease slowly until it eventually reaches a constant value equal to  $\frac{4}{3}\pi D_{1\text{cm}}^{3/2}$ , where  $D_{1\text{cm}}$  is the dose, in cGy, at 1 cm if all the activity in the implant were concentrated at a point—calculated using Equation 54.1. Close to the wires the dose rate will be quite large but  $dV/dU$  will tend towards 0.

\* Some authors (e.g. Moerland et al. 2000) derive LD from half the peak in the same way as HD, but this gives an unnecessarily pessimistic view of the implant and is not what Anderson intended.

The histogram provides an immediate visual assessment of a treatment plan. A plan with regular applicator geometry and even dose coverage is characterised by a high narrow peak. Greater inhomogeneity is represented by a broader, shallower peak.

Anderson defined a low dose point, LD, and a high dose point, HD, determined as shown in Figure 54.28. The peak of the distribution corresponds approximately to the basal dose (see Section 54.1.2.5) of the Paris system (Langmack and Thomas 1995). The difference between LD and HD, and between HD and  $D_{peak}$ , relative to the prescribed dose provide an indication of the uniformity of the implant.

Three approaches to dose prescription using natural dose volume histograms are possible:

- The prescription dose, PD, can be derived from the histogram as the point at which the curve flattens out (NPD in Figure 54.28).
- The prescription dose, PD, can be defined as the minimum dose in the target volume and can then be compared to the value NPD.
- The prescription dose, PD, can be taken as  $0.85 D_{peak}$ .

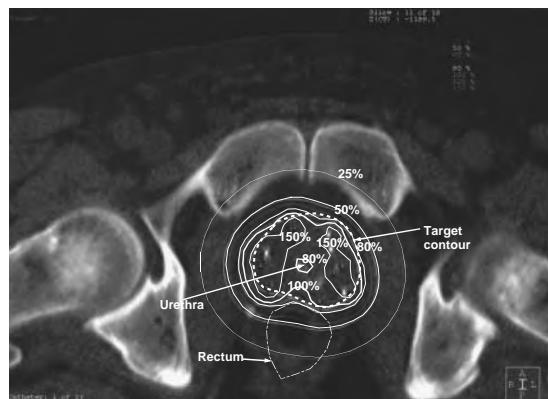

Anderson also described a uniformity index where:

$$U = \frac{V_{(PD \text{ to } HD)} / (u(PD) - u(HD))}{V_{(\text{above } PD)} / (u(PD) - u(\infty))} \quad (54.2)$$

Thomadsen et al. (1994) modified this to provide a quality index which is independent of the prescription dose as follows:

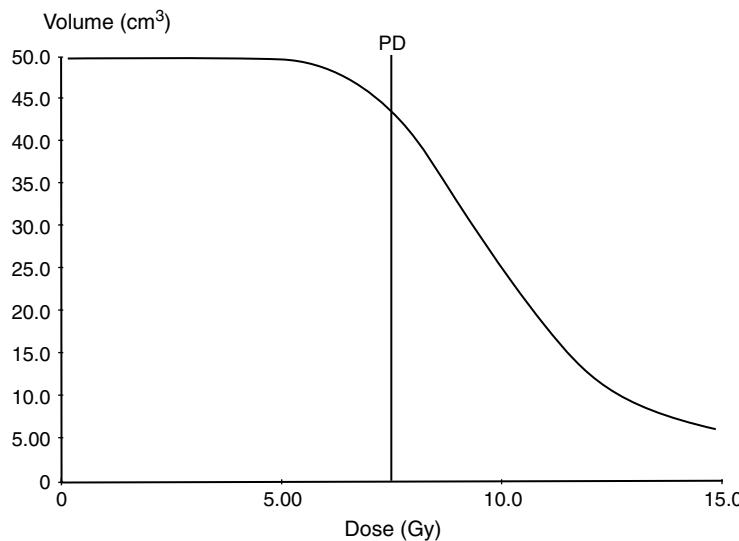

$$U = \frac{V_{(LD \text{ to } HD)} / (u(LD) - u(HD))}{V_{(\text{above } LD)} / (u(LD) - u(\infty))} \quad (54.3)$$

To illustrate the application of this concept in practice, a seventeen catheter prostate implant is considered. The implant is shown in Figure 54.29. Geometrical optimisation was used to achieve the dose prescribed at dose points placed around the surface of the target volume (indicated by the dotted line on the dose distribution.) The cumulative histogram

**FIGURE 54.29**

(See colour insert following page 590.) Seventeen-catheter prostate implant. The intended target volume is shown dotted and the thick line represents the prescription 100% isodose line. Note the sparing of the urethra in the centre of the prostate which is only given 80% of the dose.

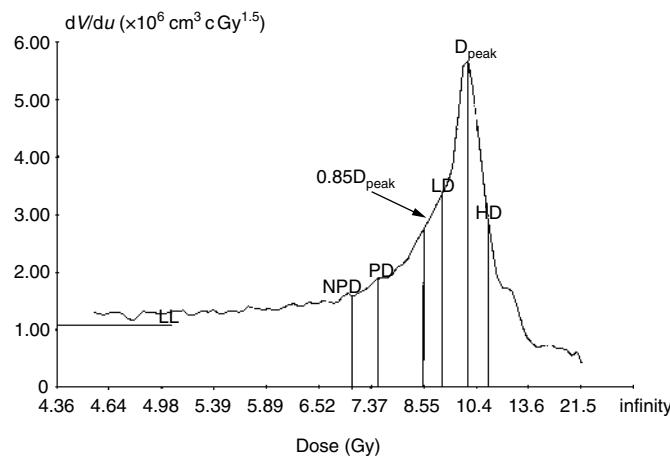

**FIGURE 54.30**

Cumulative histogram for the implant in Figure 54.29. PD is the prescription dose (100% on Figure 54.29).

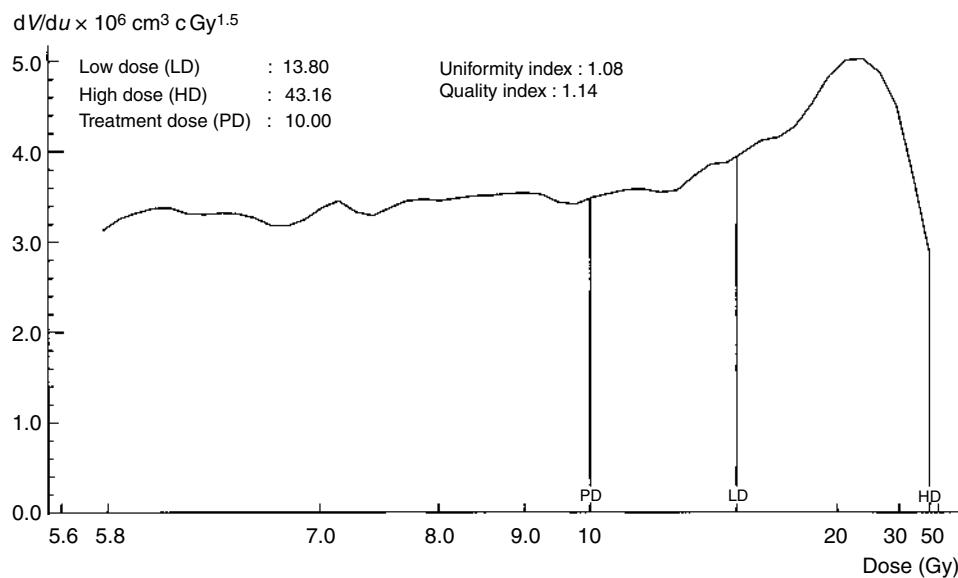

for the target (Figure 54.30) shows whether the target was encompassed by the chosen dose rate. The marker PD in Figure 54.30 indicates the position of the prescription dose.

The natural dose volume histogram (Figure 54.31) shows the prescription dose compared to 0.85 D<sub>peak</sub> and the NPD at the inflection of the curve. It will be seen that the prescribed dose, PD, derived from the mean of the dose points is above the NPD but below 0.85 D<sub>peak</sub>. This is because of the deliberate sparing of the urethra. One measure of the quality of the implant is the natural dose ratio (NDR) which is the ratio NPD/PD. If NDR > 1 it implies that the implant is overdosed, whereas if NDR < 1, as here, it implies that a lower prescription isodose could be chosen.

As an illustration of how natural dose volume histograms can demonstrate a poor quality implant, Figure 54.32 shows the histogram for the inadequate rectal implant which was shown

**FIGURE 54.31**

Natural dose volume histogram for the implant in Figure 54.29. D<sub>peak</sub> is the dose corresponding to the peak of the histogram. PD is the prescription dose based on the mean of the dose points. NPD is the natural prescription dose. LL, LD and HD are as defined in Figure 54.28. Note that the prescription based on 85% of D<sub>peak</sub> gives a higher dose.

**FIGURE 54.32**

Natural dose volume histogram for the unsatisfactory implant of [Figure 54.25](#). PD is the prescription dose, and LD and HD are as defined in [Figure 54.28](#). The quality index is defined in Equation 54.3 and the uniformity index in Equation 54.2.

in [Figure 54.25](#). The broad shallow peak demonstrates the dose inhomogeneity within the target volume. The peak dose occurs at a dose of greater than twice the prescription dose, which is indicated as PD on the histogram. The quality and uniformity indices are both low.

Geometrically conformal brachytherapy can be made dose conformal using optimisation techniques with or without image-based planning. Dose volume analysis enables detailed comparisons to be made between old and new techniques. It can also give detailed critical organ dose information rather than using doses to fixed reference points.

To use new techniques to the full extent, one needs to have a treatment volume defined. This is not always the case in brachytherapy but the increasing availability of CT and MRI should make it more common practice in the future (Nag et al. 2004; Haie-Meder et al. 2005; Pötter et al. 2006).

## 55.1 INTRODUCTION

The underlying radiobiology of brachytherapy is essentially the same as that for external-beam radiotherapy and this chapter should, therefore, be read in conjunction with Part B. For brachytherapy in particular, the all-pervasive nature of the inverse-square law means that there is a complex interplay between the physical and radiobiological aspects. This interplay influences the way in which brachytherapy treatments should be evaluated, both in absolute and comparative terms. In planning any brachytherapy procedure it is probably true to say that attention to physics should always take precedence over attention to radiobiology, because the radiobiological considerations are of little value when applied to treatments with poor source geometry or that are misplaced.

This section covers some aspects of this physics/radiobiology interaction. As the linear-quadratic (LQ) dose-effect model continues to be the standard method of evaluating radiobiological effects, it will be used here. There remain a number of improperly understood factors in radiobiology and quantitative radiobiological assessments, which although useful, should be used with a modicum of caution. They should be used to help inform the clinical decision-making process, never to override it.

---

## 55.2 $\alpha/\beta$ RATIOS

For any type of radiotherapy, one of the principal determinants of biological effect is the  $\alpha/\beta$  ratio. Despite being sometimes referred to as *fractionation factors*,  $\alpha/\beta$  ratios provide an indication of the sensitivity of a given tumour or organ to changes in dose-rate, as well as to changes in dose per fraction.  $\alpha$  (in units of  $\text{Gy}^{-1}$ ) and  $\beta$  (in units of  $\text{Gy}^{-2}$ ) are the two radiosensitivity coefficients used in the LQ model and are respective measures of the initial slope and degree of downward curvature (*bendiness*) of the underlying cell-survival curve. The  $\alpha/\beta$  value (in units of Gy) is generally higher for tumours (typical range 5–25 Gy) than for late-responding normal tissues (typical range 1–5 Gy). An important exception to this generalisation about the tumour values is prostate adenocarcinoma, for which the  $\alpha/\beta$  ratio may be as low as around 1 Gy (Bentzen and Ritter 2005).

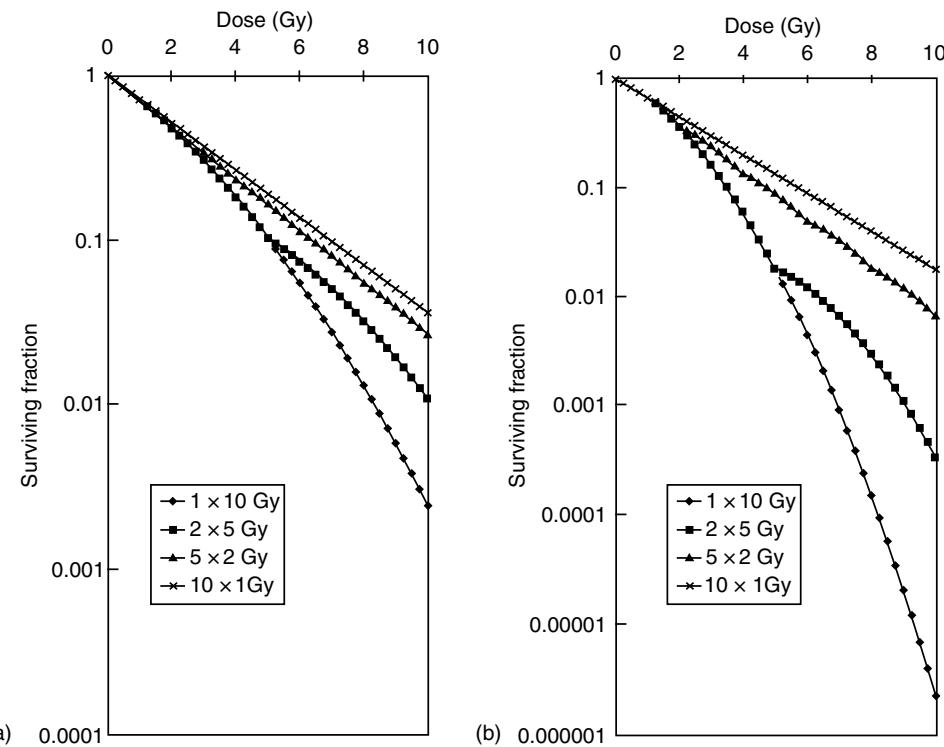

Tissues with lower values of  $\alpha/\beta$  are said to have more sparing capacity than tissues with higher values. This means that the reduction in cell kill, brought about by a reduction in dose per fraction or dose rate, will be relatively greater in low  $\alpha/\beta$  tissues. Therefore, compared to tumours, late-responding normal tissues would be preferentially spared in treatments involving small fraction sizes or low dose rates.

The principle involved is demonstrated in Figure 55.1 and Figure 55.2. It will be seen that the sparing effect resulting from lowering of dose rate exhibits itself as a *straightening out* of the cell-survival curves. It is thus analogous to the sparing effect associated with the use of multiple small-dose fractions. Excellent clinical results have often been claimed for traditional continuous-low-dose-rate (CLDR) treatments, delivered over periods of several days, and it is clear from the graphs that CLDR essentially emulates what might be expected of a hyperfractionated treatment. In both cases a relatively higher degree of radiobiological sparing is likely in the tissues with low  $\alpha/\beta$  values. However, in most CLDR implants the sources are arranged within the tumour, where the dose and dose rate are maximised. Adjacent normal structures usually receive a lower dose, delivered at a lower dose rate. This is a physical characteristic of brachytherapy which may also explain the good clinical results attributed to CLDR.

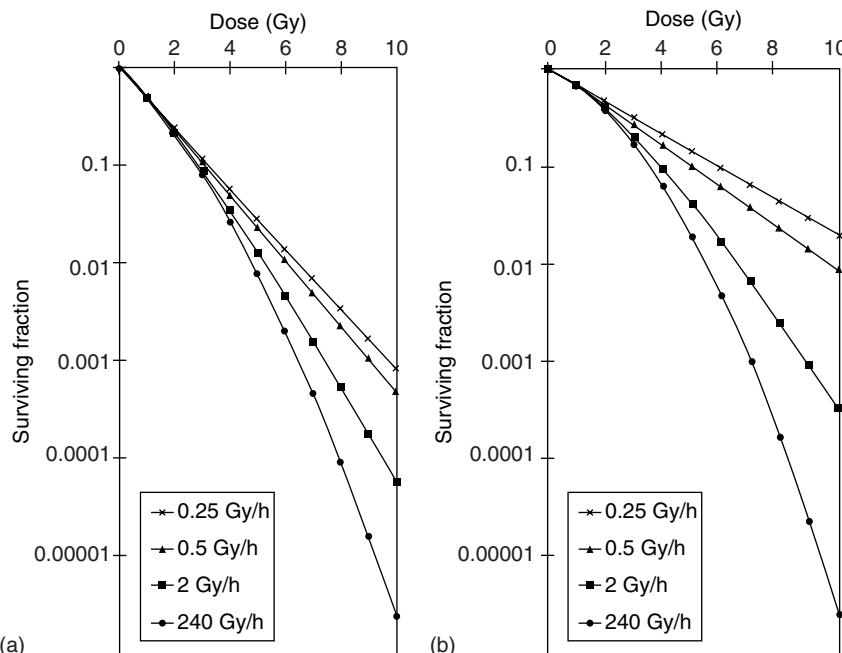

---

## 55.3 REPAIR RATES ( $\mu$ VALUES)

Sub-lethal DNA damage in cells may repair if allowed sufficient time. If further damage accrues before the earlier damage has repaired, then the sub-lethal damage becomes lethal.

**FIGURE 55.1**  
Effect of fractionation (a) on tumour (b) on late-responding normal tissue.

**FIGURE 55.2**  
Effect of changing dose rate (a) on tumour (b) on normal tissue.

Although this is a simplistic explanation of the repair process, it can help in the understanding of several facets of clinical radiotherapy.

Average repair half-times for mammalian tissues are usually approximately 0.5–3 h, with increasing evidence that tumour repair half-lives are probably shorter than those for late-responding normal tissues. If the repair process is assumed to be mono-exponential, then the repair rate ( $\mu$ ) is related to the repair half-time ( $T_{1/2}$ ) by:

$$\mu = \frac{\ln 2}{T_{1/2}}$$

In conventional external-beam radiotherapy, the sub-lethal damage remaining after each fraction is essentially fully repaired by the time of delivery of the next fraction. In CLDR treatments, the repair mechanism works in competition with the induction of further damage caused by the ongoing irradiation.

## 55.4 THE CONCEPT OF BIOLOGICAL DOSE

*Biological dose* is specified within the LQ model in terms of the biologically effective dose (BED). The unit of measure of BED, as for physical dose, is the Gray (Gy). In any particular irradiated tissue, BED is related to the logarithm of the surviving fraction of cells. Irrespective of the type of radiotherapy involved, BED is always calculated from the total physical dose (TD) in the following way:

$$\text{Biologically Effective Dose (BED)} = \text{Total Physical Dose (TD)} \times \text{Relative Effectiveness (RE)}$$

$$\text{i.e. } \text{BED (in Gy)} = \text{TD (in Gy)} \times \text{RE (dimensionless)}$$

BED is used for inter-comparing the biological effects of various radiotherapy schedules. It is also useful in the inter-comparison of different types of radiotherapy. BED can be thought of as the notional physical dose that could be delivered if the radiation were administered in a very large number of tiny fractions, although this is not a perfect definition.

The RE factor takes account of the other physical details of the treatment (e.g. dose per fraction, dose rate, etc.), together with the radiobiological factors ( $\alpha/\beta$ ,  $\mu$ , etc.) associated with the irradiated tissue or organ. Because the radiobiological factors are tissue-specific, it is usually the case that two adjacent tissues, each receiving the same total dose, dose per fraction, dose rate, etc., will be associated with different BEDs.

If the normal-tissue  $\alpha/\beta$  value is less than that for the tumour then, provided the two tissues each receive the same dose and pattern of irradiation (i.e. dose rate and/or number of fractions), the normal-tissue BED will always exceed that for the tumour. This does not mean that the normal tissue is receiving a higher biological dose, it simply reflects what was discussed earlier, i.e. that there is greater potential to bring about preferential damage sparing in the normal tissue if the fractional dose (or dose rate) is reduced. The numerical difference between the BED and the physical dose is a measure of the potential capacity of a tissue to be spared radiation damage.

It is common to write both the BED symbol and its numerical value with a suffix indicating which value of  $\alpha/\beta$  is being used in the calculation, i.e.  $\text{BED}_3$ ,  $\text{BED}_{10}$ , 100 Gy<sub>3</sub>, 72 Gy<sub>10</sub>, etc.

### 55.4.1 EFFECT OF CELLULAR REPOPULATION ON BIOLOGICAL DOSE

Irrespective of the physical dose delivered, if the cells in an irradiated tissue repopulate during a course of treatment then the resultant biological dose to that tissue is less than it would

be if no repopulation occurred. This is because some of the delivered dose will be *wasted* in combating the cellular repopulation that occurs during treatment, with the result that fewer cells are killed. The incorporation of the repopulation effect in BED equations is achieved through the use of a subtractive repopulation factor (RF) that takes account of the treatment time and the repopulation rate, i.e.:

$$\text{BED} = \text{TD} \times \text{RE} - \text{RF}$$

Repopulation is a significant phenomenon in many tumour types and is particularly important when treatment times are protracted. Repopulation is related to the overall treatment time ( $T$  days) via the relationship:

$$\text{RF} = kT$$

The parameter  $k$  may be thought of as the amount of biological dose which is *used up* each day in sterilising the new cells born that day. It is the hypothetical daily BED that must be delivered simply to stop the tumour growing further during treatment. For some squamous cell carcinomas  $k$  may be in excess of  $0.9 \text{ Gy day}^{-1}$ , but it is still not clear if  $k$  retains a fixed value throughout treatment or whether it is small at the beginning and increases after a lag time. For head and neck cancers the lag time may be of the order of 28 days, but there are few data available for other tumour sites (Roberts and Hendry 1993; Dale et al. 2002). If  $k$  does change during treatment, then an average value should be used in the RF, or an explicit allowance for the lag time prior to the onset of fast repopulation should be made.

#### 55.4.2 FRACTIONATED HIGH DOSE-RATE (FHDR) BRACHYTHERAPY

For any fractionated treatment (teletherapy or brachytherapy) for which each fractional dose is given in a short period of time the relative effectiveness factor to use is:

$$\text{RE} = 1 + \frac{d}{\alpha/\beta}$$

where  $d$  is the dose per fraction. Hence, because  $\text{BED} = (\text{TD} \times \text{RE}) - \text{RF}$ , then:

$$\text{BED} = Nd \left[ 1 + \frac{d}{(\alpha/\beta)} \right] - kT \quad (55.1)$$

where  $N$  is the number of fractions.

Equation 55.1 is valid only if the fractions are sufficiently well-spaced (usually a minimum of 6 h) to allow complete recovery of sub-lethal damage between successive fractions.

#### 55.4.3 DOSE-RATE EFFECTS

For the delivery of any given physical dose, reducing the dose rate means that treatment time is proportionately extended. As treatment time becomes longer there is more time available for intra-cellular repair to occur. This phenomenon will reduce the biological effectiveness of the delivered dose and, for any given physical dose, BED is less than it would have been for a shorter exposure time. Hence the key characteristic of the dose-rate effect (a reduction in radiation effect as the dose rate is lowered) essentially results from more time being available for sub-lethal damage repair, rather than the reduced dose rate per se.

In addition to intra-cellular repair, the phenomena of cell-cycle progression and repopulation are also dose-rate related. The approximate time scales over which the principal effects operate are as follows:

1. Intra-cellular repair: from minutes to hours.
2. Cell cycle progression: tens or hundreds of hours.
3. Repopulation: days or weeks.

In terms of their quantitative impact, effects 1 and 3 are reasonably well understood and are probably the most important. Repopulation can occur in any treatment, but is likely to be more significant in fractionated high dose-rate (FHDR) treatments, as they will usually be of longer duration than CLDR treatments.

Cell-cycle progression can lead to an inverse dose-rate effect, whereby radiosensitivity increases, rather than decreases, as dose rate is reduced. Although the effect has been observed *in vitro*, its influence in clinical practice is not known with certainty. For CLDR brachytherapy, its impact is likely to be small on account of the inevitable dose-rate inhomogeneities that exist.

#### 55.4.4 CONTINUOUS LOW DOSE-RATE (CLDR) BRACHYTHERAPY

For continuous brachytherapy treatments lasting up to a few days, the repopulation effect is thus usually negligible and may be omitted. Thus,  $BED = TD \times RE$ .

Because:

$$RE = 1 + \frac{2R}{\mu(\alpha/\beta)}$$

then:

$$BED = RT \left[ 1 + \frac{2R}{\mu(\alpha/\beta)} \right] \quad (55.2)$$

where  $R$  is the dose rate ( $\text{Gy h}^{-1}$ ),  $T$  (h) is the treatment time and  $\mu$  ( $\text{h}^{-1}$ ) is the time constant for exponential repair. Equation 55.2 is a simplified form of a more complex expression, but may be used when  $T$  is more than about twelve hours (Dale 1985; Thames 1985).

Equation 55.2 assumes that the intra-cellular repair follows a mono-exponential pattern. There is evidence to suggest that several repair components may exist in some tissue types. If there are  $m$  exponential repair components, each with repair constant  $\mu_i$  and fractional presence  $a_i$  such that:

$$\sum_i^m a_i = 1$$

then Equation 55.2 is better written as:

$$BED = RT \left[ 1 + \frac{2R}{(\alpha/\beta)} \sum_{i=1}^m \left( \frac{a_i}{\mu_i} \right) \right] \quad (55.3)$$

If the treatment is delivered via a permanent implant, the BED is given as:

$$BED = \frac{R_0}{\lambda} \left[ 1 + \frac{R_0}{(\mu + \lambda)(\alpha/\beta)} \right] \quad (55.4)$$

where  $R_0$  is the initial dose rate ( $\text{Gy h}^{-1}$ ) and  $\lambda$  is the radioactive decay constant ( $\text{h}^{-1}$ ).

## 55.5 THE CONCEPT OF EQUIVALENCE

A particular type of treatment (Treatment A) will be associated with a particular pattern of biological effects in the tumour and critical normal tissues. If an alternative treatment (Treatment B) is given and produces exactly the same pattern of biological effects, then the two treatments can be said to be *equivalent*. Equivalence does not mean that both treatments produce the same amount of biological damage in all the irradiated structures; rather it means that Treatments A and B produce the same differential pattern of damage.

In reality, it is almost impossible to attain true equivalence between alternative treatments. It is possible to arrange for treatments A and B to produce a similar effect on the tumour (tumour-control rate unchanged) or a similar normal-tissue response (complication-rate unchanged), but rarely both. Generally two or more treatments can be designed to be equivalent only for one specific biological end-point. A more balanced assessment of the relative merits of alternative treatments can only be achieved by separately considering the radiobiological consequences for each critical structure, e.g. by using BED values to review the likely changes to the therapeutic index.

Considerations about equivalence typically arise when seeking to replace an existing treatment (CLDR, say) with a newer alternative. In some of the older literature the concept of equivalence between treatments was used fairly loosely and the potential shortcomings of the idea need to be appreciated.

## 55.6 INTERCOMPARISONS BETWEEN CLDR AND FHDR

The use of CLDR has been superseded in many Centres by FHDR brachytherapy. Modern high-dose-rate (HDR) afterloading systems offer the ability to treat patients in fully protected rooms, using fractions of short duration. However, practical FHDR treatment is only possible if the number of fractions is kept relatively small, which often necessitates a relatively large dose-per-fraction.

As conventional radiobiological wisdom indicates that large fractional doses are best avoided, does this mean that FHDR brachytherapy with small fraction numbers is an unsafe option?

The answer to this is that physical-dose gradients may sometimes work in the patient's favour, as the following examples demonstrate.

### *Example 1*

A CLDR treatment involves delivering 60 Gy in 144 h. What total dose is required using six FHDR fractions to obtain a similar biological effect on the tumour? (Use generic  $\alpha/\beta$  values of 10 Gy and 3 Gy, respectively for tumour and late-responding normal tissue, and  $\mu=0.5 \text{ h}^{-1}$  for both tissues. Neglect any repopulation effects.)

For the CLDR, dose-rate ( $R$ ) is  $60/144=0.417 \text{ Gy h}^{-1}$ . From Equation 55.2:

$$\text{BED}_{10} = 60 \left[ 1 + \frac{2 \times 0.417}{0.5 \times 10} \right] = 70.0 \text{ Gy}_{10}$$

$$\text{BED}_3 = 60 \times \left[ 1 + \frac{2 \times 0.417}{0.5 \times 3} \right] = 93.4 \text{ Gy}_3$$

The six-fraction FHDR treatment that delivers the same tumour effect must achieve this

same  $\text{BED}_{10}$  value, i.e.:

$$6d \left[ 1 + \frac{d}{10} \right] = 70.0 \text{ Gy}_{10}$$

leading to  $d=6.91$  Gy, i.e. a total FHDR physical dose of  $6 \times 6.91 = 41.46$  Gy.

For such a treatment, the  $\text{BED}_3$  value will be given by:

$$\text{BED}_3 = 41.46 \left[ 1 + \frac{6.91}{3} \right] = 137.0 \text{ Gy}_3$$

i.e. relative to the original CLDR treatment the critical late-responding normal tissues appear to be significantly overdosed (47% increase in  $\text{BED}_3$ ) by this FHDR regime. This indeed suggests that attempting to treat in a small number of fractions, with correspondingly large dose per fraction, is a bad option.

Suppose, however, that it is possible to position the FHDR applicators such that a physical sparing of 0.8 is afforded to the critical normal tissues, i.e. the dose per fraction to such structures is reduced by 20%. The sparing factor of 0.8 operates on both dose per fraction and total dose, therefore the net  $\text{BED}_3$  given is:

$$\text{BED}_3 = 41.46 \times 0.8 \times \left[ 1 + \frac{0.8 \times 6.91}{3} \right] = 94.3 \text{ Gy}_3$$

This  $\text{BED}_3$  value is only 1% higher than that associated with the original FHDR treatment. Thus, a modest degree of extra geometrical sparing (a physical effect) with FHDR has offset a potentially dangerous biological disadvantage.

Geometrical sparing of normal structures is usually more easily achieved in gynaecological than in other applications.

#### *Example 2*

A CLDR treatment involves delivering 60 Gy in 144 h. What TD is required using a permanent implant of  $^{103}\text{Pd}$  (half-life of 17 days) to obtain a similar biological effect?

$$\text{Radioactive decay constant } (\lambda) = 0.693/17 = 0.04076 \text{ day}^{-1} = 1.66 \times 10^{-3} \text{ h}^{-1}$$

To find the required physical dose it is necessary to use Equation 55.4 to determine  $R_0$ , the initial dose rate that will give the required  $\text{BED}_{10}$  value which, from Example 1, is 70.0 Gy<sub>10</sub>.

$$\frac{R_0}{1.699 \times 10^{-3}} \left[ 1 + \frac{R_0}{(0.5 + 0.001699) \times 10} \right] = 70.0$$

leading to  $R_0=0.1162$  Gy h<sup>-1</sup> and, hence, a total dose ( $R_0/\lambda$ ) of 68.4 Gy (using the mean life as in Section 2.2.3.2.2).

For adjacent late-responding normal structures receiving this same dose (and dose rate), the associated  $\text{BED}_3$  is:

$$\text{BED}_3 = 68.4 \times \left[ 1 + \frac{0.1162}{(0.5 + 0.001699) \times 3} \right] = 73.7 \text{ Gy}_3$$

Thus, the  $^{103}\text{Pd}$  implant can achieve a better therapeutic index (same  $\text{BED}_{10}$ , lower  $\text{BED}_3$ ) than the original CLDR treatment without any physical sparing of the normal tissues. This is because, despite the requirement for a higher physical dose, the palladium delivers that dose

over a longer period than the 6 days of the CLDR treatment, thus providing greater opportunity for normal-tissue sparing.

These calculations ignore the RF factor. When radionuclides of very long half-life are used, tumour repopulation can become a significant factor and may diminish the potential benefits (Dale 1989; Ling 1992; Armpilia et al. 2003).

---

## 55.7 PULSED BRACHYTHERAPY

Pulsed brachytherapy (usually wrongly called pulsed-dose-rate (PDR) brachytherapy) seeks to offer the same clinical advantages as CLDR but without the need for visitor and staff access to be restricted throughout the whole period of treatment. The intention with pulsed brachytherapy is to emulate the radiobiological effects associated with a CLDR treatment. The dose which would have been given by CLDR is delivered in the same overall time period, but as a series of short fractions (pulses) with radiation-free gaps between each pulse.

As the number of pulses and dose-per-pulse are inversely related, a treatment using a very large number of closely-spaced pulses becomes increasingly identical to a CLDR treatment as the number of pulses is increased. However, to realise one of the main practical benefits of pulsed brachytherapy treatment (freedom for the patient to receive visitors or move around between fractions), it is desirable to keep the pulse durations short and the inter-pulse times long. The essential radiobiological question is this: What is the maximum dose per pulse and maximum inter-pulse interval that can be allowed before the therapeutic ratio (relative to CLDR) becomes significantly compromised?

The question is not easily answered, although guidelines are emerging (Fowler and Mount 1992; Millar et al. 1996). The radiobiology (and the associated mathematics) of pulsed brachytherapy is complex and, more so than in the case of FHDR or CLDR, the reliability of the predictions is more dependent on the radiobiological assumptions that are made. This is particularly true in relation to the mechanism of sub-lethal damage repair; because the pulses are closely spaced, the repair between fractions is incomplete and this leads to a cascading amount of additional cell lethality as treatment progresses.

The overall indications are that, provided there is a modification to the total dose, intervals as long as 3 h may be adequate if the pulsed brachytherapy treatment is being used merely as one component of a radical treatment. If the entire treatment is to be given by pulsed brachytherapy then gaps of no longer than 1 h may be required (Visser et al. 1996).

---

## 55.8 DOSE GRADIENTS AND INTEGRATED BIOLOGICAL RESPONSE

In most brachytherapy applications the dose prescription point will be part of an isodose surface that encloses volumes of tissue where the doses will rise rapidly in the close vicinity of the sources. Clearly this means that the physical dose and its radiobiological counterpart, the BED, are only correctly defined at the prescription point. Just a few millimetres on either side of this point the dose-rate (and hence the delivered dose) may be very different.

