# PREFACE

Radiotherapy is a comprehensive and fast-moving discipline which plays a major role in cancer care. Safe and effective radiotherapy requires close collaboration between radiation oncologists, radiation technologists and medical physicists, and all must have an understanding of each others' disciplines. Our aim has been to provide a comprehensive text providing most of the theoretical and practical knowledge that medical physicists need to know, including the essential underlying radiation biology. Although principally aimed at practising medical physicists, this book will also be useful to all other professionals involved in radiation therapy, whether they be students (master's and PhD level), university teachers, researchers, radiation oncologists, or radiation technologists.

The book is organised into 13 Parts, each dealing with a major self-contained subject area. Each part begins with an introduction by the editors and is subdivided into chapters mostly written by a single author. References are collected together at the end of each part. In order to cover in detail all aspects of radiotherapy physics and biology, a high level of expertise was required. Contributions have been brought together from eminent specialists in the field, mostly from Europe, but also some from North America. The editors have, where necessary, combined contributions from different authors in order to provide a logical flow—as far as possible details of who wrote what are shown on the title page of each chapter.

Parts A through C provide the fundamentals of the underlying physics, radiobiology and technology respectively. Parts D through H provide the practical information needed to support external-beam radiotherapy: dose measurements, properties of clinical beams, patient dose computation, treatment planning and quality assurance. An appendix to Part D gives complementary details to enable a thorough understanding of the methods and data used for absolute dose measurement. Part I seeks to capture the exciting new developments in the subject including those in particle therapy, thus providing a basis for the reader to understand the ever expanding literature in this area. Parts J and K deal with brachytherapy using sealed and unsealed sources respectively. The framework of radiation protection is covered in Part L including an appendix describing the detailed application of UK legislation. Part M contains useful tables of physical constants, and electron and photon interaction data.

In a multi-author book of this length there will inevitably be a certain unevenness of style and level of detail and also some repetition; we see this as a strength rather than a weakness although we as editors have sought to ensure consistency. We wish to thank our many authors for their high-class contributions and not least for their patience during the time it has taken to bring together this work. It is unavoidable that some chapters are even more up-to-the-minute than others which were written more promptly. We would also like to thank Don Chapman and Helen Mayles who have read and commented on some of the chapters.

Finally, we have tried to make the content as international as possible by taking into account different practices and terminology in different parts of the world. For example we have used the words *Radiation Oncologist* and *Radiation Technologist* to describe the medical staff who prescribe radiotherapy and who operate the treatment machines respectively. Colleagues who carry out computer planning are referred to as *Dosimetrists*.

It is our hope that our readers will learn as much from reading this book as we have from editing it.

**Philip Mayles  
Alan Nahum  
Jean-Claude Rosenwald**

# THE EDITORS

**Philip Mayles** Philip Mayles was born in 1947. He graduated from Gonville and Caius College, Cambridge with a BA in natural sciences in 1968. He completed a master of science degree in radiation physics at St Bartholomew's Hospital Medical School, following which he joined the staff of Guy's Hospital, where he worked until 1986. During this time he obtained a PhD from the Faculty of Medicine in London University. In 1986 he was appointed head of clinical radiotherapy physics at the Royal Marsden Hospital Surrey Branch under Professor Bill Swindell.

In 1994 he moved to Clatterbridge Centre for Oncology near Liverpool, as head of the Physics Department. During his time there he has overseen the expansion of the Radiotherapy Department from having five linear accelerators with conventional collimators to nine machines all equipped with multileaf collimators and portal imaging devices. The department uses modern imaging technology to enable 3D treatment planning for a high proportion of its patients and has been one of the pioneers of intensity modulated radiotherapy and image guided radiotherapy in the UK.

As chairman of the Radiotherapy Topic Group of the Institute of Physics and Engineering in Medicine he was instrumental in producing Report 75 on the design of radiotherapy treatment facilities and Report 81 on quality assurance in radiotherapy. He has an active interest in research especially in improving the physical basis of radiotherapy treatment and treatment planning.

In 1992 he and Alan Nahum established the Royal Marsden Course in Radiotherapy Physics which has been running successfully ever since, now under the direction of Margaret Bidmead and Jim Warrington. This course provided the inspiration for this book.

He and his wife, Helen, also a medical physicist, met at Guy's Hospital, London and have two daughters.

**Alan Nahum** was born in Manchester in 1949. He read physics at Worcester College, Oxford University. He gained his PhD in 1975 on theoretical radiation dosimetry using Monte Carlo methods at Edinburgh University under the supervision of Professor John Greening.

Alan then trained and worked as a school science teacher and worked as a gas cutter in a Volvo factory in Arvika, Sweden, before re-entering the medical physics world in 1979 as forskarassistent at the Radiofysik department, University of Umeå, where he taught and organised courses in radiation dosimetry, worked on ion-chamber response and on dosimetry codes of practice with Professor Hans Svensson, and where his two daughters Rebecka and Marie were born. He took a sabbatical (in Spring 1983) in Ottawa at the National Research Council of Canada working with Dave Rogers and Alex Bielajew on Monte Carlo simulation of ion-chamber response. He became a docent of Umeå University

Medical Faculty in 1983. He published *The Computation of Dose Distributions in Electron Beam Radiotherapy* just before leaving Umeå.

In 1985 Alan joined the Joint Department of Physics at the Institute of Cancer Research and Royal Marsden Hospital, Sutton, UK where his interests were redirected towards conformal (radio)therapy and subsequently to radioiological modelling. He co-directed (with Ralph Nelson and Dave Rogers) a course on Monte Carlo Transport of Electrons and Photons in Erice, Sicily in 1987 also co-editing a book with this title. In 1992 he and Philip Mayles started an annual  $2 \times 1$ -week course in radiotherapy physics which is still running. His PhD students at ICR were Charlie Ma, Mike Lee, Richard Knight, Paul Mobit, John Fenwick, Francesca Buffa, Mark Atthey and Margarida Fragoso. Postdoctoral scientists on his team included Beatriz Sanchez-Nieto, Frank Verhaegen, Cephas Mubata, Stefano Gianolini and João Seco, working on Monte Carlo simulation applied to dosimeter response and treatment planning, on biological modelling, and on building a database for analysis of clinical trials in conformal therapy. In 1997 he became Reader in Medical Physics of London University. He served as an associate editor for the journal *Medical Physics* between 1997 and 2004.

Alan left the ICR/Marsden in 2001 and after brief spells as a visiting scientist in Philadelphia, Reggio Emilia and Copenhagen, joined Clatterbridge Centre for Oncology, in June 2004, as head of physics research, becoming a Visiting Professor of Liverpool University in 2005. He was a member of the teaching faculty on the ESTRO course on IMRT and other conformal techniques from 1998 to 2005. His main current research is on using TCP and NTCP models in treatment