Does this mean that the BED concept is meaningless when applied to brachytherapy? The answer is that although the dose gradients have a significant effect, the net increment in BED caused by the dose gradients can be quantified and is usually not more than 15–30% in most clinical cases. Therefore, calculated reference point BEDs can be corrected by the use of multiplying factors which take account of the specific treatment conditions. The issues involved are discussed in depth elsewhere (Dale et al. 1997), but [Table 55.1](#) and [Table 55.2](#) summarise the multiplying factors which apply in a range of circumstances. These multiplying factors are

**TABLE 55.1**

BED Multiplying Factors for FHDR Brachytherapy

Dose per fraction (Gy)	$N=1$	$N=2$	$N=4$	$N=6$	$N=8$	$N=10$
2	1.72	1.54	1.39	1.32	1.27	1.24
4	1.55	1.39	1.27	1.21	1.18	1.15
6	1.45	1.31	1.21	1.16	1.13	1.11
8	1.38	1.26	1.17	1.13	1.10	1.09
10	1.33	1.22	1.14	1.10	1.08	1.07

It is assumed that  $\alpha/\beta=20$  Gy,  $\alpha=0.35$  Gy $^{-1}$ . N is the number of fractions. To obtain the BED, the BED calculated at the reference point is multiplied by the factor in the Table.

derived from a purely analytical approach based on ideal single source geometries, but direct assessment of integrated BED around clinical gynaecological applications indicates that the theoretical values are very representative of what happens in practice.

The integrated BED (i.e. the BED at the prescription point multiplied by the factor from the relevant table) is the biological dose associated with the uniform physical dose that would have to be applied to the same volume of tissue to yield the same surviving fraction of cells as does the brachytherapy. The concept of integrated biological response is particularly useful in cases where brachytherapy is combined with teletherapy, as it allows a more realistic summation of the respective biological doses delivered by the two components.

The multiplying factors are a function of dose per fraction and number of fractions (N). The BED at the dose reference point is calculated in the usual way, using the most appropriate radiobiological factors. The net BED within the volume enclosed by the reference iso-effect surface is found by multiplying the calculated BED by the value from the appropriate table. Unlike the BED, the multiplying factors are relatively insensitive to changes in the radiobiological parameters. A more detailed review of the relationship between the multiplying factors and the BEDs from which they are derived has been undertaken by Armpilia et al. (2006). The article considers CLDR, FHDR and pulsed brachytherapy treatments.

## 55.9 CONSEQUENCES OF DYNAMIC CHANGES DURING THE COURSE OF A BRACHYTHERAPY TREATMENT

During the course of a brachytherapy treatment the treated volume may shrink (due to cell depletion) or swell (due to oedema). If the treatment involves placing radioactive sources or

**TABLE 55.2**

BED Multiplying Factors for CLDR Brachytherapy

Dose-rate (Gy h $^{-1}$ )	$T=25$ h	$T=50$ h	$T=75$ h	$T=100$ h	$T=125$ h	$T=150$ h	$T=175$ h	$T=200$ h
0.2	1.48	1.35	1.28	1.25	1.21	1.19	1.17	1.16
0.4	1.35	1.24	1.19	1.16	1.14	1.12	1.11	1.10
0.6	1.28	1.19	1.15	1.12	1.10	1.09	1.08	1.08
0.8	1.24	1.16	1.12	1.10	1.09	1.07	1.07	1.06
1.0	1.21	1.14	1.10	1.08	1.07	1.06	1.06	1.05

It is assumed that  $\alpha/\beta=20$  Gy,  $\alpha=0.35$  Gy $^{-1}$ ,  $\mu=1$  h $^{-1}$ . T is the treatment time.

afterloading applicators directly within the tumour, then the dose may be significantly enhanced or reduced because of these respective effects (Dale and Jones 1994).

In the case of pseudo-exponential shrinkage, if the linear shrinkage rate is  $z$  (day $^{-1}$ ), then Equation 55.1 and Equation 55.2 are respectively modified to Equation 55.5 and Equation 55.6:

$$\text{BED} = NdX \left[ 1 + \frac{dX}{(\alpha/\beta)} \right] \quad (55.5)$$

$$\text{BED} = RTY \left[ 1 + \frac{2RY}{\mu(\alpha/\beta)} \right] \quad (55.6)$$

where  $X = 1 + (N - 1)zt$ ,  $Y = 1 + zT$ , and  $t$  is the average time interval between successive fractions.

Some imaging studies have demonstrated that, where brachytherapy is preceded by a course of chemotherapy, tumour shrinkage is indeed exponential with time (Tan et al. 1996).

In cases where brachytherapy causes short-term swelling rather than shrinkage, the same equations made be used but with the positive  $z$  replaced by an appropriate negative coefficient.

## 55.10 THE RBE EFFECT IN BRACHYTHERAPY

Although relative biological effectiveness (RBE) effects are usually ignored in brachytherapy assessments, they may be of major importance. Some brachytherapy radionuclides emit radiations that are more efficient in producing biological damage than are the conventional x-rays used in external-beam therapy (Scalliet and Wambersie 1987; Ling et al. 1995; Wuu and Zaider 1998). A smaller physical dose is thus required with the radionuclide to produce a particular biological effect, the increased efficiency being measured in terms of RBE. For example,  $^{125}\text{I}$ , with an RBE of around 1.45, requires in principle only to deliver  $(1/1.45 = 0.69 \text{ Gy})$  to produce the same effect as 1 Gy of conventional x-rays.

However, allowance for RBE effects is made potentially problematic on account of the fact that they vary with dose (or dose rate), the RBE values being highest at very low dose (or dose rate). Fortunately, the incorporation of the RBE phenomenon into LQ equations is easily accomplished by changing the format of the expression for the relative effectiveness in all BED equations from  $[1 + \dots]$  to  $[\text{RBE}_{\max} + \dots]$ , where  $\text{RBE}_{\max}$  is the maximum RBE occurring at zero dose. For example, Equation 55.4 is changed to:

$$\text{BED} = \frac{R_0}{\lambda} \left[ \text{RBE}_{\max} + \frac{R_0}{(\mu + \lambda)(\alpha/\beta)} \right]$$

This simple generic change to BED equations allows the variation of RBE with dose (or dose rate) to be properly allowed for and also results in BED values that may be used for direct inter-comparison with those associated with treatments using conventional x-rays. The incorporation of RBE into radiobiological equations is described by Dale and Jones (1999), and the practical implications relevant to permanent implant brachytherapy have been examined by Antipas et al. (2001) and Armpilia et al. (2003).

## INTRODUCTION

Radionuclide therapy has been used to treat both benign and malignant diseases for many years. For example,  $^{131}\text{I}$  is a standard form of treatment for thyrotoxicosis and thyroid cancer using the natural property of the thyroid gland to take up iodide, and radionuclide therapy with  $^{32}\text{P}$  and  $^{89}\text{Sr}$  has also been widely practiced to relieve bone pain. More recently, other short- and long-lived radionuclides have been introduced. This Part deals with the scientific basis of this unique form of radiotherapy. When compared to external-beam radiotherapy, therapy with unsealed sources has the potential to deliver larger internal radiation doses more selectively to target tissues. It also has the advantage of relative ease of use because it is often a noninvasive procedure with relatively few side-effects and, in many applications, can be performed on an outpatient basis.

Most early treatments involved the intravenous or oral administration of the therapeutic agent and were referred to as systemic radionuclide therapy. These systemic treatments relied on the preferential uptake and prolonged retention of the radiolabelled agent by the tumour, resulting in a high tumour-to-normal-tissue dose ratio.

With the improved availability of a broader range of therapy radionuclides (see [Chapter 57](#)) and the development of new tumour-specific pharmaceuticals (see [Chapter 58](#)), there has been a gradually increasing interest in the therapeutic applications of unsealed radioactive sources. The latest terminology—targeted radionuclide therapy—refers to the selective delivery of the therapy radionuclide to tumour cells using a biologically-targeted molecule to which the radionuclide is attached. This seeks to satisfy the fundamental aim of all forms of radiotherapy, that is, to maximise the therapeutic ratio, i.e. to deliver the highest possible radiation dose to the tumour while limiting the dose to normal tissues (see [Section 43.1](#)).

Both physical and biological mechanisms can be used to achieve tissue targeting. Improvements in *physical* targeting have been achieved by careful selection of the most appropriate radionuclide. The basis for selection is to match the physical range of the particles emitted to the size of the tumours to be treated together with careful consideration of the distribution of the radionuclide within the tumour at both the macroscopic and cellular level. Improved physical targeting has also been achieved by the introduction of alternative, more-direct routes of administration (e.g. intra-arterial, intra-cavitory, and intra-lesional). Improvements in *biological* targeting are being achieved by the development of new carrier molecules that can provide selective targeting of tumour sites, for example, on cell surface membrane receptors, in the cytoplasm, or in the nucleus. Biologically-targeted (or cell-directed) radiotherapy provides the opportunity to deliver radiation dose directly to tumour cells with almost complete sparing of normal tissues.

The traditional approach to the practice of radionuclide therapy was to prescribe a fixed amount of radioactivity. The amount was either based on previous experience or determined by gradually increasing the amount until unacceptable toxicity was observed. More recently, pre-therapy tracer studies have been introduced to measure the uptake of the radionuclide in different organs and tissues. This enables the treatment prescription to be given, not in terms of activity administered, but of absorbed dose to the tumour or in terms of the limiting dose to an organ-at-risk. Although this is a significant improvement when compared to the traditional approach, careful consideration must be given to the fact that dose estimates are often subject to large uncertainties. This is due to oversimplification of the models used in conventional internal dosimetry that will be described in [Chapter 56](#). The latest approach at research centres with facilities for quantitative tomographic imaging and multi-modality image registration is to use much more realistic models so that patient-specific 3D dose-distribution maps can be produced (see [Section 56.4](#)). For details on the more practical (including radiation protection) aspects of radionuclide therapy, the reader is referred to Flower and Chittenden (2000).

### **56.1 MEDICAL INTERNAL RADIATION DOSIMETRY (MIRD) IN THEORY**

The conventional method of calculating absorbed dose delivered internally is known as the medical internal radiation dosimetry (MIRD) scheme (Loevinger et al. 1991). The body is considered as a set of source organs that have a significant uptake of the radiopharmaceutical, and a set of target organs that are irradiated by the source organs. It is important to note that the MIRD definition of target organs is very different from that used in external-beam radiotherapy (see [Section 29.2](#)). For unsealed source therapy, the target organs are any organs (or tissues) of interest for which the absorbed dose is to be estimated and hence can include normal tissues (e.g. those at risk) as well as tumours.

For a self-irradiating tumour with uniform uptake, the mean absorbed dose,  $D$  (in Gy), to the tumour is given by:

$$D = \frac{\tilde{A}}{m} \sum_i \Delta_i \phi_i \quad (56.1)$$

where  $\tilde{A}$  is the cumulated activity in the tumour (in MBq h),  $m$  is the tumour mass (in g),  $\Delta_i$  is the equilibrium absorbed-dose constant for each nuclear transition (in g Gy/(MBq h)), and  $\phi_i$  is the absorbed fraction of energy. For more general cases, the absorbed dose  $D_{t \leftarrow s}$  (in Gy) to a target organ from activity in a source organ is given by:

$$D_{t \leftarrow s} = \frac{\tilde{A}_s}{m_t} \sum_i \Delta_i \phi_i \quad (56.2)$$

where the subscripts t and s denote the target and source organs, respectively. The total dose to a single target organ is simply the sum of the absorbed doses from all the source organs.

The cumulated activity,  $\tilde{A}_s$ , is proportional to the total number of radioactive disintegrations which occur in the source organ, and depends on the activity administered; the uptake of, retention by, and excretion from the organ; and the physical decay of the radionuclide.  $\tilde{A}_s$  is equal to the area under the activity-time curve for that organ.

It is helpful when considering both  $\Delta_i$  and  $\phi_i$  to separate the different emissions into nonpenetrating radiation ( $\beta$ -particles and electrons) and penetrating radiation (x- and  $\gamma$ -rays).  $\Delta_i$  (in g Gy/(MBq h)) is given by:

$$\Delta_i = 0.576 n_i \bar{E}_i \quad (56.3)$$

where  $n_i$  is the mean number of the  $i$ th type of radiation emitted per disintegration, and  $\bar{E}_i$  is the mean energy (in MeV) of each emission.  $\Delta_i$  is found from nuclear decay tables for each type of radiation emitted. MIRD tables (MIRD 1975a) list the values for most radionuclides used in nuclear medicine.

For nonpenetrating radiation,  $\phi_i$  is equal to zero when the target and source organs are geometrically separated, or is equal to 1.0 when they are the same organ. At a source-target interface,  $\phi_i$  is set to 0.5 (e.g. when considering the absorbed dose to the wall of a body cavity, such as the bladder containing radioactive urine). For penetrating radiation, the fraction  $\phi_i$  depends strongly on both the radiation energy and on the geometry of the source-target configuration. Values of  $\phi_i$  derived from Monte Carlo calculations can be found in MIRD Pamphlet 5 (MIRD 1969) for various radionuclides and pairs of source and target organs.

Equation 56.2 can be simplified by the introduction of the mean dose per unit cumulated activity  $S_{t \leftarrow s}$  (in Gy/(MBq h)) defined by:

$$S_{t \leftarrow s} = \frac{1}{m_t} \sum_i \Delta_i \phi_i \quad (56.4)$$

Values of the mean dose per unit cumulated activity (known as  $S$  values) have been tabulated for a variety of radionuclides and for different source-target configurations in both standard man (MIRD 1975b) and children (NRCP 1983).  $S$  values for a wider range of mathematical models of the human body including models for pregnant women are now available on the Radiation Dose Assessment Resource (RADAR) website (see References).

The traditional MIRD scheme, as described above, for calculating the dose from internally administered radionuclides makes the assumption that the activity is uniformly distributed in the source organ. It also assumes that the shape, size and position of the organs are as

represented by the human phantom described in Pamphlet 5 (MIRD 1969). The traditional MIRD scheme does not permit the determination of a maximum or minimum dose to each target organ considered, but simply provides the mean dose to the target volume. The MIRD Committee has started to address the requirement for the dosimetry of nonuniform activity distributions by providing  $S$  values at the cellular (Goddu et al. 1997) and image-voxel level (Bolch et al. 1999). A more recent development is the availability of  $S$  values for dosimetry using  $\alpha$ -particle emitters (Stinchcomb and Roeske 1999). Clairand et al. (2000) have developed mathematical models to allow consideration of the patient height, which they show affects the calculated dose.

---

## 56.2 MIRD IN PRACTICE

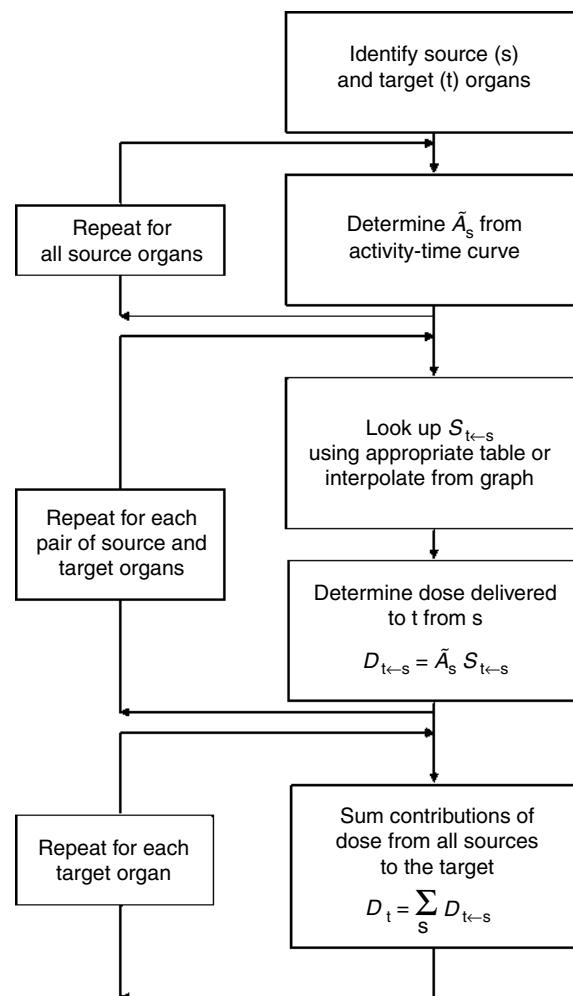

A program called MIRDOSE (Stabin 1996) is often used for calculating absorbed doses. This program is particularly useful when dealing with new radiopharmaceuticals or when special biokinetic models need to be considered. The MIRDOSE code has been renamed OLINDA (organ level internal dose assessment) after it was rewritten for greater computer platform independence. OLINDA is deployed on the RADAR website for rapid electronic access.

The total dose to a single target organ arising from radiation emitted by several source organs is simply the sum of the absorbed doses from all the source organs. [Figure 56.1](#) is a flow chart that summarizes how MIRD is applied in practice. Sequential planar gamma camera imaging is often used to obtain activity-time curves needed for the determination of the cumulated activity. Alternatively sequential quantitative tomographic imaging (SPECT (Zanzonico et al. 1989) or PET (Ott et al. 1992)) can be used to assess the specific cumulated activity.

However, many problems can be encountered when trying to use the gamma camera for imaging therapy radionuclides, since camera design has been optimised for diagnostic imaging of tracer levels of radioactivity. These problems are associated with high count rates (especially during the first few days after a therapy administration), and poor resolution (as a result of collimator penetration of any high-energy photons and the broad energy spectrum of bremsstrahlung radiation). Special low-sensitivity collimators or lead sheets attached to the front face of the camera can be used to reduce the count rate. Other options are to perform a pre-therapy tracer study using a radioisotope more suited to gamma-camera imaging (e.g.  $^{123}\text{I}$  instead of  $^{131}\text{I}$ ) or to use dual radionuclides, using a simultaneous injection of both imaging and therapy radionuclides (see [Section 57.7](#)).

In addition to the count-rate limitations of the gamma camera, the need to limit doses to staff and other patients also makes data acquisition at early time points difficult. A combination of early measurements during a tracer study and late measurements following therapy administration is a reasonable compromise. However, the kinetics of the radiopharmaceutical may not be identical in the tracer and therapy studies as a result of cell damage, so extrapolation of data can be subject to error.

It is difficult to achieve precise estimates of the magnitude and distribution of internal dose delivered from unsealed sources (Flux et al. 2002). Major sources of error are associated with the practical difficulties of obtaining enough time points for the accurate determination of  $\bar{A}_s$  and the accuracy of methods used to estimate  $m_t$ . A review of radio-nuclide therapy practices and facilities in Europe (Hoefnagel et al. 1999) showed that dosimetry was still not routinely performed in most centres and Fisher (2003) reported that this was also the case in the U.S. However, with the advent of improved imaging and counting techniques, estimates of internal dose are becoming more commonplace. These estimates are either *predictive* using a pre-treatment tracer study or *retrospective* using data acquired during therapy.

**FIGURE 56.1**

Flow chart illustrating how MIRD is applied in practice. (From Cormack, J., Towson, J. E. C., and Flower, M. A., Radiation protection and dosimetry in clinical practice, *Nuclear Medicine in Clinical Diagnosis and Treatment*, Murray, I. P. C. and Ell, P. J., Eds., 2nd Ed., Vol. 2, Churchill Livingstone, Edinburgh, 1998. With permission.)

## 56.3 DOSE-LIMITING ORGANS

The dose-limiting organs for new targeting agents are not necessarily known in advance and therefore detailed dosimetry and toxicity studies are required for each new carrier molecule considered for targeted radionuclide therapy. The organs at risk depend on both the route of administration and on the radiopharmaceutical. In systemic therapy the dose-limiting organ is often the bone marrow: if there is a risk of bone-marrow ablation, either a bone marrow harvest will be performed prior to therapy, for subsequent regrafting if necessary, or peripheral blood stem cell support is used. For intrathecal administrations, the dose-limiting organ is the spinal cord. If there is high uptake in the liver, this could lead to radiation hepatitis and chronic veno-occlusive liver disease. The bladder is also at risk from radioactivity in the urine, and patients should be hydrated and/or catheterised to reduce the dose to the bladder wall.

As the bone marrow is often the dose-limiting organ, bone-marrow dosimetry merits special attention. Various methods (Siegel et al. 1990) have been used to calculate the marrow dose but inaccuracies are caused by:

- Inadequate knowledge of the distribution of radionuclide within the marrow
- Treating the  $\beta$ -rays as nonpenetrating
- Ignoring the photon dose to the marrow from source organs other than the bone marrow
- Ignoring the effects of backscattering of electrons at the marrow-bone interface

In the estimation of absorbed dose to red marrow from nonspecific uptake of radiolabeled antibodies, it was recommended initially (Siegel et al. 1990) that the following assumptions be made:

- Marrow specific activity is one-third of blood specific activity.
- Clearance of activity from bone marrow is equal to that from blood.
- Marrow activity is uniformly distributed.

Subsequently, Sgouros (1993) presented a simple equation for calculating the red-marrow-to-blood activity concentration ratio given the haematocrit and red marrow extracellular fluid fraction of a patient. He also presented a series of equations that may be used to correct the activity concentration in bone-marrow biopsies for bone, yellow-marrow and blood contamination. Given the uncertainties associated with marrow dose estimates, the current method of choice for the assessment of bone-marrow toxicity from radioimmunotherapy (RIT) is the radiobiological endpoint method whereby the activity administered is slowly escalated until critical haematopoietic depression is reached.

---

## 56.4 PATIENT-SPECIFIC CALCULATIONS

In research centres, patient-specific dosimetry is being introduced, especially for RIT, to overcome some of the limitations of the MIRD system. The program MABDOS (Johnson 1988) starts with reference man but permits the inclusion of a spherical tumour at any site in the body. Also, with the increasing availability of multimodality imaging and image registration techniques, several groups (Giap et al. 1995; Tagesson et al. 1996; Flux et al. 1997; Kolbert et al. 1997; Thierens et al. 2001; Guy et al. 2003) have started to produce patient-specific 3D dose distributions resulting from radionuclide therapy. Dose volume histograms and tumour control probabilities (TCPs) can be derived from the 3D dose maps in the same way as for external-beam radiotherapy. The equivalent uniform dose (EUD), proposed initially for external-beam radiotherapy (see [Chapter 36](#)), can be applied to radionuclide therapy (O'Donoghue 1999). The EUD is based on the radiobiological linear quadratic (LQ) model and a 3D absorbed-dose distribution.

---

## 56.5 ALTERNATIVE DOSIMETRY METHODS

### 56.5.1 IN VIVO DOSIMETRY

Two alternative methods of in vivo dosimetry are autoradiography (Puncher and Blower 1994) and the use of miniature thermoluminescent dosimeters (TLDs) (Wessels and Griffith 1986). These techniques have been developed and evaluated in tumour models and/or biopsy specimens and provide valuable insight into the optimal properties of therapy agents. An

indirect method of in vivo dosimetry is biological dosimetry which involves the analysis of chromosomal aberrations in cultured blood cells (IAEA 1986). The results from in vivo studies can provide valuable input into theoretical calculations of dose distributions which can be performed at both the macroscopic and microscopic level. Evidence from microautoradiography and from miniature dosimeters suggests that the assumption of a uniform distribution of uptake is incorrect. There may be significant heterogeneity in the 10–100 µm range (Adelstein and Kassis 1987).

### 56.5.2 THEORETICAL APPROACHES

Dose distributions can be calculated using Monte Carlo techniques (Humm and Cobb 1990; Tagesson et al. 1996; Coulot et al. 2003; Descalle et al. 2003) or by integrating theoretically-derived (usually by Monte Carlo methods) dose point kernels over the spatial radionuclide distribution (Giap et al. 1995; Kolbert et al. 1997). An example of the latter is a theoretical model that has been used to predict TCP for spherical neuroblastoma tumours of different size (Nahum 1996) and used to demonstrate the advantages to be gained from using cocktails of β emitters to treat tumours with a broad range of sizes simultaneously (Zweit et al. 1997). This model was extended to include the radiobiological effects of cellular repair and proliferation (Atthey et al. 2000). Theoretical microdosimetry at the multicellular level (Coulot et al. 2003; Malaroda et al. 2003) is particularly valuable in assessing the dose distribution from inhomogeneous depositions of short-range emitters. For example, in RIT, cell killing will depend on whether or not the antibody binds to the cell-surface membrane or is internalized by the tumour cells (Humm and Cobb 1990; Hartman et al. 2000).

---

### **57.1 INTRODUCTION**

There are three basic considerations when choosing a radionuclide for targeted radiotherapy:

- Physical properties of the radionuclide (i.e. type, yield and energy of emissions, and physical half-life)
- Chemical properties in relation to: conjugation and binding stability; targeting molecule; and accumulation, retention and clearance profiles for the tissues of interest
- Production methods in relation to radioactivity levels and chemical and radiochemical purity suitable for clinical application and specific activity requirements when, for example, conjugated to a receptor ligand type molecule (Zweit 1996)

The types of radionuclide decay that are of greatest potential use in unsealed source therapy are those which involve the emission of  $\beta$ -particles, Auger and conversion electrons, and  $\alpha$ -particles. These particles can be considered as nonpenetrating radiation in contrast with x- and  $\gamma$ -rays, which are penetrating radiation. Although the  $\beta$ -emitters  $^{131}\text{I}$  and  $^{32}\text{P}$  have been the most commonly used radionuclides in the past, their physical properties are not necessarily ideal. Other  $\beta$ -emitting radionuclides have been introduced into the clinic, especially over the last couple of decades. Emitters of Auger and conversion electrons and  $\alpha$ -particles may be more widely used in the future (see [Section 57.3](#) and [Section 57.4](#)).

---

## 57.2 BETA EMITTERS

There is a wide choice of  $\beta$ -emitting radionuclides for targeted radiotherapy and hence a flexibility in the choice of  $\beta$  range in tissue. [Table 57.1](#) lists the physical properties of  $\beta$  emitters that have been used or are of potential use in radionuclide therapy. The radionuclides are listed in order of increasing  $\beta$  energy, and only the most abundant  $\beta$  and  $\gamma$  radiations are included. The values of  $\Delta_p$  and  $\Delta_{np}$  (the total equilibrium dose constants for penetrating and nonpenetrating radiations, respectively) listed in Table 57.1 are useful indicators of the  $\gamma$  dose relative to the  $\beta$  dose for each therapy radionuclide. These parameters were defined in [Section 56.1](#).

Beta decay (see Section 2.2.2.4) gives rise to a continuous spectrum of  $\beta$  energies. Details of spectra can be found in Cross et al. (1983). For those radionuclides with more complex decay schemes, the resulting spectrum is a sum of the continuous spectra for each  $\beta$  emission. The average energy is approximately one-third of the maximum energy for each  $\beta$  emission. The maximum range, in water or soft tissue (in mm), is approximately equal to the maximum energy (in MeV) multiplied by five (Adelstein and Kassis 1987). More precise relationships between the range and the  $\beta$  energy have been given by Cole (1969) and by Prestwich et al. (1985). The maximum range is often calculated using the continuous slowing down approximation (CSDA) (see [Section 3.4.3](#)). This is then referred to as the CSDA range. However, the latter does not take account of the contorted paths of the  $\beta$ -particles as they interact with their surroundings, nor of the decay scheme, since the  $\beta$ -particle with maximum energy may not be very abundant. In addition to the maximum range, two other parameters (mean range and  $X_{90}$ ) have been used, especially in the context of radionuclide therapy, to describe the distance over which most of the  $\beta$  energy is deposited. The mean range usually refers to the CSDA range for a  $\beta$ -particle with the mean energy. The  $X_{90}$  value, used by Simpkin and Mackie (1990) and Johnson and Yanch (1991), is defined as the radius of the sphere in which 90% of the emitted energy is absorbed. More recently, the  $X_{90}$  value has been referred to as the therapeutic range (Johnson et al. 1995). Both the mean range and the  $X_{90}$  value can be calculated from the full energy spectrum using Monte Carlo techniques (see [Chapter 5](#)). Some examples of these values are given in [Table 57.2](#).

Pure  $\beta$  emitters (e.g.  $^{32}\text{P}$ ,  $^{89}\text{Sr}$  and  $^{90}\text{Y}$ ) may be considered as ideal for delivering a high local dose while sparing tissues at a distance. However, radionuclides which emit  $\gamma$ -rays in addition to  $\beta$ -particles (e.g.  $^{131}\text{I}$ ,  $^{153}\text{Sm}$  and  $^{186}\text{Re}$ ) have the advantage that external counting and imaging techniques can be applied more easily to assess the uptake and distribution of the therapy agent. The disadvantage is that the  $\gamma$ -rays increase the whole-body dose to the patient and, in some cases (e.g. for  $^{131}\text{I}$ ), their energy may not be well-matched to the gamma camera, so only poor resolution imaging is available. In this regard, the lower flux and energies of the  $\gamma$ -rays from, for example  $^{153}\text{Sm}$  and  $^{186}\text{Re}$ , are advantageous compared to  $^{131}\text{I}$ . Imaging the bremsstrahlung radiation from pure  $\beta$  emitters is also a possibility for monitoring the bio-distribution of these therapy agents, but again the spatial resolution is poor (Smith et al. 1988; Siegel et al. 1995).

The range of the  $\beta$ -particles is very important in relation to the size of the tumour to be treated (Wheldon 1993; O'Donoghue et al. 1995). High-energy  $\beta$ -particles (see Table 57.1) provide radiation cross-fire, which can reduce the problem of heterogeneous uptake in large tumours. These long-range  $\beta$ -particles are also better suited to the treatment of large volumes. If the  $\beta$  emitter is uniformly distributed throughout the tumour, the dose rate will be uniform

throughout this volume except for a reduction close to the outer edge where electronic equilibrium no longer exists. This is illustrated in Figure 57.1. For very small tumours (less than a few mm in diameter), a large fraction of the total energy from  $\beta$  particles emitted within the tumour will be deposited in surrounding tissues. Hence, for the treatment of micrometastases, short-range electrons and  $\alpha$  emitters would be more appropriate, provided that the activity distribution is uniform on a microscopic scale.

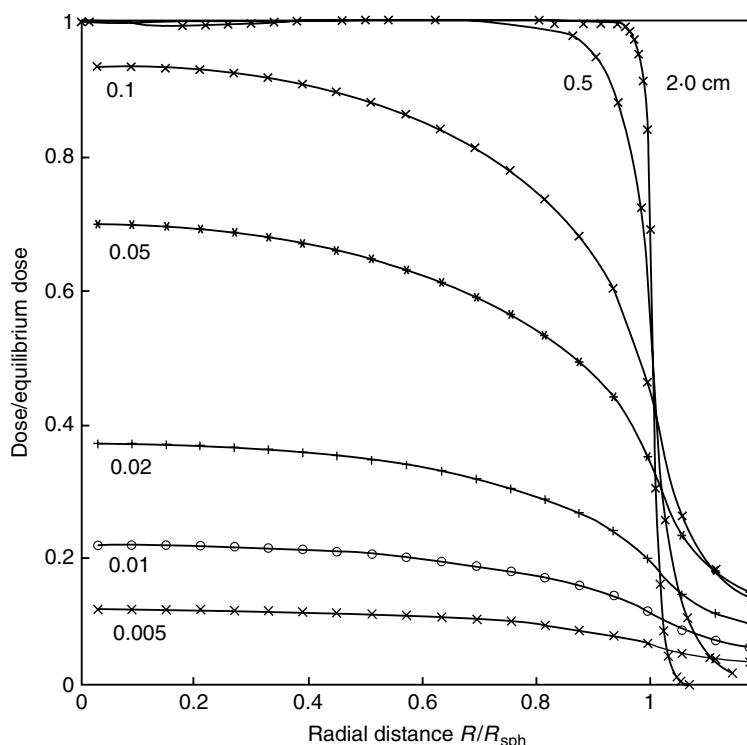

One practical advantage of using pure  $\beta$  emitters is that there is little risk of irradiating other people, and patients can therefore often be treated in out-patient clinics (Zanzonico et al. 1999). Beta emitters with accompanying  $\gamma$ -rays, however, pose a significant radiation risk to others, and in some cases, an in-patient stay of several days is required before the activity level is sufficiently low for the patient to return home. Radiation protection considerations are discussed further in Section 61.4.2

## 57.3 AUGER-ELECTRON EMITTERS

Radionuclides, which decay by electron capture or internal conversion, emit low-energy characteristic x-rays and Auger electrons (see [Section 1.4.4](#)). In some cases, low-energy conversion electrons are also emitted. Most Auger electrons have very short range ( $< 1 \mu\text{m}$ ) and are therefore only of use in therapy if the source is attached to, or very close to, the cell nucleus. Table 57.3 lists the physical properties of Auger-electron emitters, some of which have been considered for radionuclide therapy. The total equilibrium dose constant for Auger electrons alone ( $\Delta_{\text{Auger}}$ ) has been listed separately from  $\Delta_{\text{np}}$  for all nonpenetrating radiations. Once again, a comparison of the total equilibrium dose constants is a useful indication of radiation dose contributions from the different types of radiation. It indicates, for instance, that  $^{117\text{m}}\text{Sn}$  emits both Auger electrons as well as conversion electrons and  $\gamma$ -rays, and hence has been proposed as a useful therapy radionuclide when conjugated to diethylenetriamine pentaacetic acid (DTPA) and used in palliative bone therapy (Krishnamurthy et al. 1997). The 159 keV  $\gamma$ -photons are well suited for imaging with the gamma camera.

The potential use of Auger-electron emitters for targeted radionuclide therapy has been discussed by Humm (1986) and O'Donoghue and Wheldon (1996). Biological efficacy is critically dependent on the sub-cellular and sub-nuclear localisation of Auger-electron emitters. Potential methods of targeting include the use of analogues of DNA precursors (e.g. iodo- and bromodeoxyuridine) and of molecules that bind to DNA (e.g. oligonucleotides and other compounds

which internalise to the nucleus). Unfortunately, heterogeneity of radionuclide uptake is a serious limitation on the success of targeted therapy with Auger-electron emitters. Experimental studies (Neshasteh-Riz et al. 1998) have suggested that combinations of  $^{131}\text{IUDR}$  (iodo-deoxyuridine) (with cross-fire  $\beta$  irradiation) and  $^{123}\text{IUDR}$  or  $^{125}\text{IUDR}$  may be more effective than Auger-electron emitters alone if proliferative heterogeneity of the tumour cell population exists.

---

## 57.4 ALPHA EMITTERS

The advantages of  $\alpha$  emitters (e.g.  $^{211}\text{At}$ ,  $^{213}\text{Bi}$ ) for radionuclide therapy are their short range (typically 50–90  $\mu\text{m}$ , i.e. several cell diameters), high linear energy transfer (LET) and hence increased biological effectiveness (see [Section 7.14](#)).  $^{213}\text{Bi}$  has the advantage of being available from an  $^{225}\text{Ac}/^{213}\text{Bi}$  generator system (McDevitt et al. 1999). A single  $\alpha$ -particle can deposit approximately 0.25 Gy in a 10  $\mu\text{m}$  diameter cell nucleus (Humm 1986). This offers the possibility of combining cell-specific targeting with radiation of similar range. Preclinical studies with a variety of  $^{213}\text{Bi}$ - and  $^{211}\text{At}$ -labelled radiopharmaceuticals have produced exciting results. Several approaches have been explored, including labelled colloids, monoclonal antibodies, metabolic precursors, receptor-avid ligands and other low molecular weight molecules (Vaidyanathan and Zalutsky 1996; McDevitt et al. 1998). However, patient studies are not recommended until highly specific tumour targeting can be guaranteed. One way to achieve this would be to find more direct routes of administration that confine the agent to the region of the tumour. Alternatively,  $\alpha$ -emitting compounds could be used in vitro, e.g. to purge bone marrow and/or peripheral blood of tumour cells.

---

## 57.5 RADIOCHEMICAL CONJUGATION

Methods for incorporating the radionuclide into a carrier molecule (radiolabelling) vary from direct labelling, in which the radionuclide is directly attached to a chemical moiety on the molecule, to indirect methods using pre- and post-conjugate approaches. The latter can sometimes involve complex reactions and purifications. In both scenarios the stability of attachment and the metabolic profile of the radiolabelled compound must be evaluated in preclinical studies. Radiochemistry aspects of radiolabelled therapeutic conjugates have been extensively reviewed (Wilbur 1992; Blower et al. 1996) and are beyond the scope of this chapter. The choice of labelling approach is governed by a number of factors, which include:

- The chemical properties of the radionuclide and conjugate molecule
- The site of attachment on the carrier molecule
- The overall pharmacokinetic profile of the targeting molecule, the conjugate, the radionuclide and other radiolabelled and unlabelled species which could be produced as a result of *in vivo* metabolism.

---

## 57.6 RADIOBIOLOGICAL CONSIDERATIONS

In contrast to fractionated high-dose-rate external-beam radiotherapy, radionuclide therapy delivers continuous irradiation at relatively low dose rates. In addition, the dose rate varies during therapy, increasing initially during the uptake phase, then decreasing at a rate which depends on both the physical half-life of the radionuclide and the biological clearance rate of the radiolabelled compound.

From radiobiological considerations (Wheldon and O'Donoghue 1990), continuous low-dose-rate irradiation may be viewed as being a particularly effective type of radiotherapy, as it ensures that the differential sparing between tumour and normal tissues is maximised. A given dose has a reduced biological effect if delivered at a low dose rate, but the magnitude of this reduction varies for different tissues. For early-responding tissues (bone marrow, epithelium) the effect is small; for late-responding tissues (vascular endothelium, nervous tissue, kidney) it can be large. Only at the later stages of radionuclide therapy, when the dose rate is low, will the advantageous effect of low dose rate (i.e. in sparing late-responding normal tissues) be maximised. Dale (1996) pointed out that the beneficial effect of low dose rate may be reduced by its lack of effect on cell proliferation. Further discussion of these issues can be found in Chapter 55.

The linear-quadratic (LQ) model for cell survival (see Part B), applied originally to external-beam therapy and brachytherapy, can also be applied to radionuclide therapy. When so applied, the model has to be modified to allow for the period of accumulation of the radionuclide in the tissues of interest and to take into consideration the proliferation and repair rate of normal and tumour tissues. Howell et al. (1998) have shown that the modified LQ model can be helpful when choosing a radionuclide for a particular type of therapy such as radioimmunotherapy. In particular, for a given therapeutic effect in a tumour, a longer-lived radionuclide (i.e. a lower overall dose rate) can result in a lower detrimental effect on the bone marrow than a short-lived radionuclide. The optimal physical half-life is about two to three times the biological clearance half-time of the therapeutic compound in the tumour.

---

## 57.7 MATCHED PAIRS FOR IMAGING/THERAPY

The dosimetry of radionuclide therapy relies on quantitative *in vivo* uptake measurements of the therapeutic agents. These measurements can be best achieved by high-resolution positron-emission tomography (PET) imaging if a positron- and  $\beta$ -emitting radioisotope of the same element is available. The use of a radioisotope of a different element, even when linked to the same carrier molecule, could influence the biodistribution. Pre-therapy imaging with an isotope of the same element is therefore essential. Some examples of PET radionuclides, which have analogues that are potentially suitable for therapy (see list in Table 57.1) are  $^{64}\text{Cu}$ ,  $^{71}\text{As}$ ,  $^{72}\text{As}$ ,  $^{83}\text{Sr}$ ,  $^{86}\text{Y}$ , and  $^{124}\text{I}$ . Of this group,  $^{64}\text{Cu}$  looks the most promising. It is one of the very few radionuclides which combine  $\beta$ , positron, and Auger-electron emissions in its decay. The biological effects of  $^{64}\text{Cu}$  emissions in tumour cells have been found to be at least as lethal as those from the  $\beta$ -emitter  $^{67}\text{Cu}$  (Apelgot et al. 1989)\*. This makes  $^{64}\text{Cu}$  a good candidate radionuclide both for PET imaging and for targeted therapy (Obata et al. 2003). Also, the chemistry of copper is amenable to the development of compounds, which could potentially exploit certain targeting approaches such as redox mechanisms (Blower et al. 1996).

---

\* In fact, there is no reason to believe that a given dose delivered by positrons will have a different biological effect to the same dose delivered by electrons of similar energy.

## 58.1 INTRODUCTION

The number of available and potential radiopharmaceuticals for targeted radiotherapy has increased greatly since the early days of systemic radionuclide therapy. Table 58.1 provides some examples of radiopharmaceuticals together with current or potential applications.

**TABLE 58.1**

Examples of Radiopharmaceuticals for Targeted Radiotherapy

Mechanism	Radiopharmaceutical <sup>a</sup>	Application
Incorporation into DNA	$^{125}\text{I}$ -IUDR	Choriocarcinoma, colorectal carcinoma
Metabolic	$^{131}\text{I}$ -iodide	Thyrotoxicosis, goitre, differentiated thyroid carcinoma
Metabolic	$^{131}\text{I}$ -mIBG	Neural crest tumours
Metabolic	$^{32}\text{P}$ -phosphate	Polycythaemia vera, essential thrombo-cythaemia
Receptors	$^{80\text{m}}\text{Br}$ -oestrogen, $^{125}\text{I}$ -tamoxifen; $^{111}\text{In}/^{90}\text{Y}/^{188}\text{Re}$ -octreotide	Breast; abdominal tumours
Immunologic	$^{131}\text{I}/^{90}\text{Y}/^{177}\text{Lu}/^{153}\text{Sm}/^{186}\text{Re}/^{188}\text{Re}/^{67}\text{Cu}/^{211}\text{At}/^{212}\text{Bi}$ -antibodies	Radioimmunotherapy
Extracellular adsorption	$^{32}\text{P}$ -orthophosphate, $^{89}\text{Sr}$ -chloride, $^{153}\text{Sm}$ -EDTMP, $^{186}\text{Re}$ -HEDP, $^{117\text{m}}\text{Sn}(4+)$ -DTPA	Relief of bone pain
Extracellular adsorption	$^{166}\text{Ho}$ -DOTMP	Multiple myeloma
Radiolabelled cells	$^{114\text{m}}\text{In}$ -lymphocytes	lymphoma
Intra-arterial	$^{131}\text{I}$ -lipiodol, $^{90}\text{Y}$ -microspheres	Hepatic tumours
Intracavitary	$^{32}\text{P}$ -phosphate, $^{90}\text{Y}$ -silicate colloid	Malignant effusions
Intra-articular	$^{90}\text{Y}/^{198}\text{Au}$ -colloid, $^{153}\text{Sm}$ -PHYP, $^{165}\text{Dy}$ -FHMA, $^{169}\text{Er}$ -citrate colloid	Radiation synovectomy
Intravesical	$^{67}\text{Cu}$ -595 antibody	Superficial bladder cancer
Intralesional	$^{131}\text{I}$ -antiteneascin; $^{111}\text{In}/^{90}\text{Y}/^{188}\text{Re}$ -octreotide	Glioma; abdominal tumours
Endovascular	$^{188}\text{Re}$ -perrhenate	Balloon angioplasty

<sup>a</sup> IUDR, iodo-deoxyuridine; mIBG, metaiodobenzylguanidine; EDTMP, ethylene diamine tetramethylenglyphonate; HEDP, hydroxyethylidene diphosphonate; DTPA, diethylenetriamine pentaacetic acid; PHYP, particulate hydroxyapatite; FHMA, ferric hydroxide macroaggregates.

The following sections provide more information on the principles of the tumour-targeting mechanisms involved.

## 58.2 INTRACELLULAR MECHANISMS

### 58.2.1 INCORPORATION INTO DNA

Nucleosides (i.e. a subunit of a nucleic acid) radiolabelled with an Auger-electron emitter (e.g.  $^{123}\text{I}$ IUDR,  $^{125}\text{I}$ IUDR,  $^{77}\text{Br}$ UdR and  $^{80\text{m}}\text{Br}$ UdR) have been shown using experimental systems to produce extensive DNA damage in the cell nucleus. This damage is due to the fact that these nucleosides bind covalently to DNA so that the Auger-emitting radionuclide is in close proximity to the genome. The greater the proliferation of the cells, the higher the uptake of the radiolabelled nucleoside. To facilitate targeting to tumours and to reduce toxicity in normal cells with high proliferation rates (e.g. gut and bone marrow), the direct injection into tumours of nucleosides labelled with Auger-electron emitters is currently under investigation (Kassis et al. 1996).

### 58.2.2 METABOLIC PROCESSES

The oldest types of radionuclide therapy are the treatment of thyroid disorders with radioiodine (Clarke 1998) and the treatment of polycythaemia vera with radiophosphorus

(Berk et al. 1986). Both of these treatments make use of metabolic processes to deliver a therapeutic radiation dose to selective tissues. In radioiodine therapy, because iodine is a precursor of the thyroid hormone thyroxine, it is taken up into the follicular cells of the thyroid. In radiophosphorus therapy, incorporation of orthophosphate into the nucleic acids of rapidly proliferating cells is considered to be the targeting mechanism in the treatment of myeloproliferative diseases. The  $^{32}\text{P}$  is selectively concentrated by the mitotically-active bone-marrow cells and later incorporated into the calcium phosphate of adjacent bone, from which the marrow is irradiated further.

Meta-iodobenzylguanidine (mIBG) has structural similarities to both guanethidine and the endogenous catecholamines (noradrenaline and adrenaline).  $^{131}\text{I}$ -mIBG can therefore be incorporated into the cellular cytoplasm via the catecholamine pathways, and has been used to treat tumours which are derived from the neural crest (e.g. neuroblastoma and phaeochromocytoma) (Hoefnagel and Lewington 1998). There has been a lot of research into elucidating the uptake and retention mechanisms of different tumour cell types (Wafelman et al. 1994). Cellular uptake of mIBG occurs by two distinct mechanisms, active and passive. The passive mechanism is nonsaturable and occurs in all cells synthesising the noradrenaline transporter (NAT) molecule. Selective uptake of mIBG depends on cellular expression of the NAT gene (Mairs et al. 1994).

## 58.3 CELL-SURFACE RECEPTORS

It is possible to attach radionuclides to the cell membrane surface via receptor binding of hormones and antibodies. To achieve an effective radiation dose, the tumours must have sufficient and accessible binding sites. Also, the radiopharmaceutical must be of a high specific activity (amount of radioactivity per mass of the radiolabelled compound) to prevent saturation of the binding sites by unlabelled compound. Other variables to be considered are the receptor density, the receptor homogeneity, any loss of affinity for the receptor of the radiolabelled compound compared to the native (unlabelled) molecule, and whether or not cellular internalisation occurs.

### 58.3.1 HORMONES

Many tumours have hormone receptors—in the cytoplasm or at the cell membrane—to which radiolabelled hormones, analogues, or antihormone drugs may be targeted. Examples of hormone–receptor binding radiopharmaceuticals for treating breast cancer are  $^{80\text{m}}\text{Br}$ -oestrogen and  $^{125}\text{I}$ -tamoxifen (Hoefnagel 1991).

### 58.3.2 PEPTIDES

Radiolabelled octreotide, a synthetic 8-amino acid analogue of the naturally occurring regulatory peptide somatostatin, is a potential therapeutic agent. Early clinical treatments (Fjälling et al. 1996) used the Auger-electron emitter  $^{111}\text{In}$ , but the  $\beta$  emitters  $^{90}\text{Y}$  and  $^{188}\text{Re}$  have also been considered (De Jjong et al. 1997; Zamora et al. 1997). One limitation of octreotide is that it only recognises two of the somatostatin subtypes (i.e. SSTR2 and SSTR5). A combination of multiple peptide receptors may be the best way of overcoming the dependence of binding and internalisation on the peptide subtype.

### 58.3.3 ANTIBODIES

The development of radiolabelled monoclonal antibodies (mAbs) that bind to tumour-associated antigens opened up the possibility of radioimmunotherapy (RIT) (Humm 1986;

Bruland 1995; Wilder et al. 1996). Experimental and clinical RIT studies have been carried out with a wide range of  $\beta$  emitters, and  $\alpha$  emitters have also been considered (see Table 58.1). Despite the obvious potential, there are many difficulties with this type of therapy that have limited its success to date. These difficulties are mainly caused by nonspecific binding, slow clearance rates and moderate specificity. An enormous effort is being made to overcome these difficulties. The combination of biological targeting (using radiolabelled mAbs) and physical targeting (with more direct routes of administration, e.g. intrathecal (Papanastassiou et al. 1995), intravesical (Hughes et al. 1997), intralesional (Riva et al. 1994), and direct injection into surgically-created resection cavities (Akabani et al. 1999) may finally enable RIT to realise its inherent potential.

---

## 58.4 EXTRACELLULAR MECHANISMS

Radionuclides can be brought into close proximity to tumour cells by various extracellular mechanisms, e.g. by targeting the extracellular osteoid, by using radiolabelled cells, and by using more direct routes of administration.

### 58.4.1 BONE-SEEKING AGENTS

A variety of bone-seeking radiopharmaceuticals are now available for targeted radiotherapy of bone metastases (Lewington 2002). Although external-beam radiotherapy is of value in the management of well-localised pain, systemic targeted radiotherapy offers the advantage that multiple sites can be treated simultaneously, whilst minimising the normal-tissue absorbed dose. However, the exact mechanism of pain relief is not fully understood. Initial clinical experience was with  $^{32}\text{P}$  orthophosphate and  $^{89}\text{Sr}$  chloride (Porter et al. 1993). Comparisons have been made with newer agents  $^{186}\text{Re}$ -HEDP (De Klerk et al. 1996),  $^{153}\text{Sm}$ -EDTMP (Bayouth et al. 1994) and  $^{117\text{m}}\text{Sn}$  (IV)-DTPA (Krishnamurthy et al. 1997). Early results showed that the speed of onset and duration of pain relief is governed by the half-life of the radionuclide. Early response correlated with shorter half-life, whereas prolonged duration correlated with longer half-life. This is due to the fact that if the half-life is shorter, then the initial dose rate is higher (assuming the same total dose). However, there are other issues to be considered with short half-lives, e.g. if a patient is too ill to undergo treatment, then it may not be possible to use the ordered radiopharmaceutical for another patient. Another application of a skeletal-targeted radiotherapeutic agent is  $^{166}\text{Ho}$ -DOTMP, which was used in patients with multiple myeloma (Bayouth et al. 1995). With this agent, the long range of the high-energy  $\beta$ -particles allowed ablation of marrow from radioactivity localized in bone matrix.

### 58.4.2 RADIOLABELLED CELLS

$^{114\text{m}}\text{In}$ -labelled lymphocytes have a potential therapeutic role in the management of lymphoma (Sharma et al. 1997). The principle here is that the malignant lymphocytes may retain their ability to migrate and recirculate into the spleen, liver, bone marrow and lymph nodes. After harvesting, labelling with  $^{114\text{m}}\text{In}$  and reinjecting, the lymphocytes can carry and deliver a therapeutic radiation dose to the lymphoreticular system.

### 58.4.3 INTRA-ARTERIAL INFUSION

Intra-arterial infusion has been used for the treatment of hepatic malignancies. This is because hepatic tumours derive their blood supply almost entirely from the hepatic artery,

whereas normal liver is supplied mainly by the portal venous system. Therefore, administration of the radiolabelled agent into the hepatic artery can be used to deliver high doses to small liver tumours. Various radiopharmaceuticals have been investigated, including  $^{131}\text{I}$  Lipiodol (Leung et al. 1994), but these have now generally been replaced by  $^{90}\text{Y}$  glass microspheres (Andrews et al. 1994; Ho et al. 1996). More recent studies (Dancey et al. 2000; Salem et al. 2002) have shown that significantly higher doses of radiation can be delivered to hepatocellular carcinoma (HCC) by intrahepatic arterial administration of  $^{90}\text{Y}$ -microspheres than by external beam radiation. These groups have also demonstrated that this new alternative treatment appears to be beneficial in unresectable HCC with acceptable toxicity.

#### 58.4.4 INTRACAVITARY ROUTES

A large number of intracavitory routes have been used for targeted radiotherapy (e.g. intraperitoneal, intrapleural, intrapericardial, intrathecal, intra-articular). The basic principle of this type of treatment also applies to intracystic and intravesical administration. In intracavitory treatments, the colloidal particles are assumed to plate out on the cavity/cyst/vessel wall after administration. Therefore, the therapy radionuclides are chosen to match the  $\beta$  range to the thickness of surface to be treated so that underlying tissues are spared. For example, in radiation synovectomy (Deutsch et al. 1993)  $^{169}\text{Er}$  colloid (mean  $\beta$ -range in tissue = 0.3 mm) is used mainly to treat joints in the fingers whereas  $^{90}\text{Y}$  colloid (mean  $\beta$ -range = 3.6 mm) is commonly used to treat knee joints.

#### 58.4.5 INTRALESIONAL INSTILLATION

Direct instillation of a therapy agent is only appropriate for local control of isolated lesions, where the rationale is that the radiopharmaceutical will be retained within the tumour volume, thus improving the therapeutic ratio. Examples are intralesional administration of  $^{131}\text{I}$ -labelled antitenascin MAb in patients with glioma (Riva et al. 1994), and infusional brachytherapy of nonresectable pancreatic cancer using  $^{32}\text{P}$  chromic phosphate (Order et al. 1994).

#### 58.4.6 ENDOVASCULAR CATHETERS

Local irradiation using a liquid-filled balloon is a new approach for the efficient and cost-effective reduction of restenosis after angioplasty (Kotzerke et al. 2000). The most attractive radionuclide for this purpose is the high-energy- $\beta$  emitter  $^{188}\text{Re}$ , which is available from a  $^{188}\text{W}/^{188}\text{Re}$  generator system. It could be argued that this type of therapy should not be included here because the liquid source is *sealed* in the balloon rather than unsealed. However, this recent development in therapeutic nuclear medicine will result in the availability of generator-produced  $^{188}\text{Re}$  for other unsealed-source therapy applications.

---

### 58.5 CURRENT STATUS OF THERAPY USING UNSEALED SOURCES

There has been a considerable development in the clinical practice of radionuclide therapy over the last couple of decades. This development has been driven by the production of new radionuclides, research into new targeting agents, and by the failures and limitations of other methods of treatment, especially for malignant disease. The success of therapy using unsealed sources depends on very careful matching of the physical, chemical and biological properties of the agent to the clinical problem to be addressed. In the treatment of cancer, this depends on

**TABLE 58.2**

## Areas of Development in Radionuclide Therapy

Topic	Issues to Be Evaluated
Radionuclide	Availability, production method, activity levels, specific activity, matching of all physical properties to each specific clinical application
Carrier	Specificity of biological targeting, and dependence on targeting mechanism and/or route of administration
Therapeutic ratio	Possible pharmacological enhancement by vasoactive drugs, radiosensitising agents, pre-targeting (in RIT) to improve uptake and retention in tumour, and increased excretion from blood and normal tissues.
Dosimetry calculations	Potentially more specific targeting pathways involved in tumour aggressiveness and progression
Normal tissue toxicity	Accuracy of dose model, validity of assumptions made, propagation of errors, effect of heterogeneity of uptake in tumour
	Availability of bone-marrow harvest or peripheral stem cell support.
	Improvement in targeting and manipulation of normal tissue kinetics of carrier

factors such as tumour type, lesion size, tumour accessibility and on the presence or absence of metastatic disease. Table 58.2 provides a checklist of most of the issues that need to be considered in relation to this unique form of radiation therapy. Reviews of the status of unsealed-source therapy and molecular targeting with radionuclides can be found in Zanzonico (2000), Goldenberg (2002) and Britz-Cunningham and Adelstein (2003).

If targeted radiotherapy using unsealed sources is to become more successful, various combinations of therapeutic agents and treatment modalities will be involved, in addition to the more direct routes of administration already mentioned. Examples of such combinations are cocktails of:

- $\beta$  emitters with different ranges to treat tumours of variable size (Wheldon and O'Donoghue 1990; Zweit et al. 1997)
- Radionuclides with different half-lives, e.g. to produce both rapid response and prolonged symptom relief in palliation of bone pain (Lewington 1993)
- Radionuclides with different types of emissions, i.e.  $\beta$  emitters combined with Auger-electron emitters or  $\alpha$  emitters (O'Donoghue and Wheldon 1996; Neshasteh-Riz et al. 1998)
- Different mAbs to improve targeting in radioimmunotherapy (Wilder et al. 1996)

Therapeutic agents that use molecules with better targeting and pharmacokinetic profiles should also result in more successful treatments. For example, single-chain versions of mAbs, peptides and specifically targeted small metal or halogen complexes, can improve the therapeutic ratio by virtue of enhanced target uptake and retention and accelerated elimination from normal tissues (Blower et al. 1996; Wilder et al. 1996; Lewis et al. 1999a, 1999b).

The rationale behind the use of multiple treatment modalities in relation to tumour size is illustrated in the following example. In neuroblastoma therapy, total body irradiation or chemotherapy could be used to control micrometastases and small tumours less than 1 mm in size;  $^{131}\text{I}$ -mIBG could treat tumours with dimensions between 1 mm and 1 cm; and external beam radiotherapy could be directed at easily detected, large ( $> 1$  cm) tumour masses (Gaze et al. 1995).

## INTRODUCTION

In considering radiation protection for radiotherapy, a balance must be achieved between mitigating risk and the cost of the measures required to do so. To assess this, an understanding of the risks associated with radiation treatment is required, and this is the subject of [Chapter 59](#).

The use of radiation is governed by a regulatory framework, and [Chapter 60](#) considers issues of regulation. This regulatory framework is different in each country, but the principles are common to all. This Part is mainly concerned with minimising the exposure of staff and members of the public that may also include the protection of the foetus on the rare occasions that a patient may require radiotherapy while pregnant. When dealing with issues of legislation, U.K. and European law is sometimes referred to in order to provide a coherent context, but wherever possible, the text has been written to be generally applicable. A summary of U.K. legislation can be found in [Appendix L.1](#).

The final chapter ([Chapter 61](#)) deals with the application of these principles to practical radiotherapy. This includes the design of treatment rooms and certain practical issues relating to patient treatment.

An example of the calculations necessary in the design of a radiotherapy treatment room is included in [Appendix L.2](#).

In reducing exposure to radiation there are three factors that interact; time, distance and shielding. The interplay of these factors is a common theme throughout [Chapter 61](#). In an area where the dose rate is significant it is self evident that the dose received is directly proportional to the time spent there. The time should therefore be restricted to the minimum required to perform the necessary tasks. The fact that dose rates from a small source of radiation decrease as the inverse square of the distance from the source means that increasing the distance from the source can be very effective in reducing the dose rate. In brachytherapy, for example, the use of long forceps to handle sources is essential, but the distance factor is also an important part of shielding calculations for external-beam therapy. When time and distance are insufficient to reduce dose rates to a safe level, or in order to further improve staff protection, it is necessary to introduce shielding. This is obviously the case for the walls of a room in which teletherapy equipment or high-dose-rate brachytherapy equipment is located. Shielding is also needed for transportation of sources and for sealed or unsealed source handling. However, it should be borne in mind that individual protective shielding reduces mobility and may therefore conflict with the need to reduce the time. This becomes a consideration when deciding whether it is appropriate to wear protective clothing, which will encumber the operator.

With unsealed sources, personnel are exposed to the risk of both external exposure and contamination. Contamination may result in radioactive particles being incorporated into body tissues, either through superficial skin contamination or inhalation or ingestion. The protection against such risks is dealt with in [Section 61.3.4](#).

Radiation protection should also address the issue of protection of the patient in terms of ensuring that the dose delivered to the target as well as to surrounding normal tissues is as intended. This is the role of the quality assurance measures described in Part H and is the reason that radiation safety regulators have an interest in the oversight of radiotherapy. It is well known that radiation is a carcinogen as well as being a cure for cancer and there is growing interest in second malignancies that may arise as a result of treatment (NRPB 2000; Bhatia et al. 2003). These issues are briefly considered at the end of the Chapter 61.

59.3.6	Risk Assessment . . . . .	1243

## 59.1 BASIC CONCEPTS

### 59.1.1 DETERMINISTIC AND STOCHASTIC EFFECTS

In Part B, Gordon Steel describes the process whereby ionising radiation acts directly on the DNA of the nucleus causing cell death, as well as the mechanisms for subsequent repair. For large doses of radiation, the damage, which may occur early or late in the life of the organism, is more or less predictable and its severity may be determined by the magnitude of the dose and the timing of its delivery. For this reason, such damage is described as *deterministic*. In general, the dose-response function is sigmoid and exhibits a threshold. This threshold is large compared to the doses that will be experienced by staff and public, and with the rare exception of the foetus of a pregnant patient undergoing therapy, deterministic effects will not be discussed within this chapter\*.

At low doses, cellular repair mechanisms will usually take place and the organism suffers no damage. Occasionally, the cellular repair process may be imperfect, with the result that cells retain their ability to replicate, but with coding damage to the DNA that causes the propagation of errors in succeeding generations of cells. The consequence of this might ultimately be cancer, or if the somatic cells of the gonads are involved, the production of genetic effects in successive generations.

The consequences of this damage may be catastrophic for the individual in whom it occurs. However, as it potentially requires only one nucleus to be damaged, the magnitude of the dose determines its *likelihood* rather than its *severity*. For this reason, damage of this nature is described as *stochastic* (i.e. determined by chance).

To estimate the effect of low doses of radiation, it is necessary to know the risk (i.e. the *probability*) of cancer induction or hereditary effects as a function of exposure to radiation.

### 59.1.2 EQUIVALENT DOSE

Before considering the effects of low doses of radiation on the human body, the appropriate units in which to express the dose will be discussed. The efficacy of ionising radiation will be determined not only by the biological sensitivity of an individual organ, but also by the density of ionisation produced in the vicinity of the cell nucleus. Particles such as  $\alpha$ -particles and neutrons are densely ionising. This is represented in terms of the linear energy transfer (LET), which for these particles is high (see also Chapter 49). The *unrestricted linear energy transfer* is defined as  $dE/dl$ , where  $dE$  is the energy lost by a charged particle in traversing a distance  $dl$ . High-LET particles will be more damaging for a given physical dose because they are able to cause multiple damage within an individual cell. This leads to the definition of  $Q(L)$  (ICRP 1990), which is the *quality factor* as a function of unrestricted linear energy transfer,  $L$ . ICRP defines this as 1 for  $L < 10$ ; as  $(0.32L - 2.2)$  for  $L$  between 10 and 100, and as  $300/\sqrt{L}$  for higher values. For radiation protection purposes, a simpler quantity is required whose magnitude is likely to be related to the biological effects of the radiation. For this purpose, the *equivalent dose*<sup>†</sup> was defined in 1977.

---

\* The statement that the damage at high doses is predictable and determined by the dose is simplistic. Damage to individual cells will be randomly determined. Organ damage results from damage to large numbers of individual cells and this smooths out random fluctuations giving rise to the well known sigmoid curve. The gradient of the curve is an indication of the statistical nature of the process.

<sup>†</sup> The terms *equivalent dose* and *dose equivalent* are often used interchangeably. Strictly *dose equivalent* should be used for the product of absorbed dose and *quality factor*, where the quality factor is defined in terms of the LET. *Equivalent dose* should be used for the product of the absorbed dose and the *radiation weighting factor*, which is defined by ICRP in terms of the type and energy of the radiation, as in Equation 59.1. ICRP (2007) is proposing to replace the term *equivalent dose* with *radiation-weighted dose*.

The equivalent dose,  $H_T$ , to an organ, T, exposed to a mixture of radiations, R, is defined as

$$H_T = \sum_R W_R D_{T,R} \quad (59.1)$$

where  $W_R$  is a dimensionless weighting factor appropriate to radiation R,  $D_{T,R}$  is the dose in Gy to the organ T, and  $H_T$  is the equivalent dose.

To differentiate the equivalent dose from the physical dose defined in [Chapter 6](#), its unit has been given a special name, the sievert (Sv). When  $D_{T,R}$  is expressed in gray (Gy),  $H_T$  is expressed in Sv. In radiation protection, it is often useful to refer to millisieverts (mSv) or microsieverts ( $\mu$ Sv).

For photons and electrons, the value of  $W_R$  is 1 and consequently the physical dose (Gy) and the equivalent dose (Sv) are numerically identical. For protons,  $W_R$  is 5 and for  $\alpha$ -particles 20. The value for neutrons varies continuously with energy between 5 (at very low and very high energies) and 20 (between 0.1 MeV and 2 MeV) (ICRP 1990). Ideally, a dosimeter calibrated to read in mSv should have an energy response that matches the weighting factor curve, but this is not easy to achieve in practice. The draft ICRP publication\* (ICRP 2006d) recommends a numerical formula for neutrons of energies greater than 1.0 MeV:

$$W_R = 5.0 + 17.0 \exp\left[\frac{-(\ln(2E_n))^2}{6}\right] \quad (59.2)$$

where  $E_n$  is the energy of the neutrons. For energies below 1 MeV, the formula becomes:

$$W_R = 2.5 + 18.2 \exp\left[\frac{-(\ln E_n)^2}{6}\right] \quad (59.3)$$

### 59.1.3 EFFECTIVE DOSE

The discussion thus far has assumed that all body tissues are equally irradiated. This will often not be the case and it is then necessary to assess the likely effect taking doses to individual organs into effect. To facilitate this, the concept of *effective dose* has been defined.

The effective dose,  $E$ , to the individual is defined as:

$$E = \sum_T W_T H_T \quad (59.4)$$

where, considering each organ, T, within the body,  $H_T$  is the equivalent dose defined in equation 59.1 and  $W_T$  is a weighting factor which takes into account the ability of that organ to contribute to the overall risk of harm. By definition:

$$\sum_T W_T = 1 \quad (59.5)$$

This double summation is used to calculate the effect of nonuniform irradiation on the body where individual organs have differing individual sensitivities to ionising radiation. Values of  $W_T$  are given in [Table 59.1](#). The derivation of the values in this table will be explained in [Section 59.2.8](#), but we first need to consider the issue of risk estimation.

---

\* These formulae should not be used until the new ICRP recommendations are published.

**TABLE 59.1**

Weighting Factors for Different Body Organs Recommended by ICRP

Organ	Weight, $W_T$ (ICRP 1990)	Proposed (ICRP 2006b) Weight, $W_T$
Gonads	0.20	0.08
Red bone marrow	0.12	0.12
Colon	0.12	0.12
Lung	0.12	0.12
Stomach	0.12	0.12
Bladder	0.05	0.04
Breast	0.05	0.12
Liver	0.05	0.04
Oesophagus	0.05	0.04
Thyroid	0.05	0.04
Skin	0.01	0.01
Brain	Included in remaining organs	0.01
Salivary glands	Not specifically included	0.01
Bone surfaces	0.01	0.01
Remaining organs	0.05 <sup>a</sup>	0.12 <sup>b</sup>

<sup>a</sup> The remaining organs are adrenals, brain, upper large intestine, small intestine, kidney, muscle, pancreas, spleen, thymus and uterus.

<sup>b</sup> The ICRP (2006c) list is adrenals, extrathoracic airways, gall bladder, heart wall, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate, small intestine, spleen, thymus and uterus/cervix. The new weighting factors should not be used until the new recommendations are published by ICRP.

## 59.2 RISK ESTIMATION

The exponential attenuation of x- and  $\gamma$ -rays in passing through protective barriers means that it is impossible to completely eliminate exposure of staff and public arising from the use of ionising radiation in medicine and they will in any case be exposed to natural background radiation. Natural background radiation is responsible for a worldwide average dose of 2.4 mSv per year, of which 1.2 mSv is due to radon and its daughter products (Thorne 2003). The risk associated with the genetic effects of radiation is smaller than the risk of induction of cancer (UNSCEAR 2001), so it is the latter that is the principal consideration in determining dose limits. It is also important to ensure that the costs of reducing exposure to a given level are commensurate with the benefits (i.e. reduction in the excess incidence of cancer) so obtained. This cost benefit comparison cannot be made without knowledge of the risk of developing cancer as a function of exposure.

To calculate the risk associated with radiation it is necessary to have a model for the effect of the radiation. In a given unirradiated population, there will be a certain incidence of cancer that will depend on the population and will vary with factors such as age and gender. The system of risk estimation seeks to establish the excess risk of dying of cancer, together with an allowance for associated morbidity, resulting from a specific equivalent dose of radiation. Useful reviews of the issues involved are contained in the UNSCEAR reports (2000, 2001) and in the review article by Little (2003).

### 59.2.1 SOURCES OF DATA FOR RISK ESTIMATES

The qualitative evidence for the carcinogenic nature of ionising radiation comes from a variety of sources. These are listed in Table 59.2. Although most of these establish beyond doubt that ionising radiation is carcinogenic, very few of them provide good quantitative

**TABLE 59.2**  
Sources of Data for Risk Estimations

Exposed human populations
Atomic bombs
Japanese survivors
Marshall Islanders
Medical therapy
Pelvic radiotherapy (cervix)
Spinal radiotherapy (ankylosing spondylitis)
Neck and chest radiotherapy (thyroid)
Treatment of Hodgkins Disease
Scalp irradiation (tinea capitis)
Breast radiotherapy
Radium treatment
Medical diagnosis
Multiple fluoroscopies (breast)
Prenatal irradiation
Thorotrast injections
Occupational
Uranium miners
Radium ingestion (dial painters)
Registered radiation workers

data, and it is fair to say that almost our entire knowledge of risk estimates arises from the prolonged and ongoing studies of survivors of the atomic bombs dropped on the Japanese cities of Hiroshima and Nagasaki. These studies have relied on observations of the excess incidence of cancer and the correlation of these observations with estimates of exposure made on the basis of mathematical modelling and thermoluminescent dosimetry (using building materials exposed at the time of the explosions). These risk estimates are handicapped by the fact that the data are obtained from persons exposed to large doses of radiation delivered more or less instantaneously whereas the effects of small doses received over prolonged periods of exposure are of primary interest here. They are also handicapped by lack of precision in the dose estimates, the fact that many of those exposed are still alive and may still yet develop cancer, and the difference in the response to radiation between different population groups.

Studies of large groups of workers occupationally exposed to low levels of radiation are beginning to yield results. However, the data are subject to such large uncertainties that it is only possible to say that the risk coefficients are not inconsistent with those yielded by studies of atomic bomb survivors (Cardis et al. 1994; NRPB 2000). A more recent analysis with larger numbers in the U.K. was also consistent with these data (Muirhead et al. 1999). Data from many sources continue to be monitored by UNSCEAR (2000) and others.

Evidence for hereditary effects comes from animal studies with mice. There is no evidence of hereditary damage in the offspring of atom bomb survivors, but an estimate of the risk of genetic effects is made on the basis of these animal studies together with recent knowledge of the mutation rate in humans. These sources of data lead to an estimate of the doubling dose for mutations (i.e. the dose that will result in twice as many mutations as occur naturally) of 1 Sv (UNSCEAR 2001). This estimate of the doubling dose has been stable for a number of years, but the estimate of the genetic risk associated with the doubling dose of 1 Sv is subject to considerations such as whether a mutation is compatible with a live birth and whether its consequences are lethal. ICRP 60 (1990) gave the risk associated with doubling the number of mutations as 1 case in 100 live births (1%), but more recent risk estimates are as low as 1 in,

330 (BRER 2006). In any case, it is clear that the principal risks are of cancer induction rather than the genetic risk.

### 59.2.2 DOSE AND DOSE-RATE EFFECTIVENESS FACTOR

Current risk estimates are based on the assumption that risks are given by a linear quadratic function of dose (or equivalent dose):

$$f(D) = (\alpha_1 D + \alpha_2 D^2) \exp[-(\beta_1 D + \beta_2 D^2)]$$

where  $f(D)$  is the risk estimate at dose  $D$ , and  $\alpha_1$  and  $\alpha_2$  are coefficients of the linear and quadratic terms for the induction of stochastic effects.  $\beta_1$  and  $\beta_2$  are terms representing cell killing at higher doses (UNSCEAR 2000). There is some direct evidence from the observed incidence of leukaemia as a function of dose amongst the atomic bomb survivors that the response is indeed linear quadratic, but for solid cancers it is likely that a linear relation is the best fit to the data and the quadratic term is zero. At the low dose rates encountered in occupational and public exposure it is to be expected that repair processes can mitigate the effect of the radiation so that the effect is less than the effect at the high doses ( $>200$  mSv) received by the atom bomb survivors. To express this reduction in effect at low doses, it is therefore appropriate to reduce the estimate of risk by a factor called the *dose and dose-rate effectiveness factor* (DDREF). The ICRP (1990) recommends that the risks estimated on the basis of high-dose irradiation should be reduced by approximately a factor of two.

### 59.2.3 LOW DOSE THRESHOLD THEORIES

Because of the low incidence of radiation-induced cancer compared to the natural incidence of the disease, there is little direct evidence of the magnitude of the risk for doses below 200 mSv. The possibility of a threshold below which radiation is not harmful is a subject of much controversy. Studies of large cohorts, such as the study of British radiologists, have failed to show any increased risk associated with the low doses they received (Berrington et al. 2001). Some have argued that very small doses of radiation may even be beneficial (so-called *radiation hormesis*) (Cameron and Moulder 1998), bearing in mind the existence of natural background radiation. The Board on Radiation Effects Research (BRER 2006), ICRP (1990, 2006a) and the radiation protection community have, however, taken the view that in the absence of clear evidence to the contrary, a linear no-threshold model should be assumed. An excellent review of these issues is given by Johansson (2003). There is also a view that the effect of radiation at low doses is underestimated by the linear model (Hall 2004). The majority view of the Committee Examining Radiation Risks of Internal Emitters (CERRIE 2004) is that the linear no-threshold model is the most appropriate.

### 59.2.4 RELATIVE AND ABSOLUTE RISKS

The risk of cancer induction can be expressed either as an *added* absolute risk or as the excess *multiplicative* risk relative to the normal risk of contracting cancer. The *excess absolute risk* (EAR) model assumes that a unit of exposure results in an absolute number of increased cancers. The *excess relative risk* (ERR) model defines risk as a multiplicative factor per unit exposure operating on the natural risk, in the absence of radiation, for a given cancer in a given population. The justification for this model derives from the possibility that cancer induction is a multi-step process of which radiation is not the only factor. In extrapolating from the risk measured in the group of Japanese atomic-bomb survivors (in which men of military age were

under-represented) to other population groups in other parts of the world where the natural incidence of cancer may be different, the relative risk model has been preferred. Relative risks are also particularly appropriate when considering irradiation at a young age (BRER 2006). However, there is some evidence in particular cases, for example breast (Preston 2002) and leukaemia (Little 2003), that the excess absolute risk model provides a better correlation of cancer incidence and exposure than the excess relative risk model. In any case the aim is to estimate the absolute increase in risk in a given population.

### 59.2.5 EFFECT OF AGE AT EXPOSURE AND LIFETIME RISK

Cancer induction by radiation has a latent period which is generally taken to be 10 years for solid cancers and 2 years for leukaemia. It might be expected that the risk of dying of cancer following a single radiation episode would peak after a few years and would then revert to the background level. This has only been demonstrated for leukaemia (NCRP 1993); for other cancers, it appears that the effect of a radiation exposure continues indefinitely. The issue can only be resolved when the younger atomic bomb survivors have died. Because the onset of cancer may occur at any time after the irradiation, we need to consider the excess lifetime risk (ELR). However, because everyone has to die of something, the ELR for all causes is zero because, for example, an increase in cancer as cause of death will be associated with a reduction in heart disease as a cause of death. The UNSCEAR report (2000), therefore, recommends the *risk of exposure-induced death* (REID) as a measure of the impact of radiation exposure. It may also be useful to consider the *loss of life-expectancy* (LLE). It might be expected that because of the greater length of time during which the cancer has time to occur, the number of excess cancer deaths would be greater for those irradiated at a young age than for those irradiated late in life. However, although there is an increased risk for those exposed during childhood, for adults the REID is found to vary little with the age at exposure (UNSCEAR 2000), although this remains controversial. This can be explained on the basis that multiple events are necessary for cancer induction so that the latency for older people will be less than for younger ones (BRER 2006). This will be particularly relevant when considering second cancers associated with radiotherapy treatment (see [Section 61.5.2](#)).

### 59.2.6 THE CONCEPT OF DETERIMENT

To quantify the risk associated with radiation, it is necessary to have some measure of the damage done by the radiation. The negative impact of radiation varies in severity from death at one extreme, to the induction of an easily cured cancer at the other. The ICRP uses the concept of *detriment* as a measure of the total negative impact on health that would eventually be experienced by an exposed group and its descendants as a result of exposure to radiation. The definition of *detriment* in Report 26 (ICRP 1977) used the expected number of cases of a radiation-induced health effect, weighted by the severity of the effect. The weighting factor was 1 for death, with smaller factors for other less severe effects. Although the number of cancer deaths arising from a certain amount of radiation is relatively unambiguous, the impact of the nonfatal cancers is harder to quantify and consequently the detriment calculation can be complicated.

### 59.2.7 RISK COEFFICIENTS

To calculate the detriment associated with the exposure, it is necessary to know the probability that a given dose will result in harm. The probability of injury or harm (detriment) per unit equivalent dose is called the *risk coefficient* arising from a particular *risk factor*. Detriment values for whole-body exposure are given in [Table 59.3](#). Also shown are the proposed values in

**TABLE 59.3**

Nominal Risk Coefficients (i.e. Probability) for Stochastic Effects

Exposed Population	Detriment ( $10^{-2} \text{ Sv}^{-1}$ )			Total
	Fatal Cancer	Nonfatal Cancer	Severe Hereditary Effects	
Adult workers	4.0 (4.1) <sup>a,b</sup>	0.8	0.8 (0.1) <sup>a,b</sup>	5.6 (4.2) <sup>a</sup>
Whole population	5.0 (5.5) <sup>a,b</sup>	1.0	1.3 (0.2) <sup>a,b</sup>	7.3 (5.7) <sup>a</sup>

<sup>a</sup> Figures in brackets are the proposed values from the report of ICRP Committee 1 (ICRP 2006c).

<sup>b</sup> In the proposed ICRP recommendations the detriment from fatal and nonfatal cancers is combined by estimating the detriment associated with a nonfatal cancer.

Source: From ICRP (International commission on Radiological Protection), ICRP Publication 60, Recommendations of the International Commission on Radiological Protection, *Ann. ICRP*, 21, 1990.

the draft ICRP report in which the detriment associated with fatal and nonfatal cancer is combined.

### 59.2.8 RISK COEFFICIENTS FOR PARTIAL BODY IRRADIATION

As described in [Section 59.1.3](#), when only part of the body is irradiated we can use the effective dose to estimate the detriment. In practice, the values in Table 59.3 are derived by first considering the detriment for individual organs separately. Data from ICRP 26 (1977), ICRP 60 (1990) and the draft 2007 recommendations (ICRP 2007) are shown in [Table 59.4](#).

The calculation starts with an estimate of the cancer incidence and the number of cancers that result in the death of the patient\*. Patients who die are said to have suffered a relative detriment of 1.0. It is, however, recognised that cancer treatment is also traumatic and those who do not die also suffer some detriment. To represent this a weighting factor, or relative detriment, is required which will be used as a multiplier for the number of cancer survivors so that they can be added to the number who die to obtain an effective, or *lethality adjusted*, number of *fatalities*. This weighting factor was numerically equal to the lethality fraction in ICRP 60, but in the new draft it is proposed to modify this slightly for the more curable cancers to ensure that there is a minimum factor. Different cancers result in different numbers of years of life lost and a further weighting factor is applied representing the relative life lost. This produces a figure for the overall detriment for each cancer. The weighting factors in [Table 59.1](#) are based on the relative detriment, although somewhat simplified.

The ICRP calculations based on effective dose are intended to be used to calculate the effect of irradiation on large numbers of people—either the adult population if the irradiation is occupational exposure, or the whole population. They are not intended to calculate the expected detriment to a particular individual. Effective dose is not appropriate for use when high doses are delivered to individual organs (ICRP 1990; CERRIE 2004).

Note the improvement in the cure rates of cancer between the ICRP 1990 and ICRP 2006c reports. The increase in the estimate of the number of breast cancers caused by radiation is also noteworthy. The current estimate of the impact of genetic effects is significantly reduced. This is because of the lack of evidence of such effects, perhaps associated with the unviability of mutated cells.

\* In ICRP 60 and ICRP 26, the data are presented as shown in Table 59.4 in terms of the total number of fatal cancers. In the new draft the data are presented starting with cancer incidence and have been adapted in the table to be consistent with the earlier documents. The reader is referred to the reports themselves for a full discussion of the concepts used. A somewhat simplified discussion is given here to bring out the salient points and to assist the reader's understanding of the reports.

**TABLE 59.4**

Fatal Risk Coefficients (Probabilities) and Detriment for Individual Organs. Values Represent the Total Number of Deaths per Year among a Population of 10,000 of All Ages Receiving a Dose of 1 Sv

Organ	ICRP 26 (1977)		ICRP 60 (1990)			Proposed ICRP		
	Fatal Cancers	Fatal Cancers <sup>a</sup>	Lethality	Detriment	Fatal Cancers <sup>a</sup>	Lethality	Detriment	
Gonads		100 <sup>a</sup>		133.3	16 <sup>a</sup>	0.80	25.4	
Ovary		10	0.67	14.6			9.9	
Red bone marrow	20	50	0.99	104.0	28	0.67	61.5	
Colon		85	0.55	102.7	31	0.48	47.9	
Lung	20	85	0.95	80.3	101	0.89	90.2 <sup>b</sup>	
Stomach		110	0.90	100.0	65	0.83	67.7	
Bladder		30	0.50	29.4	12	0.29	16.7	
Breast	25	20	0.50	36.4	33	0.29	79.8	
Liver		15	0.95	15.8	29	0.95	26.6	
Oesophagus		30	0.95	24.2	14	0.93	13.1	
Thyroid	5	8	0.10	15.2	2	0.07	12.7	
Skin		2	0.00	4.0	2	0.002	4.0	
Bone surfaces	5	5	0.70	6.5	3	0.45	5.1	
Remaining organs	50	50	0.71	58.9	71	0.49	113.5	
Total	125	500 <sup>a</sup>		725.3	414 <sup>a</sup>		574	

We will use the instance of oesophagus cancer to show how the calculation works, using the figures from the draft document. If 1 Sv is given to 10,000 people, 17 will contract oesophagus cancer and of these 93% will die. The 1.9 survivors will have suffered severely from their treatment and will probably suffer lasting side effects. Thus instead of recording 15.8 lethal cancers the 1.1 survivors are said to have suffered a detriment of 0.937 so the effective number of deaths is 16.9. This is multiplied by the relative cancer free life lost (0.87) to give a detriment of 15.

- <sup>a</sup> Note that the values given for the gonads are for fatalities related to hereditary effects. These values have not been added to the totals.
- <sup>b</sup> As an example of how the calculation is carried out this figure is obtained as follows. If 1 Sv is given to 10,000 people, 114 will contract lung cancer and of these 89% will die. The 13 survivors will have suffered severely from their treatment and will probably suffer lasting side effects. Thus instead of recording 101 lethal cancers as the detriment, each of the survivors are said to have suffered a quality of life detriment of  $0.1 + 0.89(1 - 0.1) = 0.901$ ; so the effective number of lives lost is 113. This is multiplied by the *relative life lost* (0.80) to give a detriment of 90.

**Sources:** From ICRP (International Commission on Radiological Protection), Publication 26, Recommendations of the International Commission on Radiological Protection, *Ann. ICRP*, 1, 1977; ICRP, ICRP Publication 60. Recommendations of the International Commission on Radiological Protection, *Ann. ICRP*, 21, 1990. The figures in the final three columns are from the draft of the revised ICRP recommendations and represent the trends of ICRP thinking. They should not be taken as definitive values. ### 59.2.9 EFFECT OF RADIATION ON THE DEVELOPING FOETUS

Studies of the offspring of mothers pregnant at the time of the Hiroshima and Nagasaki bombs have shown a number of deterministic effects on the brain of the developing foetus. These effects, which are summarised in NCRP Commentary Number 9 (NCRP 1994) and in ICRP Report 84 (2000), are strongly linked to the post-conception age of the foetus. They include mental retardation, loss of Intelligence Quotient (IQ) points and small head size. Their incidence is greatest in the period from 8 weeks to 15 weeks post conception, is smaller between 16 weeks and 25 weeks and very low, or absent, subsequently (Otake and Schull 1998). The effects occur at low doses, perhaps as low as 100 mSv, and their incidence is

consistent with either linearity or a threshold dose of the same value. Prior to 2 weeks post conception, the most likely effect of radiation is reabsorption of the embryo. Growth retardation either as an adult or at birth can result from radiation at almost any subsequent time.

In utero exposure to x-rays for diagnostic purposes has long been linked to an excess risk of childhood cancer (Stewart et al. 1956). Wakeford and Little (2003) conclude that there is good evidence for an increased risk of cancer following foetal irradiation of 10 mSv. However, studies of Japanese children irradiated in utero by the atomic bombs indicate that the risks of irradiation in utero and in the first six years of life are similar (Delongchamp et al. 1997), but the studies also support the possibility of a higher risk in the first trimester of pregnancy. Risks of irradiation in childhood are up to 10 times greater than in adulthood (Little 2003).

## 59.3 PRINCIPLES OF RADIATION PROTECTION

### 59.3.1 PRACTICES AND INTERVENTIONS

In establishing the framework of radiation protection, the ICRP (1990, 1998) divides its areas of concern into *practices* and *interventions*. *Practices* cover those activities that lead to an increase in the overall exposure to radiation. However, much radiation exposure is either the result of naturally occurring activity (such as radon) or of accidental or inadvertent manmade contamination (such as the Chernobyl disaster). In these cases, any radiation protection activity has to be by way of an intervention in the lives of people who have no choice about their involvement. In these circumstances, ICRP recognizes that the human cost of removing the hazard may be greater than the benefit associated with the reduction in radiation dose.

In what follows, only those parts of radiation protection that involve the management of dose from practices will be considered.

### 59.3.2 BASIS FOR DOSE REGULATION

The assumption that there is no threshold dose below which damage cannot occur, leads us to the conclusion that no dose can be regarded as *safe* (however, see [Section 59.2.3](#)). On the other hand, it is not possible to reduce the dose to staff, patients and public to zero. The problem becomes one of finding an acceptable framework of compromise that allows the benefits patients derive from exposure to radiation to be balanced against the unavoidable potential harm incurred by staff and the public.

ICRP 60 (1990) provides us with the necessary framework to do this by means of the three principles of justification, optimisation and limitation:

- *Justification*: no practice shall be adopted unless its introduction produces a net benefit.
- *Optimisation*: all exposures shall be kept As Low As Reasonably Achievable\* (ALARA), economic and social factors being taken into account.
- *Limitation*: the dose equivalent to individuals shall not exceed the limits recommended for the appropriate circumstances.

Optimisation describes the process whereby the net *benefit* is maximised after taking into account the *cost*, however measured, of using ionising radiation. This is discussed further in [Section 59.3.4](#). The magnitude of dose limits is covered in [Section 60.2.2](#). In the present Chapter the theoretical basis for these limits is considered.

\* This is the wording used by both ICRP (1990, 2007) and by the EU legislation (ECD 1996a, 1997). U.K. legislation has changed this to As Low As Reasonably Practicable, ALARP (HS 1999a; HS 2000; IPEM 2002).

### 59.3.3 LIMITATION OF DOSE TO STAFF

Limits are set with a view toward ensuring that no deterministic effects can occur and that risks of stochastic effects are kept acceptably low.

The setting of limits for the avoidance of deterministic effects is a comparatively simple matter in that it requires ensuring that no organ or part of the body can receive a dose above an amount set at a level comfortably below the threshold for any relevant deterministic effect.

If there is no safe threshold dose, setting limits for adverse effects whose chance of occurrence is determined by exposure must involve a value judgement. For staff, it is assumed that the individual exposed gains some benefit, i.e. gainful employment, and the dose level is set at a level where some degree of risk is accepted. Additional limits have been set for occupationally exposed women of child-bearing age, or who are actually pregnant, to ensure that the foetus does not receive a dose greater than an ordinary member of the public.

### 59.3.4 LIMITATION OF DOSE TO THE GENERAL PUBLIC

For public exposure, there is no individual benefit; consequently, the dose limit must be set much lower than for staff. Where large numbers of people are being exposed the detriment is greater than when there are only a few. This low limit takes into account the genetic burden associated with the irradiation of the entire population.

The low value of the dose limits for the public would cause problems when certain groups of persons other than the patient are exposed as a consequence of medical treatment or diagnosis. These persons can be classified as *comforters and carers* and are discussed in [Section 60.2.3.3](#).

### 59.3.5 DOSE CONSTRAINTS

The process of optimisation may involve the application of constraints to individual doses arising from any specific practice. They are prospective figures that are used in planning and represent maximum target values that will be tolerated from that single practice. Although they appear to function as limits in that they specify maximum values, they will usually be lower than the overall dose limit that will be applied to an individual and do not have the legal force of a limit. A constraint of (say) 0.3 mSv applied to the dose arising to a member of the public from a single practice should prevent a limit of 1 mSv being exceeded when all likely artificial sources of radiation have been taken into account (see [Section 60.2.1](#)).

Constraints will also be applied to individual doses where the object of optimisation is to minimise the collective dose, i.e. the sum of all doses to all individuals. Once again, a constraint of 0.3 mSv for any single practice should prevent all members of the public receiving the legal limit of 1 mSv. Further examples of the use of constraints in conjunction with limits will be seen in [Section 60.2.3.3](#) and [Section 61.4.2.2](#). The concept of constraints in radiation protection is similar to the considerations applied to the doses received by *organs-at-risk* in planning radiotherapy, although there are no legal limits in the case of medical exposures.

### 59.3.6 RISK ASSESSMENT

Risk assessment is an essential part of radiation protection practice. A radiological risk assessment should consider fully all risks arising from a single practice taking into account previous relevant knowledge and procedures. Particular attention should be given to the possibilities of failure of each safety control system, assessment of the consequences of such

failure and the development of contingency plans to reduce the consequences of foreseeable failures to acceptable levels.

The U.K. Health and Safety Executive has published a simple guide to the five steps of the risk assessment process (HSE 1998) that involves:

- Identifying the hazards
- Deciding on who might be harmed and how
- Evaluating the risks and deciding whether the existing precautions are adequate and need to be improved
- Recording the findings
- Reviewing the assessment and revising it if necessary

The IAEA (1996) lists the following issues that must be included in a risk assessment:

- The nature and magnitude of potential exposures and the likelihood of their occurrence
- The limits and technical conditions for operation of the source
- The ways in which structures, systems, components and procedures related to protection or safety might fail, singly or in combination, or otherwise lead to potential exposures; and the consequences of such failures
- The ways in which changes in the environment could affect protection or safety
- The ways in which operating procedures related to protection or safety might be erroneous, and the consequences of such errors
- The protection and safety implications of any proposed modifications

The risk assessment should list the actions that are proposed to mitigate any identified risk. Where a risk assessment identifies the possibility of a radiation accident, contingency plans must be drawn up for such an eventuality.

## 60.1 THE REGULATORY FRAMEWORK

Many different organisations are concerned with radiation protection. The International Commission for Radiological Protection (ICRP), originally founded in 1928 by the International Society of Radiology (ISR), is an international body with charitable status whose remit is to function as an advisory body providing recommendations and guidance on radiation protection. It operates through a number of task groups convened for specific purposes and is composed of a main commission and four standing committees dealing with radiation effects, doses from radiation exposure, protection in medicine, and the application of ICRP recommendations\*. A sister organisation, the International Commission on Radiological Units (ICRU), deals largely with issues related to the measurement of ionising radiation\*.

The International Atomic Energy Agency (IAEA) serves as the world's central inter-governmental forum for scientific and technical co-operation in the nuclear field, and as the international inspectorate for the application of nuclear safeguards and verification measures covering civilian nuclear programmes\*. A specialised agency within the United Nations system, the IAEA came into being in 1957. It deals specifically with the safe generation of nuclear energy and defines many of the procedures and criteria required. The IAEA recommendations for radiation protection are contained in the Basic Safety Standards (BSS, IAEA 1996). The BSS represents an internationally agreed standard that has, in principle, been accepted by all member states and is based on the recommendations of the ICRP. The BSS sets out the requirements for a framework to regulate radiation safety in each country, including the need to investigate "any therapeutic treatment delivered to either the wrong patient or the wrong tissue, or using the wrong pharmaceutical, or with a dose or dose fractionation differing substantially from the values prescribed by the medical practitioner or which may lead to undue acute secondary effects". The IAEA will carry out accident investigations if requested by a member state (e.g. IAEA 2001).

In the U.S.A., radiation protection legislation is a responsibility of each individual state and significant variations are found between adjacent states. The National Council on Radiation Protection and Measurements (NCRP\*) provides advice to legislators in a way similar to the Health Protection Agency (HPA)\*<sup>†</sup> in the U.K.

Within the European Union, requirements for legislation are imposed on member states by means of directives that specify an obligation to achieve certain objectives, but do not directly formulate the legislation by which these objectives will be attained. The publication of ICRP 26 (1977) led directly to the adoption by the European Community in 1980 of Council Directive 80/836/Euratom (ECD 1980) (subsequently amended by Council Directive 84/467/Euratom (ECD 1984b)). This Directive laid down basic safety standards for the protection of workers and public against the dangers of ionising radiation and became known as the Basic Safety Standards (BSS) Directive. A new Basic Safety Standard was adopted in 1996 and published as Council Directive 96/29/Euratom (ECD 1996a). In parallel with this, protection of the patient was covered by the 1984 Directive 84/466/Euratom (ECD 1984a) and later by the 1997 Medical Exposure Directive 97/43/Euratom (ECD 1997) known as the *patient Directive*. After an European Council of Ministers directive has been published, it is the responsibility of each member state to interpret the directive into its own legislative framework. In what follows the U.K. legislation will often be used as an illustration of the general principles. In addition, a note on the U.K. implementation of the directives is provided in [Appendix L.1](#).

## 60.2 PROTECTION OF STAFF AND THE PUBLIC

### 60.2.1 DESIGNATED AREAS

Control of exposure to radiation is achieved partly by the *designation* of areas of work where there is a potential for such exposure.

The BSS (ECD 1996a; IAEA 1996) designates two levels of control: *controlled areas* that are areas “subject to special rules for the purposes of protection against ionising radiation and to which access is controlled” and *supervised areas*, where occupational exposure conditions need to be kept under review. The European Council Directive requires that member states should provide guidance on the circumstances that would require an area to be controlled. In Great Britain\*, the guidance defines a controlled area as one in which it is likely that persons could be exposed to more than three tenths of any applicable dose limit (i.e. an effective dose greater than 6 mSv a year), but requires that specific arrangements should be made for all areas where there is a possibility of exposure exceeding the general public limit of 1 mSv (HS 2000). For an area to be unsupervised, the regulations (ECD 1996a; HS 1999a) set a limit of 1 mSv/year, but a limit of 0.3 mSv/year for any single source of radiation is recommended by the NRPB and the IPEM (2002). The Medical and Dental Guidance Notes (MDGN, IPEM 2002, see [Appendix L.1](#)) provide detailed recommendations on the designation of areas which are reproduced in [Table 60.1](#). This table refers to three different ways of considering the dose limit. The *instantaneous dose rate* (IDR) is the dose rate averaged over 1 min. The *time averaged dose rate* (TADR) is the dose rate averaged over an 8 h day, taking into account use and workload but with an occupancy factor of 1 (for the use of the TADR see [Section 61.1.3](#)). Finally, TADR 2000 is the dose rate taking into account all factors, including occupancy averaged over 2000 h, which is considered to be the working year for an office worker. The 3 mSv/h for the TADR 2000 is directly derived from the 6 mSv per annum limit. 7.5 mSv/h<sup>†</sup> allows for an occupancy factor of 0.4. If the recommendation derived from the TADR and the TADR 2000 conflict, Appendix A of the MDGN provides a decision tree that determines the outcome depending on whether the area is open to the general public or not.

The definition of an area as controlled could be either in terms of prescribed dose rates for external radiation, prescribed levels of air concentration or surface contamination for potential internal radiation, or a combination of the two.

Entry within controlled areas, which must be adequately demarcated, is restricted to classified workers or those entering under a written system of work designed to restrict their exposure. Local rules (see [Appendix L.3](#)) must be in existence to ensure that all persons entering a designated area restrict their exposure and one or more radiation protection officers or supervisors must be appointed to ensure that work is performed in compliance with these local rules.

### 60.2.2 LOCAL RULES

The local rules must adequately describe the area and the procedures to be followed within that area. They should also contain the name of the radiation protection supervisor. All persons working under such local rules are required to have read them. Monitoring must be in place to demonstrate that doses are adequately restricted.

\* Different rules apply in Northern Ireland.

<sup>†</sup> IPEM Report 75 recommended that new rooms should be designed to limit the IDR to 7.5 µSv/h. This figure was given expecting a tightening of the regulations, but is superseded by IPEM 2002.

**TABLE 60.1**

IPEM Guidance on Radiation Levels Defining Controlled and Supervised Areas

	Controlled ( $\mu\text{Sv/h}$ )	Supervised ( $\mu\text{Sv/h}$ )	Unsupervised ( $\mu\text{Sv/h}$ )
Instantaneous dose rate (IDR)	> 2000	> 7.5	< 7.5
Time averaged dose rate (TADR)	> 7.5	> 2.5	< 0.5
Time averaged dose rate over 2,000 h (TADR 2000)	> 3	> 0.5	< 0.15

### 60.2.3 DOSE LIMITS FOR STAFF AND PUBLIC

Dose limits are set in terms of effective dose in order to restrict stochastic effects and equivalent organ doses to limit deterministic effects. The widely accepted dose limits recommended by ICRP (1990) are set for specific groups as follows.

#### 60.2.3.1 Employees

Annual limits recommended by the European Union (EU) and ICRP for employees over the age of 18 are an annual effective dose (see [Section 59.1.3](#)) of 20 mSv averaged over a five-year period\*, but subject to an annual limit of 50 mSv. Annual limits for equivalent doses (see [Section 59.1.2](#)) are set as 150 mSv for the lens of the eye and 500 mSv for hands, forearms, feet, ankles and any area of skin averaged over  $1\text{ cm}^2$ . These limits are reduced to three tenths of the above values for employees under 18 years of age. An employer is obliged to ensure, subsequent to notification of a pregnancy, that the equivalent dose to the foetus is unlikely to exceed 1 mSv in the remaining period of the pregnancy and that, whilst breastfeeding, an employee cannot incur significant radioactive contamination†.

The current limits on effective dose are lower than those previously defined because of the change in risk coefficients when the ICRP 60 recommendations replaced ICRP 26. Although there was no change in the estimate of the dose response for deterministic effects, the area over which skin doses can be averaged has been reduced from  $100\text{ cm}^2$  to  $1\text{ cm}^2$ , which effectively lowers the skin dose limit.

#### 60.2.3.2 Other Persons

Although there is no clearly defined threshold for negligible risk, analysis of general human behaviour indicates that individuals are prepared to neglect risk at a range of values according to the activity being undertaken. At currently accepted estimates of risk for the general public (see [Table 59.3](#)), a dose of 1 mSv leads to an average risk of  $5 \times 10^{-5}$  and has been recommended by ICRP as the annual public dose limit (excluding exposure from natural radiation). An annual dose constraint of 300  $\mu\text{Sv}$  is applied to public exposure from all new practices.

\* In U.K. law, the possibility of averaging over 5 years is not automatically applicable. If more than 20 mSv are to be received in any one year the employer is required to demonstrate that it is not practicable to keep the annual dose below 20 mSv.

† U.K. legislation additionally requires that for women of reproductive capacity, the equivalent dose averaged throughout the abdomen is restricted to 13 mSv in any three-month period.

Because members of the public are not subject to the same systems of control and thus liable to accumulate doses from different sources of radiation and because the public also includes children, the dose limits for hands, forearms, feet, ankles and skin are reduced by a factor of ten as compared to limits for employees to 50 mSv and 15 mSv for the lens of the eye.

Annual effective dose limits are set to 1 mSv for persons other than an employee aged over 16. This limit might be impracticable where exposure arises as a result of prolonged proximity to persons treated with radioactive substances, and it may therefore be relaxed for individuals (including children) who are exposed to radiation from patients after leaving hospital. A limit of 5 mSv in five consecutive years is applied to such persons.

#### 60.2.3.3 Classification and Monitoring of Staff

The requirements for monitoring of workers depends on the level of dose that they are expected to receive. The European Council Directive defines them as category A workers if there is a possibility that the annual effective dose received may be greater than 6 mSv or exceeds three-tenths of the limits for equivalent doses to specific organs and category B if the dose received is less\*. Category A workers must be subject to systematic dose monitoring and medical surveillance to ensure that they are fit to undertake work with ionising radiation; whereas for category B workers, the monitoring only has to be sufficient to demonstrate that they are correctly classified as category B.

Monitoring nonclassified workers working in controlled areas is important to confirm that dose restriction is adequate, and it is therefore normal to insist that all persons working within a controlled area wear personal dosimeters. Health workers rarely need to be classified as category A workers, but it may be necessary in a few cases, particularly among those who work with radioactive materials. Some previously unclassified staff may need to be classified as a consequence of the limit for skin dose being defined as the dose averaged over 1 cm<sup>2</sup> rather than 100 cm<sup>2</sup>, as was the case with the 1985 recommendations (ICRP 1985). The practice of monitoring hand or mid-finger doses may need to be replaced by monitoring fingertip doses.

#### 60.2.3.4 Dose Limitation in Special Situations: Comforters and Carers

Individuals who are exposed as nonprofessionals in the care and comfort of persons undergoing exposure for medical purposes (known as *comforters and carers* in U.K. legislation) are not subject to the dose limit of 1 mSv for the general public, but all reasonable efforts must be taken to minimise their exposure. This is of particular relevance where young children are hospitalised for unsealed source radiotherapy and when it is desirable for their parents to be nearby. Such persons must have had the risks clearly explained to them and given their agreement to this exposure. It is a requirement of EU legislation that dose constraints be applied to such exposures and that the carer receives the dose knowingly and willingly.

Singleton et al. (2003) have produced guidance on the principles that should be followed and have assessed the magnitude of doses likely to be received in different therapy situations. They conclude that only rarely should it be necessary to invoke the possibility of exceeding a limit of 1 mSv, except in the case of therapy with isotope sources. Guidance on appropriate constraints is also available in the Medical and Dental Guidance Notes (IPEM 2002). A particularly common situation is when family members are exposed by patients who

\* In Great Britain, category A workers are called *classified* workers.

return home following therapy with radioactive substances; this will be considered in detail in [Section 61.4.2.2](#).

#### 60.2.4 QUALIFIED EXPERT (OR RADIATION PROTECTION ADVISER)

Employers, when work with ionising radiation is about to take place, need to seek the advice of a *qualified expert*\* as to whether they need to appoint a qualified expert (ECD 1996a). In general, a qualified expert (RPA) will be required wherever there is a need to designate areas for work with ionising radiation (see [Section 60.2.1](#)) or there is any other significant use of ionising radiation. All hospitals giving radiotherapy will need a qualified expert, who will have a wide range of responsibilities including the evaluation of all procedures where the use of ionising radiation is involved and advising on appropriate shielding and other measures to limit dose.

#### 60.2.5 RISK ASSESSMENT

An obligation to carry out risk assessment is implied by the Basic Safety Standards (ECD 1996a) and is an explicit requirement of U.K. law. A suitable record must be made of all risk assessments. Details of what should be considered are discussed in [Section 59.3.6](#) and further advice can be found in the Medical and Dental Guidance Notes (IPEM 2002).

##### 60.2.5.1 *Critical Examination of Equipment*

The European Council Directive requires that a critical examination of plans for new installations should be carried out by a qualified expert, whereas U.K. legislation requires that this critical examination is carried out once the equipment has been installed. [Table 60.2](#) indicates those radiation protection issues that should be considered in respect of any new installation.

##### 60.2.5.2 *Contingency Planning*

Employers are required to make a hazard assessment before any work with ionising radiation is undertaken. This assessment should be recorded and take account of the likelihood of any accident and the severity of its consequences. Where this assessment indicates that there is a risk of accident, procedures should be in place to minimise this risk and *contingency plans* should be drawn up to deal with possible accidents. These contingency plans should form part of the local rules.

Work with large teletherapy units carries the risk of a source being stuck in the exposed position. Contingency plans must include clear instructions on how the patient should be moved to safety and what data should be noted to assist in assessment of the dose received by the patient. Guidance should also be given on how the unit will subsequently be made safe.

Work with radioactive substances carries the risk of spillage; contingency plans should include instructions on summoning help, preventing the spread of contamination and making the area safe.

---

\* Known in the U.K. as the *Radiation Protection Adviser* (RPA).

**TABLE 60.2**

Components Requiring Critical Examination Before Use

Interlocks	Warning Systems	Safety Design Features	Barriers
Door interlocks	Warning signals	Exposure termination	Maze design and entrance doors where fitted
Emergency off buttons or switches	Entry warning signs	Tube or head leakage	Primary and secondary barriers (position and adequacy of protection for adjacent areas)
Beam off/disable buttons	Beam on indications	Beam filtration and collimators	Protective cubicle and mobile screens
Microswitch interlocks	Indication of selected parameters (e.g. energy, HDR, tube)	Protection of exposure switch against accidental activation	Heating, ventilation, air-conditioning and cable penetrations through barriers
Alignment and filter interlocks	Unambiguous labelling	Fluoroscopy (termination and maximum skin dose rate limitation)	Provision and adequacy of personal protection (drapes, aprons, shields)
Last-man-out systems		Automatic Exposure Control (AEC) (dose rate termination, back-up timer, chamber mode selection)

## 60.3 PROTECTION OF THE PATIENT

### 60.3.1 JUSTIFICATION OF MEDICAL EXPOSURES

Whereas the Basic Safety Standards Directive (ECD 1996a) deals with protection of staff and the general public, a second Council Directive 97/43/Euratom (ECD 1997) deals with protection of the patient and is referred to as the Medical Exposure Directive.

There is no fixed limit for medical exposure of individuals. However, the Directive identifies the duties of the *prescriber*, who is the referring physician or other health professional, and the *practitioner*, who is the person (usually a radiation oncologist) who takes responsibility for the justification, optimisation, and clinical evaluation of the exposure\*. The practitioner may delegate the *practical aspects* of the irradiation to other suitably qualified people (*operators* in the U.K.). The need to justify and optimise individual medical exposures has always been part of the standard practice of radiotherapy, but the Directive makes this a legal obligation and extends the concept to diagnostic exposures.

Justification requires that there is net benefit to the patient from the exposure. In the case of exposures for research purposes, where there may not be a net benefit to the individual patient, it is required that the justification for the exposures shall be considered by an ethical committee.

### 60.3.2 OPTIMISATION OF EXPOSURES

In addition to being justified, the directive requires that exposures must be optimised. Optimisation involves the selection of appropriate equipment and techniques based on adequate information. It also requires that there is appropriate quality assurance.

\* Note that U.K. law uses slightly different terminology as discussed in [Appendix L.1](#).

In determining the optimum approach, it is permissible to consider economic and social factors. The directive requires that exposures are individually planned and that doses to nontarget tissues are as low as reasonably achievable.

### 60.3.3 DIAGNOSTIC REFERENCE LEVELS

Diagnostic reference levels (DRLs) are dose levels in medical radiodiagnostic practices or, in the case of radiopharmaceuticals, levels of activity, for typical examinations for groups of standard-sized patients or standard phantoms for broadly defined types of equipment. These levels are expected not to be exceeded for standard procedures when good and normal practice regarding diagnostic and technical performance is applied, but they do not represent an absolute dose limit. ICRP describes diagnostic reference levels in Publication 73 (ICRP 1996) and has published further recommendations on the internet ([http://www.icrp.org/docs/DRL\\_for\\_web.pdf](http://www.icrp.org/docs/DRL_for_web.pdf))\*. DRLs are an important control in diagnostic radiology and if they are regularly exceeded, an investigation should take place.

The IPEM recommends (2002) that DRLs are not appropriately applied to radiotherapy simulation or CT scanning because of the much higher doses that are going to be given therapeutically. However, the obligation to optimise exposures remains.

### 60.3.4 MEDICAL PHYSICS EXPERT

The European Council Directive creates the requirement for a medical physics expert (MPE) to be closely involved in radiotherapy treatment. The MPE is required to be appropriately trained and gives “advice on patient dosimetry, on the development and use of complex techniques and equipment, on optimization, on quality assurance, including quality control, and on other matters relating to radiation protection” (ECD 1997).

### 60.3.5 OTHER REQUIREMENTS

There are a number of other specific requirements of the European Council Directive:

- Written instructions for radioactive patients leaving a hospital must be provided to restrict the exposure of persons with whom they might come into contact.
- All female patients of child bearing age must be asked whether they might be pregnant or breast feeding where relevant.
- A clinical audit must be carried out.
- Equipment at any site should be limited to that which is necessary to prevent unnecessary proliferation of equipment.
- Adequate training for staff must be provided and recorded; training must include continuing professional development.
- Written procedures must exist for medical exposures together with written protocols for every type of radiological practice for each piece of equipment.

---

## 60.4 LICENSING ARRANGEMENTS

The IAEA Basic Safety Standards (1996) require that all radiation work is appropriately licensed. This is reflected in the EU requirement for prior authorisation of such work.

---

\* A new ICRP report entitled “Radiological Protection in Medicine” was put out for consultation in January 2007.

The licensing arrangements differ from one country to another, but have the common goal of ensuring that the uses of radiation are appropriately controlled. Licensing is principally required for the storage, use and disposal of radioactive material, but it is also required for the administration of radioactive substances to patients.

#### 60.4.1 STORAGE OF RADIOACTIVE MATERIAL

A license is required to permit the storage of radioactive material. Storage for use will have a different authorisation from storage as waste, and storage of waste materials is generally discouraged. Meticulous records of both sources-intended-for-use and classified-as-waste must be maintained. All sources must be regularly inspected, and sealed sources used for brachytherapy should be regularly leak tested; the frequency of testing will be dependent on use. The risk of possible use of radioactive material to create a dirty bomb increases the importance of such vigilance and this has led to a European Council Directive regarding the security of high-activity sealed sources (ECD 2003).

#### 60.4.2 DISPOSAL OF RADIOACTIVE WASTE

As a consequence of the use of unsealed radioactive substances in the diagnosis or treatment of patients some radioactivity is likely to be discharged into the environment. The quantity discharged will depend partly on the physical and biological half-lives of the substance. Often this discharge can be reduced by storing waste to allow physical decay of short-lived nuclides. The discharge and accumulation will be regulated by an appropriate government agency. Any organisation discharging significant amounts of radioactivity into the environment or storing waste is required to seek authorisation to do so. Authorisation will be granted if the inspectors are satisfied that there is justification for the discharge and adequate accounting for radioactive waste. The authorisation will limit the rate of discharge and the time for which radioactive waste can be accumulated on site.

A number of routes of discharge can be identified; these include discharge into the atmosphere, discharge as low-level waste for burial at landfill sites, incineration on-site or at another site, and discharge into sewers. The request for authorisation will require a list of the amounts to be discharged by each route and a radiological impact assessment of each route identified.

The inpatient treatment of patients with radionuclides, particularly  $^{131}\text{I}$  can result in gigabecquerel (GBq) quantities of nuclide being excreted in patients' urine. The comparatively long half-life of eight days means there will be little physical decay, and most iodine administered will reach the sewer unless means are adopted to prevent this.

Means to reduce (abate) discharge of  $^{131}\text{I}$  into the environment rely on its radioactive decay during storage of the urine before it is discharged from the premises. This will require either direct collection of patients' urine for storage, or systems of tanks for storage of sewage from the treatment suite or ward (Leung and Nikolic 1998; Goddard 1999). Direct collection of urine can involve the use of bottles, chemical toilets, or toilets allowing rapid freezing of contents and subsequent transfer to large freezers for radioactive decay. Examples of all of these systems can be found throughout the world.

The operation of systems to allow the physical decay of  $^{131}\text{I}$  before discharge to the environment can be either distasteful or expensive or both. A proper radiological assessment of direct discharge to the sewer will usually establish that the dose to the most exposed member of any critical group, be it recreational bathers, fishermen or sewerage workers, will be less than the IAEA *de minimis* dose (IAEA 1999) of 10  $\mu\text{Sv}/\text{year}$  with correspondingly lower population doses. There is therefore no justification for any other practice in most circumstances. In the event that water discharged from sewage treatment works is eventually abstracted downstream for drinking, the process will involve large dilutions and storage in

reservoirs with the result that, once again, dose to the population does not justify abatement procedures.

A distinction should be drawn between the disposal of a radioactive source as waste and the transfer of the source to another organisation. For example, unused brachytherapy sources are usually returned to the manufacturer. In the case of permanent implants, such as iodine-125 prostate implants, the patient will be discharged from hospital with the implant in place. This is not classified as disposal as waste for regulatory purposes.

#### 60.4.3 ADMINISTRATION OF RADIOACTIVE SUBSTANCES

The administration of radioactive substances to patients must also be controlled. Such substances may only be used under the direction of a suitably qualified doctor who holds the necessary certificate and works in an approved centre with minimum standards of staffing and equipment. However, the prescription of activities for therapy is left to the professional judgement of the clinician.

---

### 60.5 TRANSPORT OF RADIOACTIVE SUBSTANCES

The law distinguishes between the movement and transport of radioactive substances. Transport is the operative term whenever a public highway or place is involved. Because transportation of a particular consignment of goods may affect many different countries, the regulations governing transport are more closely harmonised and are based on the IAEA safety standards (IAEA 2000). The regulations do not apply to radioactive material within the body following diagnosis or therapy. The arrangements for travel from a hospital for patients who have been administered radioactive substances will be dealt with in [Section 61.4.2.2](#).

The transport regulations are relevant to the delivery of radioactive materials required for treatment to a hospital. They are also relevant to the delivery and return of sealed sources used in teletherapy and brachytherapy.

All deliveries of radioactive substances must be made in special containers (Type A) designed and tested to meet stringent conditions to ensure that there will be no dispersal of radioactive material during transport in any reasonably foreseeable circumstances. These conditions can be relaxed to allow transport in *excepted* packages where only small quantities are involved, but most aspects of the transport of excepted packages are still subject to control under the transport regulations. Therapy quantities will always exceed the limits for transport as excepted packages and will always be made in Type A containers. Type A containers are divided into further categories (see [Table 60.3](#)) depending on the external dose rate. The labelling of these containers will give some indication of external dose rates and the restrictions placed on drivers for their handling. Apart from more relaxed conditions for parking of vehicles containing only white label packages, there is little difference in the requirements made for carriers of different categories of Type A packages. The *transport index* for a single container or group of containers is numerically 100 times the dose rate in mSv/h at 1 m (being originally based on the dose rate in mrem/h).

The regulations impose obligations on consignor and carrier and clarify training, general documentation, recording and packaging requirements. They also describe the precautions required for the custody of radioactive materials in transit and the prevention of exposure of persons not directly concerned with the transport of radioactive materials. The European Council Directive R6/35/EC (ECD 1996b) created a legal requirement for entities who consign or transport dangerous goods by road, rail or inland waterways (above the threshold quantities) to appoint a suitably qualified dangerous-goods safety adviser. When sealed sources are being transported between EU countries, a certificate must be obtained from the licensing

**TABLE 60.3**

Transport Categories for Carriage of Radioactive Materials

Category	Maximum Surface Dose Rate	Maximum Transport Index <sup>a</sup>	Exclusions
I (white)	<5 µSv h <sup>-1</sup>	—	Fissile class II or III
II (yellow)	<500 µSv h <sup>-1</sup>	1.0	Fissile class III
III (yellow)	<2 mSv h <sup>-1</sup>	10	
III (yellow) <sup>b</sup>	<10 mSv h <sup>-1</sup>	>10	

<sup>a</sup> The Transport Index is the dose rate in mSv/h at 1 m multiplied by 100

<sup>b</sup> Such packages must be transported under exclusive use, i.e. the consignor has sole responsibility for the loading of the conveyance or large container.

authority of the recipient country to confirm that the consignee is licensed to hold the source in question. This is to conform to Council Regulation 1493/93 (ECD 1993).

More stringent regulations apply to the transport of large teletherapy sources which must be transported in Type B packages. The responsibility for observation of these regulations will lie with the specialist companies delivering these sources.

## 61.1 DESIGN OF EXTERNAL BEAM TREATMENT FACILITIES

The protection of staff directly concerned with the practice of radiotherapy as well as other staff and the public at large, whether as visitors to the hospital or as persons in the vicinity of the hospital, must be considered in the design of radiation treatment facilities. A discussion of the approaches available to reduce staff doses is given in the Introduction to Part L. Protection of staff and public is mainly achieved by the use of shielded rooms and warning devices that exclude persons other than patients from areas of high radiation dose.

Protection of personnel may not be the only requirement. Linear accelerators produce pulsed radiation and even where adequate protection is provided for the radiological safety of personnel, sensitive radiation equipment such as counters and gamma cameras may be affected by these pulses which will usually be intermittent and can thus lead to spurious readings or image artefacts.

In what follows, the general methodology for designing treatment rooms will be described. A more detailed treatment of the subject is to be found in IPEM Report 75 (IPEM 1997) or NCRP Report 151 (NCRP 2005) and data can be found in the *Handbook of Radiological Protection* (RSAC 1971) and the NCRP Report 49, Report 51 (NCRP 1976, 1977) and in BS4094 parts 1 and 2 (BSI 1996, 1971). An example calculation for a specific treatment room is given in Appendix L.2.

### 61.1.1 COMPONENTS OF RADIATION

Three principle components may require shielding. These are the primary beam, leakage radiation and scattered radiation. For high-energy accelerators, there may also be significant

production of neutrons. Photon bombardment of parts of high-energy linear accelerators may lead to induced activity and this can be a hazard to maintenance staff.

### 61.1.1.1 Primary Radiation

The primary beam is the first consideration in designing shielding. Adequate shielding extending beyond the maximum diagonal width of the beam as defined by the collimation system of the equipment will be required to reduce the dose to acceptable levels outside the treatment room for persons within the geometrical projection of the primary beam.

Lower-energy equipment is often designed to be used without restriction of the beam direction. This requires that all external walls are of adequate thickness to attenuate the primary beam. Special attention should be paid to the door, which will usually require incorporated lead or other shielding materials of adequate thickness.

Almost all megavoltage equipment is now mounted isocentrically\*. This restricts the area of wall that needs to be thick enough to attenuate the full primary beam. A primary barrier in the wall of the room is to be preferred, but may not always be possible for practical reasons. Installing such a barrier is usually possible for new installations. However, where new radiotherapy equipment producing more penetrating radiation is installed in treatment rooms originally designed for equipment of lower energy, it may not be possible to provide adequate attenuation of the primary beam for all gantry orientations. Beam stoppers—retractable or fixed—may be attached to the equipment such that they intercept the primary beam after it passes through the patient. However, they limit access to the patient for setting up and are best avoided wherever possible.

The expense of shielding can often be minimised by situating bunkers underground or against earth banks. Care will be needed to ensure that in future site development this shielding is not inadvertently removed.

Where there are particular weaknesses in room shielding, restrictions on use or limitation of access to external areas may be necessary.

### 61.1.1.2 Leakage Radiation

Leakage radiation is emitted by the equipment outside the useful beam of radiation. In orthovoltage or superficial units, this will arise entirely from the target and is a consequence of the side lobes of the polar emission of bremsstrahlung. It is attenuated by internal lead shielding. For orthovoltage equipment scattered radiation is not a problem because the walls must also be primary barriers (see Section 61.1.1.1).

For teleisotope equipment, leakage radiation arises from the source. In the *safe* position, leakage radiation is potentially significant for protection of staff within the room and adequate internal shielding must be provided. In some unit designs, particularly those in which the source moves into the treatment position, shielding of the source in the exposed position may be reduced to save space and weight. In such units, it is the leakage radiation while the source is exposed that must be used in calculating the thickness of the room walls (see also Section 12.3.1).

For linear accelerators, leakage radiation can arise from a variety of internal sources, including the waveguide, radio-frequency source, beam-transport system, target, filters, collimators, etc. It is a technical challenge to provide full protection against leakage radiation as the shielding materials required may be heavy and occupy considerable space. It is not uncommon to find leakage radiation from linear accelerators approaching the maximum allowed by regulatory authorities. This is usually set at 0.1% of the useful beam. Because

\* Some specialised units, such as those designed specifically for total-body irradiation may not be mounted isocentrically, but the movement of these units is likely to be more restricted and this paragraph will apply in the same way.

**TABLE 61.1**

Leakage Limits for Teletherapy Treatment Units

Energy	5 cm From Surface	1 m From Target
<b>X-ray generators</b>		
<500 kVp	300 mSv/h	10 mSv/h
>500 kVp		0.1% of main beam <sup>a</sup>
<b>Gamma units</b>		
Off	0.2 mSv/h	0.02 mSv/h
On		10 mSv/h or 0.1% of main beam

<sup>a</sup> Note that ICRP Report 33 (1982) recommended 0.2%; therefore, older units may have more leakage.

of the filtration effects of the internal shielding, it is often of an energy similar to the primary beam. In a conservative design it is assumed that this is the case and, if the same level of occupancy (see [Section 61.1.1.5](#)) is assumed, this will lead to a secondary barrier that is up to three tenth-value-thickness less thick than the primary barrier. ([Section 61.1.1.7](#) discusses the validity of the assumption that leakage radiation is of the same energy as the primary beam.) Leakage radiation is usually assumed to be isotropic in design calculations. [Table 61.1](#) shows the leakage limits generally imposed.

### 61.1.1.3 Scattered Radiation

Scatter may arise either from the walls of the room or from the patient. It will be of lower energy than the leakage radiation and it can be reasonably assumed in room design that any barrier providing protection against leakage radiation will also provide adequate protection against scattered radiation. Because scattering is by the Compton effect, for scatter through 90° the energy of the scattered radiation will be about 0.5 MeV and backscattered radiation will have an energy around 0.25 MeV (NCRP 1977) (see also [Section 4.3.2.1](#)).

Special consideration needs to be given to room access. A maze offering at least one or, if possible, two reflections from any surface irradiated by the primary beam will usually afford adequate protection against scatter. Sometimes space precludes the construction of an adequate maze and, in such situations, a protective door may be needed. Such doors are often heavy, will give the patient a feeling of being *shut in* and are to be avoided if possible\*. The provision of an adequate maze may be problematic where an existing room is to be adapted to house a higher-energy unit. The calculation of the dose rate in the maze is covered in [Section 61.1.2.3](#).

### 61.1.1.4 Neutrons and Induced Radioactivity

Neutrons are a particular problem with high energy (>10 MV) linear accelerators and a good discussion of the issues can be found in NCRP Report 79 (NCRP 1984). They can be produced by interactions between energetic electrons or photons and the nucleus (see [Section 4.3.4](#)). They can also be produced by fission induced by photons and electrons in elements heavier than bismuth. These processes result in a neutron flux while the beam is on but they also lead to induced radioactivity with the result that parts of the equipment struck by the generating electron beam (or by the bremsstrahlung) can emit radiation even after the beam is switched off. There is also a possibility of inducing radioactivity in the patient, patient support system, or treatment room fabric.

\* It is unusual in the U.K. for rooms to have protective doors. In other countries such doors are the norm.

Most neutrons will arise within the treatment head, principally from the x-ray target. They will be approximately isotropic and penetrate the photon shielding in most directions. Photon shielding is usually made of lead or tungsten for which the only sources of energy loss will be inelastic scattering and  $(n,2n)$  reactions. As a result, the effect of the head shielding is to degrade the *average* neutron energy as an exponential function of the shielding thickness.

Although the head shielding reduces the average energy of the neutrons, the number of particles will remain essentially unchanged. This is a result of the competing effects of a small amount ( $\sim 15\%$ ) of attenuation and of the  $(n,2n)$  reaction. Multiple scattering leads to a more or less isotropic emission of neutrons from the head, so that small gaps in the shielding will not lead to collimated beams of neutrons.

Within the treatment room, the treatment head can be regarded more or less as a point source of neutrons whose average energy has been degraded from around 4 MeV (for 15 MeV electrons) to around 1 MeV. The intensity of this component will fall off according to the inverse-square law. The concrete walls of the treatment room will contribute a fluence of scattered neutrons whose average energy will be about a quarter of this value. The fluence of the scattered neutrons will be more or less uniform within the room. These neutrons will contribute to patient dose.

Generally speaking, neutrons rarely contribute above 0.5% of the equivalent dose at the iso-centre, and the tenth-value-thickness for neutrons absorbed in concrete are lower than those for photons. As a consequence the shielding provided against photons will be adequate for neutrons.

However, a particular problem in shielding against neutrons arises from scatter down the maze. Three components will contribute to the dose along the maze:

1. The original high energy neutrons present in the treatment room
2. Thermal neutrons produced by repeated scatter
3. Neutron-capture  $\gamma$ -rays

The relative contributions of these components are difficult to separate, but regarding them as approximately equal is satisfactory for most purposes.

Mazes designed for lower-energy linear accelerators are unlikely to provide adequate protection against neutrons when a higher-energy linear accelerator is installed in the treatment room. A number of measures can be incorporated into mazes to improve their effectiveness against neutrons. Extra baffles will effectively increase the length of the maze, and lining the maze with polythene-loaded boron or lithium will reduce the energy of fast neutrons and provide capture for thermal neutrons. This will be more effective if placed at the inner end of the maze. Ultimately, a door may be needed. This door should incorporate neutron-absorbing material (i.e. containing highly hydrogenated components) such as boron with a layer of lead to absorb the neutron-capture  $\gamma$ -rays. Such doors will be heavy and require complicated and expensive drive mechanisms.

Induced radioactivity will be present within the accelerator structure, especially in the head (Powell et al. 1987). It may also be present in components of the beam-transport system. The intensity of this activity will increase with prolonged running of the linear accelerator and will decay with time after irradiation. Induced activity is a particular hazard to maintenance staff and care should always be taken to ensure that levels are acceptably low when maintenance or repair work on the components of the treatment head takes place after operation of linear accelerators at high energies. This may be more of a problem with the longer irradiation times associated with intensity modulated radiotherapy (IMRT) (Rawlinson et al. 2002; see also [Section 61.5.2](#)) and is also a particular problem for proton or neutron treatment facilities (Yudelev et al. 1995, 1997). Further details of radiation protection for proton facilities are given in [Section 48.3.9](#).

Extensive measurements of the neutron components of various accelerators have been made by Followill et al. (2003).

### 61.1.2 BARRIER ATTENUATION

In order to calculate the required thickness of material needed to attenuate the radiation to an acceptable level, information on barrier penetration is required. Attenuation depends on the energy of the radiation. The measurement of attenuation for kilovoltage x-ray beams was described in [Section 21.2.2](#). There the aim was to avoid any scattered radiation reaching the detector, in order to measure the attenuation of the primary beam only. This is called the *narrow beam* attenuation. In radiation protection it is the *broad beam* attenuation that is relevant. A broad beam will generally be less attenuated than would be expected from the narrow beam situation because scattered radiation remains part of the beam. This distinction is sometimes emphasised by using the expression half-value thickness (HVT) for broad beam attenuation and half-value layer (HVL) for narrow beam attenuation and we will use this convention here. For radiation protection, where the attenuation required is several orders of magnitude it is usual to record the *tenth-value-thickness*, i.e. the thickness required to reduce the dose rate by a factor of 10. As the radiation is attenuated the mean energy of the radiation is reduced and the second and subsequent TVTs will be less than the first. This is in contrast to the effect described in [Section 22.2.2](#) in which the mean energy is increased by filtration because the transmitted radiation is dominated by scatter. In attenuation tables (e.g. NRPB 2005) these may be designated as the first tenth-value-thickness ( $T_{VT_1}$ ) and the *equilibrium* tenth-value-thickness ( $T_{VT_e}$ ). Radiation that has been scattered before reaching the walls of the treatment room will have a lower energy than of the primary beam as discussed in [Section 61.1.1.3](#) and different TVT values will be appropriate for this situation.

### 61.1.3 TREATMENT-ROOM DESIGN CALCULATIONS

For a practical example of a shielding calculation the reader is referred to Appendix L.2. Here we will consider the guiding principles. The starting point in the design of a treatment room is consideration of its use. Constraints will differ depending on whether it is a new bunker or a replacement of an old machine with a new one. Ergonomic factors, such as the size of the room, the means of entry, especially for patients on trolleys, and ease of access to the patient should be considered as well as the relationship of the room with other facilities.

Design of the radiation protection should start with a consideration of the energy of the equipment and the overall workload, usually expressed as the product of the number of fields per unit time (day, week, or year) and the average dose per field. Conservative projections should always be used, and it is normal to neglect patient attenuation in all calculations. It is important to consider the locations of personnel to be protected.

For the primary beam, it may be acceptable, depending on national regulations, to take account of the fractional time that the beam will have a given orientation. This is called the *use factor*. Care should be taken that these factors are generous and take account of future evolution of treatment techniques. For example, factors of 0.5 for vertical beam orientations and 0.25 for other orientations would usually be appropriate, but the factors chosen should be justified individually taking into account any special uses of the room. Record and verify systems allow the assumptions made to be tested against real data. Because factors should be generous, their sum will be in excess of unity. Where there is no alternative, areas of low occupancy may have lower shielding: the thickness of the barriers can be reduced by the incorporation of a suitable *occupancy factor* into the barrier thickness calculation. In determining the occupancy factor, the proportion of time for which any person is present should be considered rather than the time spent by a particular individual. Thus, a corridor might have an occupancy factor of 0.25 (NCRP (2005) recommends 0.2), but a very busy corridor might have an occupancy factor of 1.

Economies in the cost of shielding can be obtained by situating high-energy installations in single-storey buildings with thinner roofs and carefully restricted personnel access. In such

cases, particular account should be taken of *skyshine*, where penetrating radiation can be scattered by air back to the ground. It is also important to consider the occupation of nearby tall buildings, present or future, within the projection of the primary beam.

According to the U.K. regulations, the aim of shielding design is to reduce the time averaged dose rate over 2000 h (TADR2000)\* to an acceptable level while ensuring that the instantaneous dose rate (IDR) is not excessive based on the criteria in [Table 60.1](#). The NCRP recommendations are based on the aim to reduce the weekly dose to 0.02 mSv week<sup>-1</sup> for uncontrolled areas and 0.1 mSv week<sup>-1</sup> for controlled areas (NCRP 2005), calculating workloads in Gy week<sup>-1</sup>. Modern accelerators can have dose rates up to 6 Gy/min or even 10 Gy/min. However, a high dose rate at the isocentre also reduces the beam on time. Assuming that fifty 2.4 Gy fractions can be delivered in an eight hour day and that the depth dose at the isocentre is about 50%, the TADR at the isocentre is about 0.5 Gy/min or 30 Gy/h. If a large number of IMRT treatments are being delivered, the beam will be on for longer and consideration therefore needs to be given to whether the shielding should be increased (Followill et al. 1997; Price et al. 2003; Stathakis et al. 2005; NRPB 2005). For the primary barrier the calculation given above is still approximately valid because the mean dose averaged over the area of an individual field is not increased; indeed, the number of patients that can be treated will probably be less. However, when calculating the protection required against leakage radiation, the *use factor* may need to be increased by up to three times. Consideration also needs to be given to the doses delivered during commissioning when the beam may be on continuously for some time. Temporary restrictions may be necessary.

### 61.1.3.1 Primary Barriers

The calculation of a typical barrier thickness against primary radiation can be based on the following equation:

$$\dot{D}_p = \frac{TF_u F_o r_{iso}^2}{r_s^2} \dot{D}_{iso}$$

where  $\dot{D}_p$  is the TADR2000 to be allowed in the area to be protected, as derived from [Table 60.1](#);  $T$  is the fraction of the incident radiation transmitted through the barrier;  $F_u$  is the use factor (the fraction of treatments with the range of beam orientations potentially irradiating the point to be shielded);  $F_o$  is the occupancy factor;  $r_{iso}$  is the source to isocentre distance (usually 1 m);  $r_s$  is the distance from the source to the point of interest; and  $\dot{D}_{iso}$  is the TADR delivered to the isocentre (30 Gy/h).

Consider a point 6 m from the source (5 m from the isocentre) where the objective is to achieve a TADR2000 of 0.15  $\mu$ Sv/h, with an occupancy factor of 0.25 and a use factor of 0.3. The wall transmission ensuring the required attenuation will be  $2.4 \times 10^{-6}$ , which corresponds to about 2.2 m of concrete for a 6 MV beam (for which the tenth-value-thickness for standard 2.355 g/cm<sup>3</sup><sup>†</sup> concrete is 343 mm). For 15 MV, the thickness will be 25% greater.

### 61.1.3.2 Secondary Barriers

The calculation of the attenuation against leakage radiation is given by the equation:

$$\dot{D}_L = \frac{T k F_o r_{iso}^2}{r_s^2} \dot{D}_{iso}$$

\* For a detailed discussion of TADR and IDR (see [Section 60.2.1](#)).

<sup>†</sup> Shielding density is often quoted in t/m<sup>3</sup> in which the unit t is 1000 kg. This is referred to as a *metric ton* in some countries (e.g. the U.S.A.) and as a *tonne* in other countries (e.g. U.K.) t/m<sup>3</sup> is numerically equal to g/cm<sup>3</sup>.

where  $k$  (usually  $10^{-3}$ ) is the fractional leakage radiation. Note that there is no use factor and that  $r$  is usually taken to be the distance to the isocentre as representing the average position of the target. Attenuation against leakage radiation needs to be provided for all areas where staff, public, or patients might potentially be located. A critical factor is the energy of the leakage radiation. IPEM Report 75 (1997) provides evidence that the assumption that the energy of the leakage radiation is equal to the energy of the primary beam is somewhat conservative, which is consistent with the findings of Nelson and LaRiviere (1984). For a point 5 m from the isocentre the barrier thickness for a 6 MV accelerator calculated assuming the energy is equal to that of the primary beam would be 1.3 m, but a more realistic calculation might lead to 1.1 m. Where possible, it is wise to be conservative, as increasing the barrier thickness after the machine has been installed is likely to be very expensive.

### 61.1.3.3 Room Entrances: Protection against Scattered Radiation

As stated above, because the energy of the scattered radiation is substantially lower than that of the primary beam, any shielding designed for leakage radiation should also be sufficient to account for the scattered radiation. However, scattered radiation is important when considering the dose rate at the entrance of the maze.

Exact calculations of attenuation of radiation in a maze are best achieved with Monte Carlo calculations (Al Affan and Smith 1996; Al Affan et al. 1998; Al Affan 2000), but an approximate method proposed in NCRP Report 51 (1977) gives reasonable results, although Al Affan found that this method tends to underestimate the dose rate at the maze entrance. The formula is:

$$\dot{D}_m = \dot{D}_{iso} \frac{\alpha_1 A_1}{d_1^2} \frac{\alpha_2 A_2}{d_2^2} \frac{\alpha_3 A_3}{d_3^2} \frac{\alpha_4 A_4}{d_4^2} \quad (61.1)$$

where  $\dot{D}_m$  is the dose rate at the entrance of the maze;  $\alpha_i$  is the reflection coefficient of the scattering material;  $A_i$  is the corresponding area of the scattering material that is irradiated, which for the maximum field size is about  $0.25 \text{ m}^2$ . As a general rule, the remaining  $A_i$  (i.e. the area of the cross-section of the maze) are between  $6 \text{ m}^2$  and  $8 \text{ m}^2$ .  $\alpha_1$  is about 0.0015 and  $\alpha_2 A_2 \approx \alpha_3 A_3 \approx 0.1$ , i.e. each bend in the maze introduces a 10% reduction in dose rate\*. This is illustrated in [Figure 61.1](#).

### 61.1.3.4 Room Entrances: Protection against Neutrons

At energies above 10 MV, it is necessary to consider the effect of neutrons. As discussed in [Section 61.1.1.4](#), the dose rate due to neutron penetration through barriers is always less than that due to photon penetration, but neutrons undergo multiple reflections at the walls and therefore are less attenuated by mazes than photons. In addition, the tissue radiosensitivity to neutrons, as expressed by the equivalent dose in Sv, is 20 times higher than for photons (see [Section 59.1.2](#)). Methods for calculating the effect of mazes on neutron dose are discussed in IPEM Report 75 (1997). NCRP Report 51 (1977) provides graphs for the attenuation of the maze depending on its design (i.e. the number of bends) and its area and length. An alternative empirical method is described by Kersey (1979). He assumes that the neutrons are attenuated within the treatment room according to the inverse square law and that a 5 m length of maze provides an equivalent tenth-value-thickness of attenuation. However, for short mazes, 3 m may be more appropriate (IPEM 1997; Carinou et al. 1999). In assessing the neutron dose rate related to the photon dose rate in the primary beam, a

\* More detailed information can be found in the *Handbook of Radiological Protection* (RSAC 1971) or IPEM Report 75 (1997). The mean energy of the primary beam may be taken as half the nominal energy for this purpose.

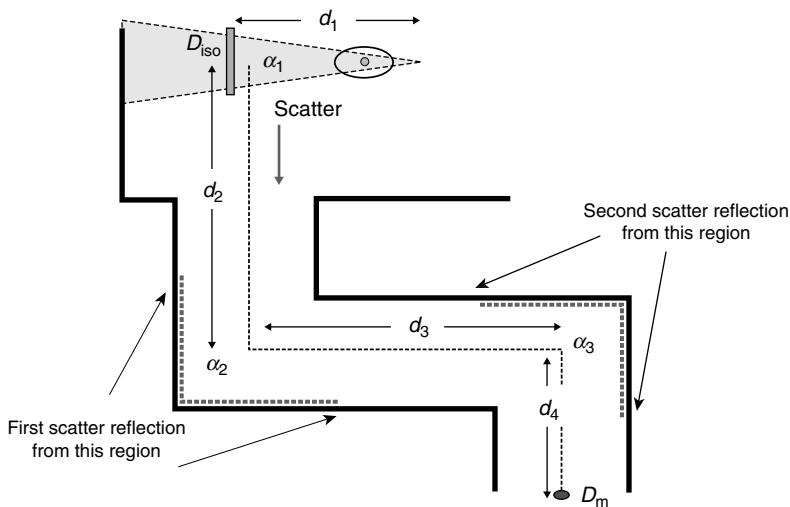

**FIGURE 61.1**

Diagram illustrating the reduction of dose rate resulting from scattered photons down a maze. (Figure courtesy of Dr. J. E. Shaw.)

figure of about 1.2 mSv/Gy at the isocentre is a reasonable assumption, although more exact figures can be found in the literature (McGinley 2002; Followill 2003; Waller 2003; Waller et al. 2003a). If the dose rate at the entrance of the maze is found to be unacceptable, lining the maze with borated polyethylene (e.g. Premadex®) or wood (Carinou et al. 1999; Waller 2003b) or the use of a neutron door containing polyethylene and borated plastic (BPE) sandwiched between lead (O'Brien 1985; NCRP 2005) can provide a solution.

### 61.1.3.5 Skyshine

The dose rate from skyshine,  $\dot{D}_{\text{sky}}$ , can be calculated by the following equation (IPEM 1997):

$$\dot{D}_{\text{sky}} = \frac{2.3 \times 10^{-2} A_{\text{iso}}^{1.3} T}{d_c^2 (d_r + 2)^2} \dot{D}_{\text{iso}}$$

where  $A_{\text{iso}}$  is the beam area at the isocentre;  $\dot{D}_{\text{iso}}$  is the dose rate at the isocentre;  $T$  is the roof transmission;  $d_c$  is the distance from the source to the roof;  $d_r$  is the off axis distance of the point of interest at roof level. All units of length are in metres.

If a roof is given adequate protection to reduce the primary beam penetration to a level such that short-term occupation will not lead to excessive dose, the residual penetrating primary radiation will not cause dangerous levels of skyshine at ground level. However, these levels may be high enough to interfere with sensitive radiation counting equipment especially that found in nuclear medicine departments.

### 61.1.4 CHOICE OF MATERIALS

The choice of the materials for room shielding will depend on factors including the energy of the radiation, available space, and cost. Representative data for some typical materials are given in [Table 61.2](#).

At low energies, the photoelectric effect may favour the use of high-atomic-number materials, such as lead or barium as in barytes plaster. The space and weight savings might justify the use of such high-cost materials.

**TABLE 61.2**

Data for Typical Shielding Materials

	Standard Concrete	Barytes Concrete	Steel	Lead	Dry Earth	Ledite®
Density (g cm <sup>-3</sup> )	2.35	3.5	7.8	11.36	1.5 <sup>a</sup>	5.6 <sup>a</sup>
TVT 4 MV (in mm)						
Primary	290	205 <sup>a</sup>	91	54	450 <sup>a</sup>	150 <sup>a</sup>
Leakage	254	180 <sup>a</sup>	79	47	400 <sup>a</sup>	130 <sup>a</sup>
TVT 6 MV (in mm)						
Primary	343	225 <sup>a</sup>	98	55	540 <sup>a</sup>	165 <sup>a</sup>
Leakage	279	185 <sup>a</sup>	80	45	440 <sup>a</sup>	135 <sup>a</sup>
TVT 10 MV (in mm)						
Primary	389	250 <sup>a</sup>	105	56	610 <sup>a</sup>	180 <sup>a</sup>
Leakage	305	470 <sup>a</sup>	85	46	480 <sup>a</sup>	145 <sup>a</sup>
TVT 15 MV (in mm)						
Primary	432	265 <sup>a</sup>	108	57	680 <sup>a</sup>	190 <sup>a</sup>
Leakage	330	210 <sup>a</sup>	87	50	520 <sup>a</sup>	150 <sup>a</sup>
TVT 20 MV (in mm)						
Primary	457	270 <sup>a</sup>	111	55	715 <sup>a</sup>	190 <sup>a</sup>
Leakage	343	210 <sup>a</sup>	88	49	540 <sup>a</sup>	150 <sup>a</sup>
Relative cost (approx)	1.0	2.6	2900	4000	0	4320

Note that costs (relative to standard concrete) are based on cost per unit mass of material only and are very approximate as they will depend on local conditions. This may be only a small proportion of the total cost of the building project and does not consider such factors as the reusability of Ledite®.

<sup>a</sup> These values are interpolated from the data in IPEM Report 75 and should be used with caution.

*Source:* From IPEM (Institute of Physics and Engineering in Medicine), *The Design of Radiotherapy Treatment Room Facilities*, Stedeford, B., Morgan, H. M., and Mayles, W. P. M., Eds., IPEM Report No 75, IPEM, York, 1997.

At high-energies, mass attenuation coefficients become independent of atomic number. Full-density concrete (usual density 2.35 g/cm<sup>3</sup>), either poured or in blocks, is the material of choice, although others including sand have been used. It is possible to obtain *high-density concrete* with a density of approximately 3.2 g/cm<sup>3</sup>, achieved by loading with barium or other high-density material, although this is relatively more expensive and only worth considering where space is limited. Siting high-energy bunkers underground may enable the use of earth as a shielding material and significantly reduce the cost of shielding. The independence of attenuation on atomic number usually makes the cost of high-atomic-number materials unattractive except in circumstances where space is especially limited. If necessary, steel sheet can be used. At 6 MV, 10 mm of steel is equivalent to 35 mm of concrete and 6 mm of lead. Materials used for construction must have the necessary rigidity and steel is generally preferable to lead for this reason. Atomic International market a proprietary material called Ledite® (Barish 1993) that consists of scrap steel cast into interlocking concrete blocks. The attenuation of these blocks is about twice that of concrete. The blocks have the advantage that if the shielding is no longer needed or the department moves to another site, the walls can be dismantled and reused.

### 61.1.5 INTERLOCKS AND OTHER ISSUES

Interlocks are required to ensure that staff have left the treatment room before irradiation can begin. It is convenient to have two buttons, one inside the treatment room and one outside. These have to be pressed in sequence and within a set time before the radiation can be turned on. Emergency-off buttons one either side of the treatment room are required in case someone is left

in the room when the machine is turned on (in spite of the door interlocks). Radiation warning lights should be displayed at the entrance to the maze and in the treatment room. These can follow a three stage process: the first stage appears when power is applied to the machine, the second when all the interlocks are complete and finally an indication that radiation is on.

Facilities are required to monitor the patient. The decrease in cost of closed circuit television has obviated the need for direct or indirect viewing arrangements such as mirrors and attenuating windows. Additionally there is a requirement for two way audio communication, although this may be less useful.

There is a need for electrical and other services to be taken through the radiation barrier inside ducts. Careful consideration must be given to the siting of these as it is possible that they will provide a route of escape for the radiation. Any break in the primary barrier should be avoided and ducts should cross the barrier at an angle. A particular requirement is for a tube to allow dosimetry cables to be passed into the room.

The lasers used to define the machine isocentre are often inset into the primary barrier in order to protect them from being knocked and this can present a weak spot in the barrier. If they are to be recessed, they should be mounted on a steel plate of equivalent thickness to the missing concrete (see [Table 61.2](#)).

### 61.1.6 UPGRADING EXISTING TREATMENT ROOMS

Installing new equipment into old rooms frequently turns out to be more complex than might be expected. Design guidelines for modern rooms have moved toward increasing the level of shielding specified. In addition, dose rates provided by modern accelerators, and hence throughput, have increased; there is also frequently a desire to install a machine with a higher energy. When installing new equipment, it is necessary to try to bring the shielding up to modern standards. Many older machines did not have full 360° rotation and consequently shielding in the roof area may be inadequate. Possible solutions to these problems include

- Building walls with interlocking concrete blocks to avoid pouring concrete
- Using steel or lead sheets or Ledite® in the walls
- Restricting use of the equipment
- Increasing the length of the maze or introducing baffles to increase the number of scattering angles
- Using a solid door, if there is not one already.

### 61.1.7 PROTECTION SURVEYS

It is important that after installation a full survey is conducted to verify the design calculations and to ensure that builders have followed instructions\*. The first step in this process is to choose the correct survey instrument. In the case of linear accelerators, the pulsed nature of the radiation can give erroneous results with equipment such as Geiger-Müller tubes that count photons, in contrast to ionisation-based instruments that measure charge. Scintillation detectors can be used, provided that their response to

\* For example, modern building regulations require that steel inside concrete should not protrude. This can be a problem with the shuttering used to create the frame into which concrete is poured and builders often use plastic sleeves around the tie rods so that the rods can be withdrawn once the concrete has been poured. Unfortunately this leaves a hole in the barrier, which must be filled with appropriate material.

pulsed radiation is verified. Film and TLD can be used for longer-term environmental surveys. Neutron measurements will be needed if the energy of the machine is above 10 MeV.

Before carrying out protection surveys, the expected instantaneous dose rates should be calculated so that they can be compared with measurements. Measurement should be made under conservative conditions (largest field size, diagonal collimator orientation, and maximum dose rate). Measurements in the primary beam projection should be made with no phantoms or other attenuating material in place, but, for scatter dose measurements, a water-equivalent scattering object should be placed in the beam. Measurements should cover all working conditions likely to be found, ensuring an adequate range of machine orientations. Full checks should also be made of all interlocks, displays, warning signs, and labels. Finally, the results should be reported to the *qualified expert* (Radiation Protection Adviser) if done by others.

### 61.1.7.1 Neutron Monitoring

Neutrons can be measured by activation, etched-track detectors, superheated-drop detectors, diodes, and ionisation detectors. Most detectors respond primarily to thermal neutrons (energy below 0.5 eV). Higher-energy neutrons are moderated to be detected as thermal neutrons. The ideal detector is not sensitive to photons because there will usually be a mixed photon and neutron beam; for this reason, the first three detector types are preferred. However, diodes and ionisation chambers are useful as direct-reading dosimeters. Neutron detectors should ideally have a sensitivity profile for different neutron energies that is matched to that of the equivalent dose ([Section 59.1.2](#)) rather than the physical dose.

Activation detectors make use of materials such as indium (half-life=54 min) or gold (half-life=2.7 days) that have high neutron absorptions. After exposure, the resulting activity can be counted to give a measure of the neutron fluence. Thermal neutrons can be distinguished from fast neutrons by the differential effects of the moderator that may or may not be incorporated into the detector.

Etched-track detectors make use of microscopic radiation damage caused by charged particles (protons) produced as secondary radiation when neutrons are captured in suitable materials (e.g. boron). Etching with caustic solution causes this damage to appear as pits that can be counted. Some etched-track detectors use polycarbonate foils, but the more recent development of CR-39 plastic or PADC (polyallyl diglycol carbonate) detects recoil protons from neutrons with an energy threshold of around 150 keV. Thermal neutrons are detected by interacting with nitrogen nuclei in the holder and this detector has good discrimination against photons (Spurney et al. 1996; Kralik and Turek 2004).

The superheated-drop detector uses superheated liquid drops suspended homogeneously in a viscoelastic gel. When neutrons interact with the gel, the drops nucleate to form vapour bubbles that can be detected by the naked eye. The dose is estimated by counting the number of bubbles, which is directly related to the dose in  $\mu\text{Sv}$ , with approximately one bubble being produced per  $\mu\text{Sv}$  (d'Errico and Alberts 1994).

Diodes are damaged by secondary heavy particles emitted by neutrons. Changes in electrical properties can therefore be related to neutron fluence (Yudelev et al. 2004). Care must be taken to avoid misreadings resulting from exposure to primary photons.

While ionisation chambers consisting of air-filled chambers respond primarily to photons, proportional counters filled with boron trifluoride respond to thermal neutrons; surrounding them with suitable moderators enhances their sensitivity to higher-energy neutrons. Their sensitivity to pulsed photon fields precludes their use where such fields

are present and confines their usefulness to measurements outside the treatment room or at the far end of the maze.

## 61.2 DESIGN OF FACILITIES FOR SEALED AND UNSEALED SOURCE THERAPY

Brachytherapy embraces the use of sources varying from iodine-125 seeds with activities on the order of tens of megabecquerels (MBq) and  $\gamma$ -ray energy of 25 keV to high-dose-rate afterloading devices with cobalt-60 sources of hundreds of gigabecquerels (GBq) and  $\gamma$  radiation of energy in excess of 1 MeV (see Part J). A wide range of treatment regimes are used from continuous irradiation lasting several days (or even many weeks in the case of permanent implants) to fractionated treatments with multiple sessions, each taking only a few minutes. Treatment may be given by sources that cannot be readily withdrawn from the patient or by using high-dose-rate remote afterloading equipment with sources that can be withdrawn instantaneously whenever this is required. Clearly, the shielding requirements will differ and the design brief will need to take these factors into account.

In the past, low-dose-rate treatments were given in open wards, but this is no longer acceptable. For medium- or high-dose-rate afterloading equipment, a specially designed facility is essential. In any event, appropriate controlled areas must be defined, except possibly for therapy with  $^{125}\text{I}$  seeds.

### 61.2.1 REMOTE AFTERLOADING

The room shielding calculations will broadly follow the same principles as for external beam therapy (Section 61.1). However, radiation will be emitted more or less isotropically, with the result that shielding will need to cover all directions. On the other hand, the product of total activity and exposure time is likely to be such that, with the exception of high-dose-rate equipment, wall thicknesses are unlikely to be much in excess of 400 mm of concrete. These are comparable to the thicknesses required for freely mounted orthovoltage equipment. It should not be forgotten that shielding of floors and ceilings may also be required. If more than one room is required, the total amount of shielding can be minimised by locating them adjacent to each other. However, consideration must still be given to radiation transmitted through the dividing wall. This will affect staff attending one patient while the other is being treated. Some regulatory authorities also require that once a patient's treatment is complete, the patient should be treated as a member of the public for protection purposes.

High-dose-rate afterloading equipment will require concrete walls between 500 mm and 800 mm thick, depending upon the size of the room and the nuclide being used. Room doors will usually incorporate lead to take advantage of the greater mass attenuation resulting from photoelectric absorption. The thickness of lead, and thus the weight of the doors, will be minimised by ensuring that no radiation from sources within the patient can fall directly on them. This can be achieved by internal mazes.

Afterloading equipment can be located in modified or shared external-beam therapy rooms, but in this event it is essential that appropriate interlocks are installed to ensure that there is no confusion.

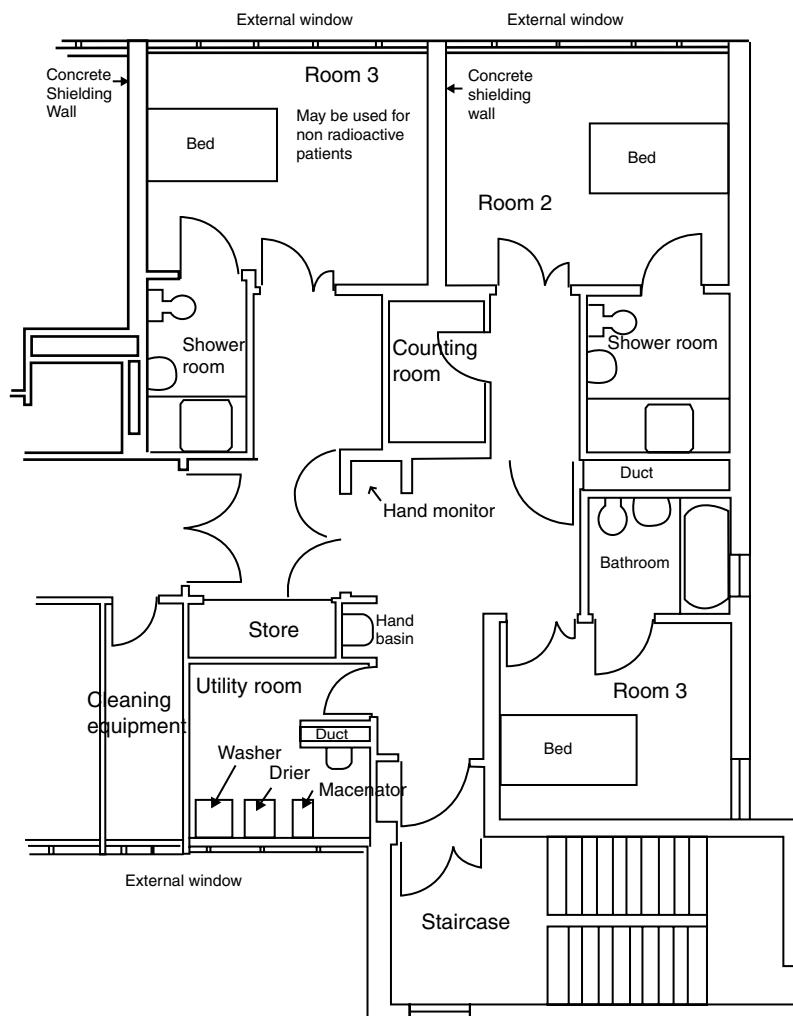

Staff safety will require that equipment is interlocked to room doors and that adequate warnings are displayed. In addition, it may be advisable to include dose-rate monitors. The dose rate in the vicinity of the patient or safe working times should be displayed. Closed-circuit television and two-way audio communication will reduce the need for staff entry.

Room design should include arrangements for visitors and contingency planning for medical emergencies that might require removal of the sources.

### 61.2.2 FACILITIES FOR UNSEALED-SOURCE THERAPY

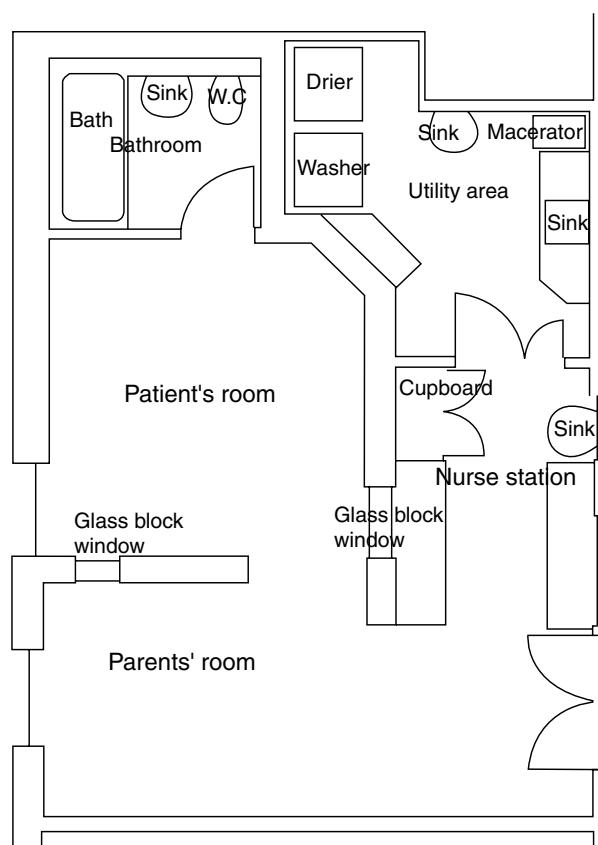

Ideally, high-activity radiotherapy with unsealed sources, especially  $^{131}\text{I}$  should be undertaken in specially designed wards with adequate shielding incorporated into the walls, floor, and ceiling.

The plans for one such three-bed, purpose-built unit are shown in Figure 61.2. Each room has its own *en-suite* bathroom and toilet, which minimises the potential for cross-contamination. The toilet may be connected to a storage facility to allow excreted radioactive substances to decay before being allowed into the main sewer (see [Section 60.4.2](#)), but this is no longer recommended by the ICRP (ICRP 2005a). All surfaces must be smooth and easy to clean. A whole-body counter (compensated Geiger-Müller tube) can be incorporated into the ceiling above each bed to enable the measurement of residual activity within the patient.

**FIGURE 61.2**

Design of ward for unsealed source therapy. The facility could also be used for manual-afterloading brachytherapy.

**FIGURE 61.3**  
Design of specialist unit for paediatric unsealed source therapy.

In addition to the design of the patient rooms, radiation hygiene will be aided by the provision of a utility room with washing and drying machines (to allow separate washing of potentially-radioactive contaminated linen) and a macerator for disposal of lightweight contaminated waste (e.g. disposable crockery, nappies, and dressings).

The treatment of young children, especially with agents such as mIBG (see Section 58.1.2) poses special problems because they are likely to be emotionally upset. A facility allowing a parent to be with the child but adequately shielded will reduce the emotional trauma. One such facility is shown in Figure 61.3, where it can be seen that the parent has a good view of the child but is able to sleep separated only by a wall that is no longer than the minimum to ensure adequate protection against penetrating radiation.

In addition to these facilities appropriate radiopharmaceutical preparation facilities will be needed (see [Section 61.3.4.1](#)).

## 61.3 EQUIPMENT AND SOURCE HANDLING

### 61.3.1 TELETHERAPY ISOTOPE SOURCES

Teletherapy equipment with high-activity sources (usually cobalt-60) poses additional difficulties compared to accelerators in that the potential for accidental exposure persists when the power supply is removed. A range of additional measures is required to ensure that inadvertent

actions cannot result in exposure to personnel when the equipment is not in use. These include the use of a radiation detector in the treatment room, leaving the equipment with the collimators closed, and perhaps a mechanical to secure the source mechanism in the safe position. Details of safety issues relating to cobalt-60 sources are discussed in [Section 12.3](#). Regular checks should be carried out to ensure that the source is still properly encapsulated ([Section 12.3.3](#)).

Because they decay, sources will be changed periodically to prevent unacceptable prolongation of treatment time. This work will always be done by external contractors. Under the European Council Directive 90/641\*, it is the responsibility of the employer responsible for a controlled area to ensure, either directly or through contractual arrangements, that radiation protection of outside workers is adequately provided for<sup>†</sup>. Because the licensed source handlers will be classified radiation workers it is the responsibility of the hospital to ensure that their radiation record books are filled in when the operation is complete<sup>‡</sup>. Additional considerations are discussed in [Section 12.4](#).

Local rules must include contingency plans for use in the event of the source not returning properly to the safe position. These are discussed in [Section 12.3.4](#).

### 61.3.2 AFTERLOADING EQUIPMENT

Although afterloading has made a considerable contribution to the radiological safety of staff, its use requires continued monitoring to ensure that this safety is achieved. In particular, all interlocks should be checked regularly and consistent retraction and insertion of sources should be verified. There will also be special procedures for source changing, although for high-dose-rate afterloading devices, this will normally be the responsibility of the manufacturer.

Provision of appropriate contingency plans for failure of the source transfer mechanism is important. For low-dose-rate afterloading systems, it is usual for the equipment to be left in the care of nursing staff and it is essential that the staff are properly trained to deal with emergencies. Consideration should be given to the provision of an emergency storage facility for the sources in the event of failure. However, the instructions for the use of this need to be carefully thought out, as damage may be inflicted on the applicators, making recovery of the sources more difficult than is necessary.

### 61.3.3 MANIPULATION OF LOW ACTIVITY BRACHYTHERAPY SOURCES

Modern afterloading equipment is the most effective means of minimising dose to the operator. However, implantation or manual afterloading of solid sources such as <sup>198</sup>Au grains, <sup>125</sup>I seeds, and <sup>192</sup>Ir wire, etc. is still a common practice. For such sources the principal considerations are

- Irradiation of staff while handling the sources (particularly the hands)
- Irradiation of medical and nursing staff while dealing with the patient
- The possibility of contamination from a leaking source
- Security of the sources
- Sterility of the sources

---

\* And the Ionising Radiation Regulations 1999 in the U.K.

† An approach to this that is sometimes used is that the contractor becomes fully responsible for the controlled area for the period of the source change using the services of a *qualified expert* (RPA) appointed by them. In that event, they remain responsible for their own radiation records.

‡ In some countries (e.g. France) records are maintained centrally which obviates the need for the hospital to do this.

Sources should be kept in shielded containers whenever possible and shielded source preparation facilities should be provided. Systems for handling sources should be established that make best use of the standard methods of dose reduction using time, distance, and shielding. The time needed to handle sources can be minimised by the provision of suitable handling equipment and the provision of an ergonomic environment. Distance can be increased by the use of long handled forceps, but self-gripping forceps should not be used as they may damage the encapsulation of the source. Shielding should be designed to allow rapid and easy work as otherwise there may be a significant time penalty. Automatic handling facilities should be considered wherever their use will reduce operator exposure.

Where sealed sources such as  $^{137}\text{Cs}$  tubes are still used, they should be subject to regular inspection and leakage tests. These leakage tests should start when sources are first received and be repeated throughout their working life at intervals not exceeding two years. For older sources and those used in automatic afterloading equipment, annual testing is advisable. Sources should also be inspected for mechanical damage after cleaning or use. Identification marks should be checked. If any source fails any of these tests, it should be returned to the manufacturer and not re-used.

In principle, solid sources should not be cut or modified in any way. A common exception is in the use of  $^{192}\text{Ir}$  wire, for which appropriate cutting facilities are available. Care should be taken that activity transferred to the cutter is not dispersed further and that short lengths of wire are not left in the handling area. The wire must be fully accounted for at all stages of its use up to its final disposal.

All equipment used in connection with sealed sources should be monitored for contamination. If contamination is found, its source should be identified and corrective action should be taken. The precautions described in [Section 61.3.4.3](#) are also relevant to the use of sealed sources.

Apart from the precautions necessary for their safe handling, careful accounting is necessary to ensure that sources are not lost. Regular audit (monthly is normally appropriate) should be performed at suitable intervals with independent annual audit by a senior staff member\*.

Sterility of sources is a particular problem for implanted seeds and these are usually delivered presterilised from the manufacturer. Resterilisation using steam sterilisation of  $^{125}\text{I}$  sources is possible, but not ideal. Iridium wires are usually encapsulated in a catheter and do not therefore need to be sterilised. With hairpins, however, the wire is in contact with tissue. The pins are usually considered self-sterilising, but it is usual to soak them in chlorhexidine, followed by rinsing in sterile water before use.

#### 61.3.4 UNSEALED SOURCES

Radiation protection for unsealed source therapy involves the same precautions as for small sealed sources, but the potential for contamination becomes a major consideration. Accidental spillage creates the potential for contamination of surfaces as well as of staff and patients and for ingestion or inhalation of radioactive substances. Such spills are common, particularly when syringes are used for injection.

##### 61.3.4.1 Dispensing and Handling of Unsealed Radioactive Substances

The preparation of radiopharmaceuticals requires full pharmaceutical facilities as well as radiation protection. For this reason, many hospitals limit their activities to dispensing prepared solutions. It is important to be prepared for the possibility of spillage by ensuring that

\* In the current international security climate, the safekeeping of sources attains an even greater importance.

appropriate containment is provided in the form of deep trays. Syringes used for drawing up radioactive liquids should be shielded. Therapeutic isotopes are likely to be  $\beta$  emitters for which a transparent polymethyl methacrylate (PMMA, known as Perspex™ or Lucite™) shield is appropriate because less bremsstrahlung is produced than with the lead or tungsten shields used for  $\gamma$  emitters. After dispensing is complete, surfaces should be checked for contamination with an appropriate detector (see below). The local rules given in Appendix L.3 indicate other precautions that should be taken.

During movement from the dispensing laboratory to the administration room (ideally nearby), the radiopharmaceutical must be well-shielded and packaged to avoid spills in the event of an accident. A sturdy trolley is useful for this purpose, but it may also be carried by hand in a shielded container. Two persons should be present during movement of therapy-level quantities of radiopharmaceuticals in case of accidents.

$^{131}\text{I}$  poses particular problems. It is used in large quantities for the treatment of thyroid carcinoma. Typical activities are in the region 3 GBq to 10 GBq, but these activities will vary widely according to local practice and the stage of disease treated. Not only does it have a penetrating  $\gamma$ -ray (360 keV) requiring thick shielding, but in the elemental form it is also volatile. Because it is readily incorporated into normally functioning thyroid glands, it constitutes a particular hazard. Therapy quantities of  $^{131}\text{I}$  should be handled in fume cupboards (or similar) behind substantial shielding. Obtaining iodine in the correct quantities for administration as a liquid or in capsule form will reduce the amount of handling required.

$^{131}\text{I}$  is also used in labelled mIBG for the treatment of neural-crest tumours (see Section 58.1.2). Although often used at larger activities (up to 35 GBq) and thus more of a problem in regard to exposure to external radiation, it is only the free iodide, i.e. between 5 percent and 10 percent formed by radiolysis that will be taken up by the thyroid. Patients receiving mIBG therapy will have their thyroids blocked by administration of inactive iodide to prevent this uptake.

#### *61.3.4.2 Monitors for Working with Unsealed Radioisotopes*

Contamination and exposure-rate monitors (calibrated for each radionuclide, e.g. in terms of the annual limit of intake) must be readily available and used at all stages of the therapy procedure. For example, a thin-end-window Geiger counter is suitable for contamination monitoring of  $\beta$  emitters, and a side-window Geiger counter or scintillation detector is suitable for  $\gamma$  emitters. Suitably mounted and shielded monitors should be available for checking contamination of hands.

#### *61.3.4.3 Monitoring of Staff Working with Unsealed Radioactive Substances*

During preparation, dispensing, and administration of a therapy radiopharmaceutical, it is advisable to monitor finger dose; this may be carried out by using small lithium fluoride thermoluminescent dosimeters. To assess external dose, a personal monitoring badge must be worn. If shielding is used and a high dose rate is expected above the level of the shielding, it is advisable to wear two dosimeters on shielded and unshielded parts of body. These precautions are also appropriate for handling sealed sources.

An integrating personal dosimeter with direct readout and a dose-rate alarm is useful at high dose rates. In the case of suspected or possible inhalation of volatile radionuclides (e.g.  $^{131}\text{I}$ ), staff are advised to monitor both their chest (immediately after exposure) and thyroid (at 24 h) with a calibrated NaI scintillation detector. Regular whole-body counting will provide reassurance, but this should be tempered with the knowledge that the effective half-life of therapy agents is often measured in days.

### 61.3.4.4 Contingency Arrangements

Most incidents involving unsealed sources in hospitals do not warrant emergency action, but can be dealt with by trained staff working in the area using a *spill kit* (container of items useful for decontamination of personnel and equipment). However, contingency plans must be drawn up to cover the possibility of a serious incident. In such an event, the radiation protection supervisor for the area must be informed. Equipment for use in an emergency with unsealed sources (e.g. respirators, barriers for restricting access, portable monitors, and a list of useful telephone numbers) must be available. The effectiveness of contingency plans should be tested in training exercises using low-activity sources.

---

## 61.4 PATIENT TREATMENTS

### 61.4.1 MANAGEMENT OF BRACHYTHERAPY PATIENTS

#### 61.4.1.1 Manual Afterloading

In manual afterloading procedures, the sources are permanently located in the patient until they are removed. This means that during hospitalization there is a potential hazard for staff or visitors entering the room and the additional risk of source loss. Appropriate warning notices must be displayed that indicate the activity implanted and any restrictions on visiting, etc. Consideration must always be given to the possibility that implanted sources may become displaced. Normal procedures may include x-ray patients to ensure that implanted sources are correctly positioned in the patient. All dressings, bedding, and other items removed from the vicinity of the patient should be monitored to ensure that sources have not been inadvertently removed. Shielded pots should be placed near the bedside of patients to receive displaced sources. Patients should be monitored after removal of sources to verify that the sources have been completely removed. Portable monitoring equipment and remote handling tools should be provided. Additional fixed radiation detectors, located at well chosen exits, are useful to make sure that sources are not inadvertently taken out of the hospital by patients, visitors or staff. Mobile shields can be used for staff safety and may also be appropriate for the safety of visitors. Typical thicknesses for such shields are between 20 mm and 30 mm of lead for  $^{192}\text{Ir}$ ,  $^{198}\text{Au}$  or  $^{137}\text{Cs}$  sources. Lead aprons as used in radiology are of no benefit for these sources. For  $^{125}\text{I}$  sources, 0.1 mm of lead or equivalent thicknesses of other metals may be used (see attenuation data in [Table M.4](#)).

#### 61.4.1.2 Automatic Afterloading

High-dose-rate afterloading will be carried out in a shielded room with appropriate interlocks in a similar way to external-beam therapy. The treatment lasts for a few minutes and there are no subsequent radiation protection issues for nursing staff. The ICRP has published recommendations on the safety of high-dose-rate brachytherapy (ICRP 2005b). For low-dose-rate or pulsed-dose-rate afterloading, the irradiation will take place while the patient is in bed and the nurses will be able to operate the equipment so that there is, in principle, no hazard to them when they are with the patient. However, it is possible when applicators are not correctly fitted for the applicators to become dislodged and a procedure to deal with the situation where the sources do not return to the safe position is required.

#### 61.4.1.3 Patients with Permanent Implants Leaving Hospital

Patients who have had their prostates implanted with  $^{125}\text{I}$  or  $^{103}\text{Pd}$  will leave the hospital shortly after the implant. Task Group 57 of the ICRP has made recommendations for this

situation (ICRP 2006b). It is unlikely that doses greater than 1 mSv/year will be received by relatives and others as a result of such implants. However, patients should be advised to restrict close contact with children and pregnant women for the first two months following the implant. There is the possibility of seeds being expelled in the urine or during ejaculation and patients should avoid sexual intercourse for a week following the implant and should use a condom for the first five ejaculations. Immediately following the implant, it is advisable to strain the urine to check for such seeds although the ICRP report points out that there will be little hazard if they are flushed down the toilet and straining is not advised after the first few days. Patients should be advised that if they find such seeds in the first week or two after the implant, they should avoid physical contact with the seed, placing it in a sealed container and returning them to the hospital. Patients and their carers should be made aware of the protection issues relating to cremation (see [Section 61.4.3](#)). The advice given is similar to that described in [Section 61.4.2.3](#).

## 61.4.2 MANAGEMENT OF THE PATIENT UNDERGOING UNSEALED-SOURCE RADIOTHERAPY

### 61.4.2.1 *In-Patient Care*

During therapy with liquid radionuclides (such as  $^{131}\text{I}$  or  $^{90}\text{Sr}$ ), as with solid sources, the patient is a source of external radiation. However, in addition, all body fluids of the patient (e.g. urine, perspiration, vomit, saliva, blood) will be radioactive, with consequent risk of contamination. Although practices may vary at different centres, the precautions described below should avoid contamination during the treatment of thyroid carcinoma with  $^{131}\text{I}$ . During other types of therapy, if there is less risk of contamination, it may not be necessary to carry out all of these precautions.

Prior to administration of the radionuclide, plastic-backed absorbent paper should be taped to the floor around the patient's toilet and on other surfaces where contamination is most likely. After administration of the therapy agent, radiation measurements should be made around the treatment facility. Warning signs must then be clearly displayed to indicate the designation of the area (i.e. controlled or supervised). These signs should show:

- The nature and activity of the radio-nuclide used
- The date and time of administration
- Instructions to attending staff such as the use of protective clothing
- Recommended maximum time close to the patient (calculated taking account of the number of patients treated each year, the remaining activity within the patient, and the dose limits for staff)

Until discharge, in-patients should be identified with special signs (e.g. wearing a wristband), indicating that they are radioactive.

Mobile lead shields may be necessary for the protection of staff working close to the patient. They may also be placed at the door of the room to shield visitors and provide a demarcation. If the patient is catheterised, the urine bag should be placed in a lead pot (with lid) to reduce exposure to staff, and to minimise errors in measurements of whole-body counts.

The patient must be confined to their own suite while their activity exceeds levels that might give rise to excess exposure to others. As a guide, this level is reached when the product of the energy of the photons emitted per disintegration and the total activity in the body exceeds 150 MBq MeV, which is an activity of 400 MBq of  $^{131}\text{I}$  (IPEM 2002). If patients are required to move to another part of the hospital (e.g. for a scan) they should be accompanied by staff suitably trained in radiation protection. Before leaving their room, the patient

should shower and change into clean clothing. Overshoes should be worn and be removed on return.

Bed linen and clothing should be changed frequently and put into plastic bags. Each item should be monitored and, if contaminated, washed in the designated washing machine, dried, and re-monitored. Items still contaminated can be placed in labelled plastic bags and stored in a designated locked room until the remaining activity can be neglected. Contaminated waste should be macerated for disposal as liquid waste or bagged for future disposal as solid radioactive waste.

All staff entering the patient's room should wear plastic overshoes, aprons, and gloves. These are discarded in designated plastic bags on exit from the room and treated as radioactive waste. If staff who enter the patient's room handle potentially contaminated items, they should monitor themselves for contamination immediately afterwards. No item should be removed from the patient's room unless first checked for contamination by trained staff. If found to be contaminated, they should either be cleaned, disposed of, or put into store to allow for return after decay to acceptable levels.

Sampling of body fluids should be avoided if possible, especially in the first few days of therapy when they are likely to be most radioactive. Samples should be monitored and, if necessary, instructions on handling given to the laboratory testing the sample.

Regular assessments of the residual activity in the patient should be made to update the time allowed for staff to spend in the vicinity of the patient and to determine the time at which it is deemed safe to discharge the patient. These may either be based on calculations of the proportion of the initial activity remaining, or preferably on measurements with hand-held survey meters. If fitted, the whole-body counter in the ceiling can be used for this purpose (see [Section 61.2.2](#)).

Some patients may require particularly intensive care. In such cases, a detailed individual risk assessment should be carried out and appropriate precautions put into place. An example of the considerations required can be found in the paper by Greaves and Tindale (2001), which also considers the issues associated with the subsequent death of the patient (see also [Section 61.4.3](#)).

After discharge of an in-patient, the treatment room should be monitored for contamination and, if necessary, decontaminated by cleaning with proprietary detergents such as Decon™ (diluted 1:100). Moveable items that cannot be adequately decontaminated may be stored until the activity remaining is negligible. Nonremovable contamination can be covered with an adhesive plastic film (e.g. Fablon™).

### *61.4.2.2 Patient Leaving Hospital*

Guidance on precautions to be taken when patients leave a hospital has been issued by the European Commission (EC 1998), the BIR (BIR 1999), and the IPEM (IPEM 2002). As discussed in [Section 60.2.3.3](#), the statutory dose limits do not apply to those knowingly and willingly helping in the support and comfort of patients, but other basic principles such as the justification of practices and optimisation of radiation protection involving appropriate dose constraints\* must be applied. In deciding on the appropriate activity levels, it is reasonable to consider the availability of appropriate facilities in the hospital, as well as the views of individual patients and carers (EC 1998). Many regulatory authorities prescribe activity levels at which patients may be discharged, but these vary widely. The IAEA (1996) give a limit of 1100 MBq, but suggest that 400 MBq would be good practice. Within the European Union (EU), recommended activity levels for  $^{131}\text{I}$  vary from 95 to 800 MBq, although the majority of states recommend between 400 and 600 MBq. While it is appropriate for general guidance

\* See [Section 59.3.5](#) for an explanation of the difference between *dose limits* and *dose constraints*.

**TABLE 61.3**

Threshold Activity Levels (MBq) for Discharging Patients after Unsealed Source Radiotherapy

Radio-nuclide	Return to Radiosensitive Work <sup>a</sup> , Contact with Children, <10 MBq MeV	No Restrictions, Except Radio Sensitive Work <sup>a</sup> and Contact with Children, <50 MBq MeV	Travel by Public Transport, <150 MBq MeV	Travel by Private Transport, <300 MBq MeV
<sup>32</sup> P	300	1500	4500	9000
<sup>90</sup> Y	100	500	1500	3000
<sup>131</sup> I	30	150	400	800
<sup>198</sup> Au	30	150	400	800

<sup>a</sup> Examples of radiosensitive work include radionuclide assays, radiation monitoring, or work with radiosensitive materials.

Source: From NRPB (National Radiological Protection Board), *Guidance Notes for the Protection of Persons against Ionising Radiations Arising from Medical and Dental Use*, HMSO, London, 1988. (While this document is now obsolete the relative values remain useful.)

to be developed (depending on national regulations) the individual circumstances of each patient should also be considered.

In addition to any nursing requirements, patients, especially those treated with iodine for thyroid cancer, may be hospitalised because they are a potential source of ionising radiation for others, either as a consequence of external radiation or the risk of contamination. The patient will usually be anxious to return home and there will be pressures to release the bed for the treatment of others. Consequently, the patient will return home as soon as it is safe for this to happen.

The main factors that determine whether it is safe for the patient to be discharged from hospital are the radionuclide administered, the residual activity in the patient, the domestic circumstances, and the method of transport of the patient to home. Consideration must also be given to the state of health and nursing requirements of the patient. For example, a patient treated with a pure  $\beta$  emitter will not present an external radiation hazard, but might give rise to a contamination hazard if incontinent. It might be advisable to delay the discharge of such a patient, or to give special instructions (e.g. regarding handling of contaminated laundry).

Current legislation emphasises the need for practice to be based on risk estimates set against dose constraints, but Table 61.3, which is taken from the U.K. Guidance Notes of 1988 (NRPB 1988) provides a useful practical baseline. While the figure of 800 MBq remains the U.K. recommendation (IPEM 2002) for discharge of a patient receiving <sup>131</sup>I therapy from hospital, the EU document (EC 1998) is based around a more conservative figure of 400 MBq. The values for other isotopes are not available in the other recommendations, but are based on the product of activity and energy of the photons emitted per disintegration (Mountford 1997). No radiation protection precautions were recommended where this product did not exceed 10 MBq MeV. At levels greater than this, a patient might be discharged, but have to observe certain restrictions after leaving the hospital. In 1988, there was little available information about doses received by persons in the vicinity of radioactive patients and the table relates to compliance with the definition of a controlled area in the vicinity of radioactive patients. An activity energy product of 150 MBq MeV will require a controlled area within one metre of a patient.

Considerable progress has been made since the 1988 guidance notes were written in measuring doses to persons exposed to radiation from radioactive patients, particularly after treatment with <sup>131</sup>I (Monsieurs et al. 1998; Barrington et al. 1999; Reiners and Lassman 1999). The European Commission guidance (EC 1998) identified six groups of people:

**TABLE 61.4**Proposed Dose Constraints [mSv] for Family and Close Friends per Treatment with  $^{131}\text{I}$ 

Groups of Persons	Dose Constraint (mSv)
Children under 10 years of age (including unborn children)	1
Adults up to about age 60 years	3
Adults older than about 60 years age	15

Consideration must be given to the possibility of exposure during the year from other sources and where this cannot be controlled (as for members of the public) a constraint of 0.3 mSv applies. The term "Family and Close Friends" used in this document is equivalent to "Comforters and Carers" used by ICRP.

*Source:* From EC (European Commission), Radiation Protection 97, Radiation protection following iodine-131 therapy, EU, Brussels, 1998, [http://europa.eu.int/comm/energy/nuclear/radioprotection/publication/doc/097\\_en.pdf](http://europa.eu.int/comm/energy/nuclear/radioprotection/publication/doc/097_en.pdf).

- Children up to 2 years of age (who are likely to spend more time in close contact with their parents and relatives)
- Children aged between 3 years and 10 years (because the risks of cancer induction when children are irradiated are 2–3 times greater than when adults are irradiated)
- Pregnant women (the foetus being equivalent to a young child)
- Partners
- Partners over 60 years of age (because their probability of contracting cancer or of passing on genetic damage is between 3 and 10 times lower)
- Other people—who must be treated as members of the public

This guidance (Table 61.4) proposes constraints for family and close friends based on risks for exposure at various ages. The guidance also provides detailed advice in a form suitable to be given to patients.

Those persons who come into contact with the patient, where they cannot be classed as comforters and carers, are still subject to limits (see also [Section 60.2.3.4](#)). For example, in the U.K. these limits are 1 mSv/year; the special circumstances of these exposures would allow averaging over 5 years, but there is no dispensation to allow exposure to the constraint of 15 mSv from a single administration. However, persons exposed as comforters and carers (including care at home) are not subject to limits and these constraints could, if necessary, be applied.

When discharging a patient to another institution (e.g. a nursing home or hospital) details of radionuclide administered, residual activity, and estimates of activity excreted in the urine must be supplied and care taken to ensure that appropriately trained staff are available (IPEM 2002).

#### *61.4.2.3 Advice to Patients and Carers*

Prior to the administration of radioactive substances, it is good practice to explain clearly to patients and their relatives what will happen to them when they are in the hospital, together with the restrictions that will be placed on visitors. This discussion should cover the arrangements for their discharge and give adequate information about radiation hygiene after leaving the hospital. Information should also be sought from the patient about their family circumstances and the nature of facilities at home. It is particularly important to explain restrictions on close contact with children.

On discharge from hospital, it is recommended that the patient be given a card with the following information (IPEM 2002):

**TABLE 61.5**

Activities of Therapy Nuclides above Which Burial or Cremation Are Not Recommended

Radionuclide	Burial (MBq)	Cremation (MBq)
$^{131}\text{I}$	400	400
$^{125}\text{I}$ seeds	4000	— <sup>a</sup>
$^{103}\text{Pd}$ seeds	15 000	— <sup>a</sup>
$^{90}\text{Y}$ colloid	2000	70
$^{198}\text{Au}$ seeds	4000	— <sup>a</sup>
$^{198}\text{Au}$ colloid	400	100
$^{32}\text{P}$	2000	30
$^{90}\text{Sr}$	2000	200

<sup>a</sup> The encapsulation of radioactive seeds is required to withstand the heat of cremation and it is therefore possible that the contents of the seeds will not be dispersed. A risk assessment should therefore be carried out to determine the point at which this will no longer present a significant risk. For  $^{125}\text{I}$  seeds ICRP (2006b) recommends that cremation does not take place before one year has elapsed.

*Source:* From IPEM (Institute of Physics and Engineering in Medicine), *Medical and Dental Guidance Notes. A Good Practice Guide to Implement Ionising Radiation Protection Legislation in the Clinical Environment*, IPEM, York, 2002.

- Name and address of the patient
- Name, address and telephone number of the hospital
- Contact name in the hospital in case of difficulty
- The name of the prescribing physician
- The type and quantity of radionuclide administered
- The date of administration
- Restrictions to be followed, especially concerning contact with young children
- The period of time for which the restrictions apply

A new problem has arisen with the potential terrorist threat to use radioactive materials to contaminate public areas. As a result, many airports and other places have installed radiation detectors and these frequently detect patients who are radioactive. It is therefore wise to determine whether a patient is expecting to travel in the foreseeable future and to warn them of the need to justify their radioactive state.

### 61.4.3 DEATH OF PATIENTS CONTAINING RADIOACTIVE MATERIALS

If a patient should die soon after receiving therapy with radioactive material, the *qualified expert* (RPA) should be notified immediately. Precautions may be required (e.g. for post mortem and/or regarding disposal of the corpse by burial or cremation). Activity limits for burial or cremation for the most common therapy radionuclides are listed in Table 61.5. It may be necessary to consider removal of the organ containing radioactive material if a risk assessment shows that the activity of the seeds will present a risk to crematorium staff. This is likely to be the case if death occurs within one year of a prostate seed implant with  $^{125}\text{I}$ . If a post mortem is necessary, appropriate precautions should be taken. Unless the minimum limit in Table 61.3 has been reached, it is recommended that embalming should not take place.

---

## 61.5 RISKS ASSOCIATED WITH RADIOTHERAPY TREATMENT

### 61.5.1 RADIOTHERAPY OF PATIENTS OF CHILD-BEARING AGE

If the patient being considered for radiotherapy is pregnant, the foetus would be at direct risk from radiation. There is also the possibility that radiation damage to the gonads of father or mother can result in sterility or genetic damage to the as-yet-unconceived child. If the mother is breast feeding, then therapy agents can be passed on in breast milk. The following paragraphs consider such issues.

#### 61.5.1.1 *External-Beam Therapy of Potentially Pregnant Women*

Radiotherapy should be avoided when a woman is pregnant. Termination of the pregnancy, other methods of therapy, or postponement of radiotherapy are alternatives that may be considered. The risk to the foetus from radiotherapy (see [Section 59.2.9](#)) must be balanced against the corresponding risk from alternative therapies and the risk to the mother of hormonal changes in pregnancy. The appropriate course of action should be decided in discussion between the patient, the oncologist, and the physicist. There may therefore be occasions when it is decided to proceed with treatment. In such cases, the dose to the foetus must be estimated and precautions taken to minimise the dose.

Although the treatment of pregnant mothers is unusual, it is important that the physicist should be aware of the possibilities so that appropriate advice can be given when required. Task Group 36 of the AAPM has produced an extensive review of the subject (Stovall et al. 1995) and guidance is available in ICRP Report 84 (2000). The foetal dose will evidently depend on the proximity of the uterus to the target volume. The dose results from a combination of head leakage, external scatter, and scatter from the patient's own tissues. Extensive data are available in the literature for peripheral doses so that foetal dose can be calculated as a function of field size, beam energy, machine type, treatment volume, and distance from the field edge to within a factor of approximately two (O'Connor et al. 1987; Ngu et al. 1992; Sneed et al. 1995; Van der Giessen 1996, 1997). This is sufficiently accurate for the purpose of advising on the risks, bearing in mind the uncertainty inherent in risk estimates. A common site to be treated is the breast and it is argued that the dose received is unlikely to be sufficient to cause an unacceptably high risk to the foetus; certainly not to the extent of recommending abortion (Antypas et al. 1998; Greskovich and Macklis 2000; Fenig et al. 2001). The risk to the foetus of radiation induced cancer is around 15% for 1 Sv.

The dose delivered to the foetus depends on the type of treatment unit and on the use of accessories such as wedge filters. By an appropriate choice of treatment and perhaps some additional shielding, it should be possible to minimise the foetal dose. For example, intensity modulated radiotherapy should probably be avoided because the contribution of head leakage will be greater. Once the beam arrangements have been decided, phantom measurements should be made to confirm the predictions. During treatment, TLD measurements should be made to verify the calculations.

#### 61.5.1.2 *Unsealed-Source Therapy of Pregnant or Nursing Mothers*

Radiopharmaceuticals used for therapy may be able to cross the placental barrier and lead to direct uptake by the foetus. There may also be irradiation of the foetus by penetrating radiation from uptake within the mother. The use of MIRD methodology (see [Section 56.1](#) and [Section 56.2](#)) will enable an estimate of this dose. Clearly shielding the foetus is not an option in this case. Particular care needs to be taken with regard to the nursing mother because radioisotopes will find their way into breast milk. The risk of uptake from breast milk can be

avoided by suspension of breast feeding. Guidance on the periods of suspension for individual isotopes can be found in Section 7 of the ARSAC guidance notes (ARSAC 1998), but for  $^{131}\text{I}$  it is recommended that breast feeding is stopped altogether.

### 61.5.1.3 *Irradiation of the Gonads*

General sound advice is that gonads should be shielded from external radiation. Treatment of young adults with a potential for future healthy life and parenthood requires that dose to the gonads is minimised and that its magnitude be estimated. High doses to the testes or ovaries can result in temporary or permanent sterilisation. A woman's ova are formed early in life and radiation exposure may lead to genetic damage expressed in future generations. Testicular shields can be used to reduce the gonad dose, although the benefit is small. Modern technology for the storage of sperm and ova provides an alternative solution. It is also possible to move the ovaries surgically prior to treatment.

In the case of radionuclide therapy, future conception should be avoided until after all significant radioactivity has been eliminated from either the father's or the mother's body. The necessary period for this will vary with the nuclide and activity administered. Practical guidance is also available in the ARSAC guidance notes (ARSAC 1998).

### 61.5.2 SECOND CANCER RISK FROM RADIOTHERAPY

The requirement for optimisation and justification of radiotherapy treatments imposed by the European Council Directive on medical exposure (ECD 1997) increases the importance of an understanding of the risks associated with radiotherapy treatment and when carrying out research studies there is a requirement to estimate the effect of any radiation delivered (ICRP 1993). While issues such as hair loss and the formation of cataracts have long been well understood, stochastic risks such as the induction of second cancers have only recently been taken seriously. The growing literature on this subject has been reviewed by the National Radiological Protection Board (NRPB 2000) and by the Board on Radiation Effects Research (BRER 2006). It is concluded that doses to tissues in the target volume are likely to be sufficiently high as to sterilise any induced cancer, but that doses to surrounding tissues may cause second cancers. The evidence is that the risk level is the same as that derived from the atomic bomb data referred to in [Section 59.2](#). However, Aird (2004) and Harrison (2004) draw attention to the problems of using the concept of effective dose ([Section 59.1.3](#)) and population-based statistics when dealing with individual radiotherapy patients. Direct proof of a causal relationship between radiotherapy and second cancers is difficult because of the conflicting factors that the patients may have an increased susceptibility to cancer whether for hereditary or lifestyle reasons.

A particular problem arises when young patients are being treated. Examples in which there is good evidence of second cancers are the contralateral breast (Gao et al. 2003) and patients treated with mantle fields for Hodgkin's disease who have a significantly increased risk of contracting breast cancer (Bhatia et al. 1996), particularly if irradiated below the age of 30 (Aisenberg et al. 1997). Fortunately, there is reasonable success in treating breast cancer (Horwich and Swerdlow 2004), but the high incidence has led to a strong desire to find other methods of treatment. Khan and Haffty (2001) have evaluated the site of second tumours within the contralateral breast and found that the site is not correlated with the area receiving the highest dose, which may call into question the causal relationship in the case of breast cancer treatment.

There is also some evidence of second cancers following the treatment of older patients. For example Movsas et al. (1998) and Brenner et al. (2000) show a small increase in second cancers following prostate treatment. Yasui et al. (2003) point out the need to consider the natural incidence of cancer with age for the subjects of studies of second cancers. Waddington

and McKenzie (2004) have analysed the expected impact of double exposure portal films and predict that these will be likely to cause cancer. However, the age of such patients may reduce the practical impact and any effect of cancer induction must be balanced against improvements in localisation increasing the potential for cancer cure. Nevertheless, it is preferable to obtain images using the actual treatment field where this is sufficient to obtain positional information and new techniques are becoming available to obtain portal images with reduced dose (Vetterli 2004).

A number of authors point out that IMRT involves a higher scatter dose and that IMRT treatment is likely to increase the number of induced second cancers (Verellen and Vanhavere 1999; Dorr and Hermann 2002; Followill et al. 2003; Hall and Wu 2003; Gregoire and Maingon 2004). Followill et al. (1997) recommended that high-energy photon beams should not be used for IMRT because of the increased risk of second cancers predicted from the associated neutron dose. Price et al. (2003) found that a Varian 18 MV machine produced significantly more neutrons than the corresponding Siemens machine because the latter had a lower electron energy (see [Section 22.2.2](#)). Further work on this has been reported by Vanhavere et al. (2004). This risk of cancer induction must be set against the benefits of IMRT.

### 61.5.3 DETERMINISTIC RISK OF ORGAN DAMAGE

It has long been known that acute radiation damage can be caused to various organs, such as the optic nerve, the spinal cord, the lungs, liver, and kidneys. However, more recently, late effects of irradiation of the heart have been identified. In a meta-analysis of breast radiotherapy treatment Cuzick et al. (1994) found that, although radiotherapy improved local control, it did not improve survival because of the increase in deaths associated with cardiac problems. More direct evidence of cardiac damage has become available since then, and it is clear that dose to the heart should be minimised (Gagliardi et al. 2001; Adams et al. 2003).

### 61.5.4 PATIENTS WITH PACEMAKERS

Patients who have implanted cardiac pacemakers may also be at risk. Early reports of the assessment of damage to pacemakers suggested that there was not a problem (Walz et al. 1975), but modern pacemakers that use CMOS logic are more sensitive to damage than older types (Adamec 1982; Last 1998). Several publications give advice on this subject including the American Association of Physicists in Medicine (AAPM) guidance (Marbach et al. 1994) and more recent publications by Last (1998) and Solan et al. (2004). The general consensus has been that the dose to the pacemaker should be less than 2 Gy and that it should therefore never be in the direct beam. However, work by Mouton et al. (2002) has identified a pacemaker failure with a dose as low as 0.15 Gy. Solan et al. suggest that pulse and blood pressure monitoring should take place before and after each treatment and that pacemaker dependent patients should be monitored using the electrocardiograph at the first treatment, but this level of monitoring may be hard to implement. Manufacturers provide advice on the susceptibility of their pacemakers to radiation, but the studies by Mouton and Solan et al. call into question the reliability of such advice. More recently, implantable cardiac defibrillator devices have been introduced and these are believed to be more susceptible to the effects of radiation; it is suggested that the dose delivered to them should be limited to 1 Gy. There does not seem to be good evidence for the view that patients with pacemakers should only be treated on cobalt-60 units, although the AAPM recommend that such patients are not treated on betatrons. It would be prudent to establish the patient's degree of dependence on the pacemaker before commencing treatment and to base the level of monitoring on this. It would also be sensible to ensure that the pacemaker is checked after treatment and that the patient is warned of the possible dangers.

## L.1 U.K. REGULATORY FRAMEWORK

### L.1.1 INTRODUCTION

As discussed in [Chapter 60](#) all radiation protection legislation in the European Union (EU) is based on directives of the European Council of Ministers, which are then interpreted into the legal framework of individual states. Each state will interpret the legislation in a slightly different way. This Appendix, which describes the U.K. legislation\*, is included both for the benefit of U.K. readers and to provide a comprehensive overview of a self-consistent legal framework. Attention is drawn to some small differences from the original Council Directives.

The legislation applies equally to therapy and diagnosis, but only the application to therapy will be considered here. The Appendix should be read in conjunction with Chapter 60, where a more international treatment is given. This summary of the legislation should not be regarded as a substitute for the original text. References are given to the specific regulations and their associated schedules.

Oversight of radiation protection issues is the responsibility of a number of government departments. The Secretary of State for Environment, Food and Rural Affairs has overall responsibility for radiation protection legislation, the Secretary of State for Work and Pensions for health and safety legislation and the Secretary of State for Health for protection of the patient. These functions are carried out through several agencies.

Because the process to introduce a new act of Parliament is complex and time consuming, all the radiation protection regulations were “laid before parliament” under the Health and Safety at Work Act 1974 and this, in spite of being a simpler process, took several years to achieve. The Health and Safety at Work Act 1974 led to the setting up of the Health and Safety Commission (HSC) and its operational arm the Health and Safety Executive (HSE). The HSC is a body of up to ten people appointed by the Secretary of State for Work and Pensions. It has a full time chair and part-time members including representatives from employers, unions, local authorities and public interest. Its function is to make arrangements to secure the health, safety and welfare of people at work and the public. It is the interface between ministers and the HSE. The HSE is formally a body of three people appointed by the HSC with the consent of the Secretary of State. It advises and assists the Commission in its functions and also has specific statutory responsibilities of its own, notably for the enforcement of health and safety law. However, the term *HSE* is also used to describe its staff (around 4000) that includes inspectors, policy advisers, technologists, and scientific and medical experts. The HSE ensures the safety of employees and public from the use of ionising radiation in hospitals and other places.

---

\* What is described is strictly the legislation for England. Detailed legislative arrangements in England, Scotland and Wales are complex, but in radiation protection terms are similar. Some minor differences exist in Northern Ireland legislation.

The Environment Agency was formed in 1996 as an independent agency charged with protecting the environment from all manner of potentially damaging agents including ionising radiation. It incorporates the Nuclear Inspectorate that is responsible for the regulation of the disposal of radioactive waste (as well as for the supervision of the nuclear industry).

The Department of Health (DoH) regulates the medical exposure of persons to ionising radiation. A committee, the Administration of Radioactive Substances Advisory Committee (ARSAC), is concerned directly with all administration of radioactive substances to patients for medicinal purposes. The Health Protection Agency was set up in 2003 to take responsibility for advice on health protection issues. It now incorporates the National Radiological Protection Board (NRPB). From November 2006 the Commission for Healthcare Audit and Inspection (Healthcare Commission) has taken responsibility for inspections relating to protection of the patient.

## L.1.2 IONISING RADIATION REGULATIONS 1999

The Ionising Radiation Regulations 1999 (IRR1999) (HS 1999a) are derived from the EU Basic Safety Standards (ECD 1996a) and also incorporate the Outside Workers Directive (ECD 1990) (replacing the Outside Workers Regulations 1993 (HS 1993a)). They set out the requirements for the protection of staff and the public and apply equally to hospitals as to other users of radiation. They are accompanied by an Approved Code of Practice (ACoP) (HSE 2000) which sets out ways of achieving compliance with the law. Those who choose to depart from the code must be prepared to show that their own approach is an equally valid way of meeting the legal requirements. Guidance on the application of IRR1999 in medicine is also provided by the Medical and Dental Guidance Notes (IPEM 2002).

### L.1.2.1 Dose Limits

The dose limits for staff and the public are set out in Regulation 11 and Schedule 4 and are listed in [Section 60.2.2.3](#). *Category A* workers who might receive more than 6 mSv per year as defined by the EU BSS (ECD 1996a) are called *classified* workers in the U.K. (Regulation 20). Classified workers must be subject to medical supervision (Regulation 24) and more elaborate record keeping (Regulation 21). Their dose records must be kept for at least 50 years by an approved dosimetry service.

### L.1.2.2 Investigations

It is a requirement that an *investigation* is carried out (Regulation 8) the first time that an employee exceeds 15 mSv in a calendar year in order to verify that the dose is indeed as low as reasonable practicable. An investigation must always be carried out if an overexposure of a member of staff occurs (Regulation 25) or if an equipment malfunction results in the overexposure of a patient (Regulation 32(6)) or if a personal dosimeter is lost or damaged (Regulation 22).

### L.1.2.3 Control of Areas

The Regulations define the requirements for *controlled* areas and *supervised* areas (Regulation 16). The EU legislation leaves the definition of these areas to be defined by the individual states. In the IRR 1999 a controlled area is defined as one in which it might be possible to receive an annual dose of 6 mSv and a supervised area as one where a dose of 1 mSv might be reached. Both controlled and supervised areas must be suitably signed (Regulation 18) and controlled areas be physically demarcated or if this is not practicable, delineated by some other suitable means.

### L.1.2.4 Equipment

Before new radiation work is carried out the employer must notify the HSE (Regulation 6). Before equipment is installed a *risk assessment* must be carried out (Regulation 7) to identify any possibility of the equipment leading to a radiation accident. If such a risk is identified, contingency plans must be set in place to mitigate the risk (Regulation 12). The supplier is obliged to carry out a *critical examination* of the equipment either in conjunction with their own Radiological Protection Adviser (RPA, see Section L1.2.5) or with the hospital's RPA (Regulation 31). The hospital is required to ensure that quality control of the equipment (Regulation 32) and its associated interlocks (Regulation 10) is carried out. The RPA should be consulted about the suitability of the *quality assurance programme*.

When an equipment malfunction occurs which results in a patient receiving a dose that is *much greater than intended* the Regulations require that this be reported to the HSE (Regulation 32). The definition of "much greater than intended" is contained in the HSE document PM77 (HSE 2006) as 10% for a whole therapy course or 20% for a single fraction. The requirement to report such overdoses is contained also in the IAEA BSS (IAEA 1996), but is not a specific requirement of the European Council Directive. In other European countries the reporting requirement is less juridical.

### L.1.2.5 Radiation Protection Adviser

The Regulations require the appointment of a *Radiation Protection Adviser* if ionising radiation is to be used (Regulation 13). The duty to comply with the law remains with the employing authority who is in principle at liberty to ignore the advice of the RPA (although this would only be done in rare circumstances). An RPA is required to have an appropriate certificate of competence the attainment of which requires a portfolio of evidence showing both academic understanding and practical application or the achievement of a national vocational qualification (NVQ). Schedule 5 of the Regulations lists the issues about which an RPA must be consulted:

- Controlled and supervised areas
- New installations including the radiation shielding and interlocks
- Calibration and correct use of monitoring equipment
- The testing of interlocks

The RPA may also advise on a wider range of issues including risk assessment, investigations of estimated doses, investigations of high exposures, and training. A fuller list is given in the ACoP.

### L.1.2.6 Radiation Protection Supervisors

The day to day oversight of radiation work is the responsibility of *Radiation Protection Supervisors* (RPS) appointed by the employer (Regulation 17). They are responsible for the application of the *local rules* (see [Section 60.2.2](#)).

### L.1.2.7 Training

The Regulations require that the employer ensures that staff are adequately trained (Regulation 14). Training must be appropriate to the work being done, but particular training must be given to those acting as RPS. Training is also required for those entering a controlled area under a *system of work*.

### L.1.3 IONISING RADIATION (MEDICAL EXPOSURES) REGULATIONS 2000

The Ionising Radiation (Medical Exposures) Regulations (IR(ME)R 2000) (HS 2000\*) derive from the European Council Medical Exposures Directive (ECD 1997). They set out the regulations governing patient safety. Guidance on the application of IR(ME)R 2000 is provided by the Medical and Dental Guidance Notes (IPEM 2002) which also covers the medical application of IRR1999. This was produced by a working group of the Institute of Physics and Engineering in Medicine (IPEM) in association with the NRPB (now HPA), the HSE, the Health Departments and the Environment Agencies and in cooperation with the Royal College of Radiologists and the College of Radiographers. As such, it has a similar (but perhaps slightly lower) standing in legal terms to the ACoP associated with IRR 1999.

#### L.1.3.1 *Definition of Roles*

The Regulations define (Regulation 2) four classes of professional contribution to radiation therapy (and diagnosis). The duties associated with these roles are defined in Regulations 5 and 9. These are:

1. The *referrer* who sends the patient for treatment and is required to provide sufficient clinical information to allow the justification of the treatment to be determined<sup>†</sup>
2. The *practitioner* who is responsible for the clinical oversight of the treatment and for justifying any radiation exposure<sup>‡</sup>
3. The *operator* carries out any “physical aspect” of the treatment process (including for example machine calibration or treatment planning)<sup>¶</sup>; the Regulations make clear that all operators are personally responsible for their own contribution to the patient treatment
4. The *medical physics expert* (MPE) who must be “closely involved” in all radiotherapy treatment

The Regulations do not define who may fulfil these roles, apart from requiring that they be health professionals and in the case of the referrer that they be state registered (HS 2006). However, they do require that each employer produces a list of named individuals together with records of their training (Regulation 11) (although not expressly for the referrer). Employers are required to define written procedures to ensure that patients are correctly identified (Schedule 1). Employees are required to follow the defined procedures (Regulation 5). Operators must identify the patient and ensure that the exposure has been *justified* (Regulation 6) before exposing the patient to radiation.

#### L.1.3.2 *Optimisation*

Regulation 7, which deals with optimisation of exposures, includes the requirement that therapeutic exposures are individually planned to ensure that non-target tissues are given doses *as low as reasonably practicable* and that the equipment selected for treatment should be appropriate. It is a requirement that the clinical outcome of every exposure is evaluated. It is common

\* Some minor amendments to the regulations came into force in November 2006 (HS 2006).

† In the EU legislation the term used is the “prescriber”, but this is not the interpretation applied in the U.K. regulations.

‡ The use of the word “practitioner” is unfortunate because of its wider use to describe level 2 in the four tier structure of health service professional groups. The term “justifier” may better describe the role.

¶ This role is not expressly recognised in the European Council Directive.

practice for therapeutic exposures to be defined to include the whole course of radiotherapy including the necessary planning and verification exposures.

### L.1.3.3 *Investigation of Errors*

In parallel with IRR 1999, the Regulations require that a human error that leads to an exposure *much greater than intended* must be reported to the Healthcare Commission (Regulation 4), who are responsible for investigation (and potentially the prosecution of individuals in the event that the error resulted from a breach of the Regulations). The Regulations do not define “much greater than intended”. A course of radiotherapy may not be compromised by a significant error (even 20%) in a single fraction and it is accepted that for this purpose the course should be treated as a whole.

Errors in positioning of the beam may be as significant as errors in the magnitude of the dose and where they have a potential impact on treatment outcome, should also be reported. Because the requirement for reporting of overdoses derives from a regulatory framework there is no statutory requirement for reporting underdoses under the Regulations, even though they may also compromise treatment outcome.

### L.1.3.4 *Training*

The requirement for staff to be adequately trained is a central part of the Regulations as it is of the European Council Directive. Comprehensive records of staff training must be kept in association with the list of referrers, practitioners and operators (Regulation 11). A list of topics which training must cover is in Schedule 2.

### L.1.3.5 *Equipment*

The employer is required to draw up a list of equipment held, to include information about the manufacturer, serial number and year of manufacture and installation (Regulation 10). There is a requirement that the equipment is limited to the amount necessary, implying that redundant equipment must be decommissioned.

## L.1.4 RADIATION (EMERGENCY PREPAREDNESS AND PUBLIC INFORMATION) REGULATIONS 2001

The Radiation (Emergency Preparedness and Public Information) Regulations (REPPIR) (HS 2001) are primarily intended to ensure that the nuclear industry has appropriate contingency plans. It requires that where sources of activity greater than a certain level are held, the employer should have appropriate contingency plans in place. Nondispersible sources (i.e. sources which by virtue of their physical or chemical form cannot cause a radiation emergency affecting the public in any reasonably foreseeable event) such as  $^{192}\text{Ir}$  and  $^{60}\text{Co}$  therapy sources used in afterloading or teletherapy equipment, are exempt except when being transported and it is therefore unlikely that there would be a requirement under these Regulations in a hospital.

## L.1.5 RADIOACTIVE SUBSTANCES ACT 1993 CONTROL OF SOURCES AND WASTE DISPOSAL

The holding and disposal of radioactive substances is governed by the Radioactive Substances Act 1993 (HS 1993b). The Environment Agency for England and Wales and the Scottish Environment Protection Agency grants a license to hold specified activities of

radioactive sources and also licenses disposal of waste. Following the European Council Directive on the control of high activity sources (ECD 2003) the government has issued the High-Activity Sealed Radioactive Sources and Orphan Sources (HASS) Regulations 2005 (HS 2005) which require that for high activity sources (e.g.  $^{60}\text{Co} > 4 \text{ GBq}$  and  $^{192}\text{Ir} > 10 \text{ GBq}$ ) appropriate arrangements are in place for source security and eventual disposal before an authorisation is given. Guidance has been issued on the implementation of these regulations (EA 2006). To allow for the replacement of therapy sources, the licensed activity should allow for the presence of both the new source and the decayed source at the same time. Use of dispersible radioactive substances in a hospital will generate radioactive waste in the form of both patient excretions and unused quantities of isotopes. An estimate must be made of the amount of all such radioactive waste and the routes by which it will reach the environment. Before applying for an authorisation for the disposal of this waste an *environmental risk assessment* must be made for each route of disposal. Advice on making such assessments has been issued by the Environment Agency (EA 2002a) and the NRPB (McDonnell 2004). A therapy source that is no longer in use becomes classified as waste and counts towards the amount of waste material that may be held. It is therefore necessary that disposal arrangements are set in place and it is better if the supplier will take back the decayed sources. For those holding an authorisation to dispose of waste the Environment Agency requires that they carry out an assessment to show that the “best practical means” (BPM) are applied to minimise the impact of waste disposals. The requirement derives from European Commission requirements (EC 2003). The Environment Agency has issued guidance on carrying out this assessment (EA 2002b).

### L.1.6 ADMINISTRATION OF RADIOACTIVE SUBSTANCES TO PATIENTS

The Regulations relating to the administration of radioactive substances to patients are contained in three pieces of legislation: The Medicines (Administration of Radioactive Substances) Regulations 1978 (MARS Regulations) (DH 1978a), The Medicines (Radioactive Substances) Order 1978 (DH 1978b) and The Medicines (Administration of Radioactive Substances) Amendment Regulations 1995 (DH 1995). The first of these is the principal one and established the Administration of Radioactive Substances Committee which oversees the grant of licenses by ministers under the Regulations. Licenses are granted to individual consultants for up to five years. The actual administration of the radioactive substance may be carried out by another person under the supervision of a license holder, but if this is to happen the agreement of the license holder must be recorded in writing. The license covers specified uses of radioactive materials in a specified location. The application for the license requires the applicant to show how scientific and radiation protection support will be provided and the responsible scientists will have to sign the application. It is the responsibility of the clinician to ensure that a valid license is held for a specific procedure. ARSAC licenses may also be issued for two years for clinical research purposes. In such cases ethical approval must be given for each study. An ARSAC license is not required for teletherapy, but is required for any form of brachytherapy.

### L.1.7 THE RADIOACTIVE MATERIAL (ROAD TRANSPORT) REGULATIONS 2002

The regulations governing the transport of radioactive substances are the Radioactive Material (Road Transport) Regulations 2002 (HS 2002a)\*, the Carriage of Dangerous

\* Rail transport has separate regulations (The Packaging, Labelling and Carriage of Radioactive Material by Rail Regulations 2002 (HS 2002b)) but these are unlikely to affect medical physicists.

Goods by Road (Driver Training) Regulations 1996 (HS 1996), the Transport of Dangerous Goods (Safety Advisers) Regulations 1999 (HS 1999b) and the Carriage of Dangerous Goods and Use of Transportable Pressure Equipment Regulations 2004 (HS 2004). As discussed in [Section 60.5](#) transport regulations are more closely aligned across the EU than other parts of the legislation. The Regulations (HS 2002a) define the classification of packages for transport purposes (Regulation 23 and Schedule 11) as specified in [Table 60.3](#) and also the design of different types of packages (Schedule 8 and Schedule 9) which must be used depending on the source activity. Contents limits for different types of package are contained in Schedule 4 which relates to the detailed list of activity levels given in Table I of Schedule 1. All packages other than Type A packages require an approval certificate (Schedule 10 and Schedule 12, Part IV). The documentation and vehicle labelling that is required when consigning radioactive packages (Regulation 48) is listed in detail in Schedule 6 which contains details of the wording that must be used, etc. These include UN numbers (Schedule 1, Table VIII). The Regulations require that a quality assurance programme (Regulation 18) is in place to ensure compliance with the Regulations. Small packages containing activities less than those listed in Table III of Schedule 1 (HS 2002a) can be defined as “excepted packages” under the Transport Regulations, but the conditions of such exemptions are rarely met. The Regulations are not relevant when the radioactive substance is contained in a patient.

HS 1996 requires the training of drivers of vehicles carrying radioactive packages. HS 1999 requires (Regulation 4.1) that where packages are consigned for transport the employer has appointed someone who has undertaken an approved course of training in the Transport Regulations (HS 1999b). This can be an onerous requirement and for this reason it is common practice for the transport company to take responsibility for the whole process including the consignment of the packages. However, an employer who only occasionally engages in the transport of dangerous goods within the United Kingdom, and if that transport does not create a significant risk to the health and safety of persons and to the environment, is exempt (Schedule 1, Section 4). This exemption is interpreted as not more than 10 Type A packages with a total transport index of up to 3 (IPEM 2002).

## L.2 EXAMPLE WALL-THICKNESS CALCULATIONS

[Figure L.1](#) shows a treatment room originally designed to accommodate a 4 MV accelerator in about 1970. Since then, the 4 MV machine has been replaced by a 5 MV machine and some thickening of the walls at A was carried out. It is now due to be used for a modern 6 MV accelerator. This room will be used to illustrate some of the considerations in designing a linear accelerator treatment room. (For further examples of treatment rooms, the reader is referred to IPEM Report 75 [IPEM 1997] and NCRP Report 151 [NCRP 2005].)

The dose at point A, which is located on the main hospital corridor, is considered first. The dose rate at the isocentre is 3.70 Gy/min. The distance to point A from the source is 5.97 m, so the unattenuated dose rate is:

$$\frac{3.70 \times 1^2}{5.97^2} = 0.104 \text{ Gy/min} \quad (\text{L.1})$$

The tenth-value-thickness (TWT) for 4 MV is 290 mm and for 6 MV is 343 mm. Therefore, for 5 MV a value of 316.5 mm is appropriate (see [Table 61.2](#)). The wall is apparently 1.8 m thick, so the attenuated instantaneous dose rate is:

$$0.104 \times e^{-\frac{-\ln(10) \times 1.8 \times 1000}{316.5}} \times 60 = 12.8 \mu\text{Sv/h} \quad (\text{L.2})$$

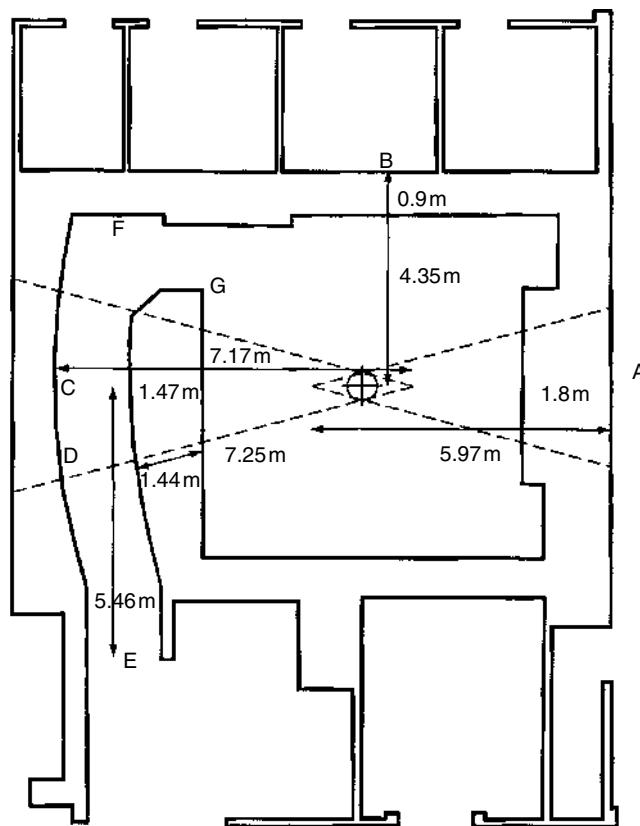

**FIGURE L.1**

Diagram of a 5 MV treatment room that is to be upgraded to a 6 MV room.

The dose rate actually measured at this point is  $50 \mu\text{Sv/h}^*$ . This indicates that the density of the concrete in the wall was not quality controlled at the time of building; consequently, the effective thickness is only about 1.6 m. For the modern 6 MV accelerator, the dose rate is 6.0 Gy/min and the TVT for 6 MV is 343 mm, so the attenuated dose rate at A can be expected to increase to  $200 \mu\text{Sv/h}$ . To calculate the time-averaged dose rate (TADR), it is appropriate to consider:

- The duty cycle of the machine: about 1 in 10-calculated as the total dose delivered to the isocentre in a working day divided by the number of hours
- An orientation, or *use* factor: for standard use, a factor of 0.33 is appropriate
- An occupancy factor: taken as 1.0 for the TADR

This leads to a TADR of  $1.7 \mu\text{Sv/h}$  for the 5 MV machine and  $6.6 \mu\text{Sv/h}$  for the 6 MV machine. TADR2000 can include an occupancy factor for which a value of 0.3 for a busy corridor might be appropriate (noting that the occupancy does not need to refer to one individual). Thus, the calculated TADR2000 is  $0.5 \mu\text{Sv/h}$  and  $2.0 \mu\text{Sv/h}$  for the two machines, respectively.

\* The use of Gy and Sv is somewhat arbitrary since for photons they are numerically equal. Here Gy is used to express therapy-level dose rates and Sv to express protection-level dose rates.

Note that this point needs to be a supervised area, but not a controlled area, on the basis of the TADR. It is not really practicable to have a supervised area in a corridor, but with the 5 MV machine and on the basis of the predicted dose rather than the measured dose, the situation is almost acceptable. For the new machine, when current recommendations should be followed, at least an additional TVT is to be recommended. This could be achieved with 100 mm of steel or 180 mm of Lelite blocks.

At point B, leakage radiation is being considered. For this purpose, it is customary to measure distances from the isocentre rather than from the source and the nearest point is at 4.35 m. Leakage radiation is usually less than 0.1% of the dose rate in the beam, so the unattenuated dose rate at B is

$$\frac{3.70 \times 1^2}{4.35^2 \times 1000} = 0.00020 \text{ Gy/min.} \quad (\text{L.3})$$

The wall thickness at that point is 0.9 m and the TVT is 266.5 mm for scattered radiation. Thus, the instantaneous dose rate is calculated as

$$0.00020 \times e^{\frac{-\ln(10) \times 0.9 \times 1000}{266.5}} \times 60 = 4.9 \mu\text{Sv/h.} \quad (\text{L.4})$$

The dose rate actually measured at this point was 1.5  $\mu\text{Sv/h}$ . On the inside of the wall at this point, the dose rate was 20  $\text{mSv/h}$ , as would be expected; it therefore appears that the leakage radiation is less penetrating than expected by a factor of three\*. The reason for this is unclear.

Consider now the dose rate in the maze. At C, the dose rate can be calculated by analogy to point A as

$$\frac{3.70 \times 1^2}{7.17^2} \times e^{\frac{-\ln(10) \times 1.47 \times 1000}{316.5}} \times 60 = 98 \mu\text{Sv/h} \quad (\text{L.5})$$

whereas at D, the dose rate is

$$\frac{3.70 \times 1^2}{7.25^2} \times e^{\frac{-\ln(10) \times 1.44 \times 1000}{316.5}} \times 60 = 119 \mu\text{Sv/h} \quad (\text{L.6})$$

Going down the maze, the dose rate falls off. An approximate estimate of the dose rate at the maze entrance can be calculated using Equation 61.1. The scatter function (from IPEM 1997) for this condition is 0.022 and so the dose rate at the entrance of the maze, which is 5.46 m from the central axis of the primary beam is:

$$108.5 \times \frac{0.022 \times 3.5^2}{5.46^2} = 0.98 \mu\text{Sv/h} \quad (\text{L.7})$$

In fact, the dose rate measured at the entrance of the maze is about 29  $\mu\text{Sv/h}$  with the largest field size. Measurements at point F showed a reflected dose rate of 32  $\text{mSv/h}$  when a scattering phantom is placed at the isocentre; inspection of the figure shows that there is a direct line of sight from the isocentre to the wall, allowing radiation to access the maze entrance with only a single reflection. This was corrected by adding a nib to the maze wall at G. This reduced the dose rate at F to 1.65  $\text{mSv/h}$  and the dose rate at the maze entrance to 3  $\mu\text{Sv/h}$ .

\* A similar finding was recorded for the point C in Table III2.4 of IPEM report 75 (IPEM 1997). The calculated TVT is 232 mm rather than 266 mm, which endorses the use of a lower value to the TVT for leakage radiation.

## L.3 LOCAL RULES FOR HANDLING RADIOACTIVE SOURCES

The following is an example of local rules that could be laminated and displayed in an unsealed source preparation lab:

1. Film badges must be worn at all times.
2. Laboratory coats must be worn and done up.
3. Eating, drinking, smoking, and application of cosmetics are forbidden.
4. Tissue handkerchiefs provided must be used, not your own, and hands monitored before use.
5. Open wounds and cuts must be covered with a waterproof dressing.
6. Rubber/PVC gloves must be worn. They must be removed before leaving the radiation areas to prevent possible spread of contamination.
7. Gloves and surfaces should be monitored frequently during, and immediately after, working. Contaminated gloves should be changed immediately.
8. Wash and monitor hands before leaving the working area.
9. Full use must be made of appropriate protective devices i.e. syringe shields, lead pots, handling tools, and shielding devices. Radioactive materials are to be handled at the greatest distance consistent with safety and minimising time of exposure.
10. Do not work alone in a controlled area unless another member of staff is aware of this and able to render assistance if required.
11. Where possible, secondary containment should be used for working with, and movement of, unsealed sources. In the event of a spill or suspected contamination, follow the spill procedures given in the full Local Rules.
12. Staff handling radioactive materials should not be interrupted.
13. Radioactive materials must be stored in designated places.
14. Waste disposal must be in accordance with Local Rules.
15. The local RPS is: .....

## TABLES M.1 PHYSICAL CONSTANTS AND USEFUL DATA

*Compiled by Jean-Claude Rosenwald*

### INTERNATIONAL SYSTEM OF UNITS (SI)\*

**TABLE M.1a**

SI Basic Quantities and Units

Quantity	Name <sup>a</sup>	Symbol <sup>b</sup>
Length	metre	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

<sup>a</sup> According to the SI system, the full names or the units are always treated like ordinary nouns (i.e. written in lower-case upright letters, in the plural if appropriate).

<sup>b</sup> The symbols of the units are printed in upright lower-case letters unless they are derived from a proper name, in which case the first letter is a capital letter (with the exception of the "litre" symbol which may be written as "L").

**TABLE M.1b**

Useful SI-Derived Quantities and Units with Special Names and Symbols

Quantity	Name	Symbol	Expression in Other SI Units
Plane angle	radian	rad <sup>a</sup>	—
Solid angle	steradian	sr	—
Force	newton	N	$\text{m kg s}^{-2}$
Pressure	pascal	Pa	$\text{N m}^{-2}$
Energy	joule	J	$\text{N m}$
Power	watt	W	$\text{J s}^{-1}$
Electric charge	coulomb	C	$\text{A s}$
Electric potential difference	volt	V	$\text{W A}^{-1}$
Celsius temperature	degree Celsius <sup>b</sup>	°C	K
Activity	becquerel	Bq	$\text{s}^{-1}$
Absorbed dose, kerma	gray	Gy	$\text{J kg}^{-1}$
Dose equivalent	sievert	Sv	$\text{J kg}^{-1}$

<sup>a</sup> Radian (rad) should not be confused with the obsolete unit for absorbed dose (rad).

<sup>b</sup> The degree Celsius is the special name for the kelvin used to express Celsius temperatures. The degree Celsius and the kelvin are equal in size, so that the numerical value of a temperature difference or temperature interval is the same when expressed in either degrees Celsius or in kelvins.

\* A full description of the International System of Units may be found in the official brochure of the Bureau International des Poids et Mesures (see [http://www.bipm.org/fr/si/si\\_brochure/](http://www.bipm.org/fr/si/si_brochure/)).

**TABLE M.1c**

Conversions of Obsolete Units (All Coefficients Are Exact Values)

Quantity	Obsolete Unit	Coefficient	SI Unit
Activity	1 Ci (curie)	$3.7 \times 10^{10}$	Bq
Exposure <sup>a</sup>	1 R (röntgen)	$2.58 \times 10^{-4}$	$\text{C kg}^{-1}$ (in air)
Kerma or absorbed dose	1 rad	$1 \times 10^{-2}$	Gy
Dose equivalent	1 rem	$1 \times 10^{-2}$	Sv

To convert the *quantity in obsolete units* to the *quantity in SI units*, multiply by the relevant *coefficient*. Other obsolete units associated with source specification in brachytherapy are discussed in [Section 53.6](#).

<sup>a</sup> Air kerma is the modern replacement quantity for exposure (see [Section 6.3.2](#)).

**TABLE M.1d**

SI Prefixes

Decimal Multiples			Decimal Submultiples		
Factor	Name	Symbol	Factor	Name	Symbol
$10^1$	deka	da	$10^{-1}$	deci	d
$10^2$	hecto	h	$10^{-2}$	centi	c
$10^3$	kilo	k	$10^{-3}$	milli	m
$10^6$	mega	M	$10^{-6}$	micro	$\mu$
$10^9$	giga	G	$10^{-9}$	nano	n
$10^{12}$	tera	T	$10^{-12}$	pico	p
$10^{15}$	peta	P	$10^{-15}$	femto	f
$10^{18}$	exa	E	$10^{-18}$	atto	a
$10^{21}$	zetta	Z	$10^{-21}$	zepto	z
$10^{24}$	yotta	Y	$10^{-24}$	yocto	y

## USEFUL PHYSICAL CONSTANTS

**TABLE M.1e**

Constant	Symbol	Value	Unit	Comment
Speed of light in vacuo	$c$	299792458	$\text{m s}^{-1}$	Exact value
Avogadro's number	$N_A$	$6.0221 \times 10^{23}$	$\text{mol}^{-1}$	
Atomic mass constant	$m_u$	$1.6605 \times 10^{-27}$	kg	
Molar mass of carbon		$12 \times 10^{-3}$	kg	Exact value
Planck's constant	$h$	$6.6261 \times 10^{-34}$	J s	
Boltzmann's constant	$k$	$1.3807 \times 10^{-23}$	$\text{J K}^{-1}$	
Elementary charge	$e$	$1.6022 \times 10^{-19}$	C	Electron or proton charge
Standard atmosphere		101325	Pa	Exact value
Melting point of ice at 101 325 Pa		273.15	K	
Standard acceleration of gravity	$g_n$	9.80665	$\text{m s}^{-2}$	Exact value
Standard air density		1.200	$\text{kg m}^{-3}$	At 20°C, 101 325 Pa, 50% relative air humidity
Density of dry air at 0°C	$\rho_{\text{air}}$	1.293	$\text{kg m}^{-3}$	At 273.15 K, 101 325 Pa
Mean energy expended in air per ion pair formed	$W_{\text{air}/e}$	33.97	$\text{J C}^{-1}$	

From Mohr and Taylor; CODATA Recommended Values of Fundamental Physical Constants: 2002, published in Review of Modern Physics 77, 1 (2005) and available at <http://physics.nist.gov/constants>. Most constant values are given here to 4 significant figures, which is sufficient for applications in radiotherapy physics. More precise statements of uncertainty are given by Mohr and Taylor. See also more accurate figures in [Chapter 1](#).

## ENERGY CONVERSION

---

**TABLE M.1f**

	Equivalence⇒	Mass ( $m$ )	Wavelength ( $\lambda$ )	Frequency ( $\nu$ )	Temperature ( $T$ )
Unit	Relation⇒	$mc^2$	$hc/\lambda$	$h\nu$	$kT$
J		kg	m	Hz	K
1 J	1	$1.1127 \times 10^{-17}$	$1.9858 \times 10^{-25}$	$1.5092 \times 10^{33}$	$7.24297 \times 10^{22}$
1 eV	$1.6022 \times 10^{-19}$	$1.7827 \times 10^{-36}$	$1.2394 \times 10^{-6}$	$2.4180 \times 10^{14}$	$1.16045 \times 10^4$

This table shows how mass, wavelength, frequency, and temperature are related to energy. For example the energy equivalent to 1kg is  $1/1.1127 \times 10^{-17}$  J.

---

## PARTICLES

---

**TABLE M.1g**

Constant	Value	Unit	Comment
Unified atomic mass unit	$1.6605 \times 10^{-27}$	kg	Symbol=u
Electron rest mass	$9.1094 \times 10^{-31}$	kg	$1/1823$ u
Proton rest mass	$1.6726 \times 10^{-27}$	kg	1.0073 u
Neutron rest mass	$1.6749 \times 10^{-27}$	kg	1.0087 u
Alpha particle rest mass	$6.6447 \times 10^{-27}$	kg	4.0015 u
Electron rest equivalent energy	0.51100	MeV	Derived from $E=mc^2$
Proton rest equivalent energy	938.272	MeV	Derived from $E=mc^2$

## TABLES M.2 ELECTRON STOPPING POWERS, RANGES, AND RADIATION YIELDS

*Compiled by Alan Nahum*

Table M.2a through Table M.2z give stopping powers, ranges and radiation yields for electrons in a number of materials of medical interest. Elements have been placed first (a–f), then compounds (g–i), in order of increasing  $I$ -value (see below), then mixtures (j–q) and body tissues (r–z), in alphabetical order. The electron energies extend from 0.01 MeV (10 keV) up to 50 MeV, covering the range of interest in radiotherapy; at energies below 10 keV the validity of the Bethe-Bloch expression for the mass collision stopping power becomes questionable, especially in high atomic-number materials. The values have been obtained using the ESTAR computer code, accessed via <http://physics.nist.gov/PhysRefData/Star/Text/ESTAR.html> where full details of the calculational procedures are given (Berger et al. 2005).

Each table also contains the mass density  $\rho$ , the ratio  $\langle Z/A \rangle$ , the mean excitation energy  $I$  (see Section 3.2.2) and the atomic composition ( $Z - f_w$ ) of each substance, as given in the ESTAR database, where  $f_w$  is the fraction by weight of the element  $Z$  within the material. The mass stopping powers are given in  $\text{MeV cm}^2 \text{ g}^{-1}$  which are the units most commonly used in radiotherapy, due to the beam energies also being expressed in MeV. To obtain linear stopping powers the values in the tables should be multiplied by the density  $\rho$ .

Collision stopping power is covered in detail in Section 3.2, radiative stopping power  $S_{\text{rad}}/\rho$  and radiation yield in Section 3.3, and the csda range  $R_{\text{csda}}$  or  $r_o$  in Section 3.4.3. The expression used to evaluate  $S_{\text{col}}/\rho$  in the ESTAR code is identical to Equation 3.7 given in Section 3.2.2 and hence the values in Table M.2a through Table M.2z can be verified by substituting  $\langle Z/A \rangle$ ,  $I$  and the density-effect correction  $\delta$  into Equation 3.7 for the desired electron kinetic energy. In this way exact values at intermediate energies can be computed if desired.

The numbers in Tables M.2a–z are identical to those given in ICRU (1984) for the same substance, with the exception of water; the reason for this difference is that ICRU (1984) uses the density-effect correction for water derived by Ashley (1982). For substances not included here, ICRU (1984) should be consulted, where tables of all the parameters required to evaluate  $S_{\text{col}}/\rho$  from Equation 3.7 can be found.

**TABLE M.2a**

Electrons in Carbon (Graphite)

 $\langle Z/A \rangle: 0.49954; \rho: 1.7000 \text{ g cm}^{-3}; I: 78.0 \text{ eV}; \text{Composition } (Z-f_w): 6-1.0000$

<sup>a</sup> The density of lung encountered clinically is generally around  $0.3 \text{ g cm}^{-3}$ ; however, for the purposes of evaluating  $(S/\rho)_{\text{col}}$ , which above  $\approx 0.5 \text{ MeV}$  is generally *not* independent of the density due to the *density effect* (see Section 3.2.3), the *local* density of lung tissue, i.e.,  $1.05 \text{ g cm}^{-3}$ , is the more correct one to use; therefore the correct *linear stopping power* will be given by multiplying the values in this table by the clinical *bulk* lung density. The very small amount of air in inflated lung will make a negligible difference to the linear stopping power derived from these numbers, which strictly only apply to lung *tissue*.

## TABLE M.3 PHOTON INTERACTION COEFFICIENTS

*Compiled by Alan Nahum\**

**Table M.3a** through **Table M.3z** give interaction coefficients for photons in a number of materials of medical interest. The materials are identical to those included in **Table M.2**. Elements have been placed first (a–f), then compounds (g–i), then mixtures (j–q) and body tissues (r–z), in alphabetical order. The photon energies extend from 0.001 MeV (1 keV) up to 50 MeV, covering the range of interest in radiotherapy. The values for the partial coefficients (coherent,  $\sigma_{coh}/\rho$ ; Compton,  $\sigma_C/\rho$ ; photoelectric,  $\tau/\rho$ ; pair + triplet production,  $\kappa/\rho$ ) and the total attenuation coefficient,  $\mu/\rho$ , have been obtained using the XCOM computer code, accessed via <http://physics.nist.gov/PhysRefData/Xcom/Text/XCOM.html> where full details of the calculational procedures are given (Berger et al. 2005). The mass energy-transfer coefficient,  $\mu_{tr}/\rho$ , mass energy-absorption coefficient,  $\mu_{en}/\rho$ , and (1-g) were supplied by Steve Seltzer of NIST; these were evaluated using the procedures described in Seltzer (1993) and Hubbell and Seltzer (1995).

Each table also contains the mass density  $\rho$  and the atomic composition (by weight) of each substance. The units are  $\text{cm}^2\text{g}^{-1}$ ; to convert to  $\text{m}^2\text{kg}^{-1}$  the numbers should be multiplied by 0.1. To obtain linear coefficients the values in the tables must be multiplied by the density  $\rho$ . For substances not included here, ICRU (1989) and Hubbell and Seltzer (1995) can be consulted.

The various photon interaction processes are covered in detail in **Chapter 4**; the macroscopic quantities  $\mu/\rho$ ,  $\mu_{tr}/\rho$  and  $\mu_{en}/\rho$  are defined in **Section 4.4.1** and **Section 4.4.2**, respectively.

---

\* We acknowledge the generous assistance of Steve Seltzer, NIST, in providing values of the mass energy-transfer coefficient  $\mu_{tr}/\rho$ , mass energy-absorption coefficient  $\mu_{en}/\rho$ , and (1-g) for all the substances in the tables.

<sup>a</sup> The density of lung encountered clinically is generally around  $0.3 \text{ g cm}^{-3}$ ; therefore the correct linear attenuation coefficient will be given, to a good approximation, by multiplying the values in this table by the clinical bulk lung density. The very small amount of air in inflated lung will make a negligible difference to the linear values derived from these numbers, which strictly only apply to lung tissue.

**TABLE M.3v**

## Photons in Muscle, Skeletal (ICRP)

$\rho$ : 1.040 ( $\text{g cm}^{-3}$ ), Composition ( $Z - f_w$ ): 1–0.100637; 6–0.107830; 7–0.027680; 8–0.754773; 11–0.000750; 12–0.000190; 15–0.001800; 16–0.002410; 17–0.000790; 19–0.003020; 20–0.000030; 26–0.000040; 30–0.000050

The most important emissions are shown in bold. In the Half-life column "d" and "y" are used for "days" and "years".

<sup>a</sup> Unless indicated otherwise, data are from Longworth et al. (1998). While every effort to ensure the accuracy of the data has been made, the table is not intended as a definitive reference.

- <sup>b</sup> Attenuation is quoted as an indication of penetrative ability and is the approximate value for a point source. The HVT in lead gives an indication of the amount of material needed for radiation protection purposes. When shielding β-emitters it is better to use a low atomic number material close to the source as lead will produce bremsstrahlung photons which will be more penetrating than the original β-particles.
- <sup>c</sup> When calculating dose rates for radiotherapy purposes the calculation should be based on source strength or air kerma rate at 1 m (see Chapter 53). However, it is sometimes necessary to be able to convert from air kerma rate to MBq for regulatory purposes or to be able to calculate the expected dose rate for a particular activity for radiation protection purposes. In such circumstances these values may be used. Where data were not available the value has been calculated based on the decay scheme. The formula used is:

$$\Gamma = \frac{\sum_i f_i \times E_i \times (\mu_{en}/\rho)_{E_i}}{4\pi(1-g)} \times 3600$$

where  $\Gamma$  is the specific γ-ray constant (in  $\text{Gy m}^2 \text{ h}^{-1} \text{ Bq}^{-1}$ );  $f$  is the probability of emission, per disintegration, of a γ-ray of energy  $E$  (expressed in J);  $\mu_{en}/\rho$ , is the mass energy-absorption coefficient for air in  $\text{m}^2 \text{ kg}^{-1}$ ; 3600 is the number of seconds in an hour. Normally  $E$  is in MeV and it is therefore necessary to multiply by  $1.602 \times 10^{-13}$  to convert to joules and, if the activity is in MBq, to multiply by  $10^6$ . Tables of mass energy-absorption coefficient are usually in  $\text{cm}^2 \text{ g}^{-1}$  (see Table M.3k) and these must be converted to  $\text{m}^2 \text{ kg}^{-1}$  by dividing by  $10^2$ . If these units are used the formula becomes:

$$\Gamma = \frac{4.59 \sum_i f_i \times E_i (\text{MeV}) \times (\mu_{en}/\rho)_{E_i}}{(1-g)} \quad \mu\text{Gy m}^2 \text{ h}^{-1} \text{ MBq}^{-1}$$

This method may slightly underestimate the air kerma rate because it ignores bremsstrahlung contributions from the βs (Glasgow and Dillman 1979).

<sup>d</sup> Isotopes shown with an arrow indicate the daughter of the parent isotope and its associated decay products.

<sup>e</sup> This is the isotope which results from the initial decay process.

<sup>f</sup> The HVL for water is very dependent on the measurement conditions. For many sources (e.g.  $^{192}\text{Ir}$ ) scattered radiation often compensates for attenuation close to the source so that the dose rate in water is actually higher than in air. The data presented here have been calculated based on the linear attenuation coefficients for the individual energies. The values presented give an indication of the relative penetration, but should not be given greater weight. As discussed in Part I, in brachytherapy the dose rate is principally determined by the inverse square law.

<sup>g</sup> From Burger (2003).

<sup>h</sup> From BIR (1987).

<sup>i</sup> α-particles are stopped by less than a millimetre of tissue and so these parameters are not relevant. However, there is some γ-ray output which requires some shielding (HVT approximately 0.1 mm of lead).

<sup>j</sup> From Aird et al (2000).

<sup>k</sup> For β-particles the value quoted is calculated from the formula  $R=412 E^{1.265-0.0954\ln E}$  where  $E$  is the maximum energy in MeV and  $R$  is expressed in  $\text{mg cm}^{-2}$  (Bull 1998) using a density of  $1.15 \text{ g cm}^{-3}$  for perspex (PMMA).  $R$  is the thickness of perspex required to completely absorb all β-particles.

<sup>l</sup> Based on nomogram Figure 6.3 in Bull (1998).

<sup>m</sup> This value is calculated from the attenuation coefficients in the same way as for the HVL in water (Note f) and similar reservations apply.

<sup>n</sup> Emissions at 27 keV and 31 keV are characteristic x rays from Te.

<sup>o</sup> The Radium decay series is very complex and is included for general information only. Less important emissions with less than 4% probability have been omitted.
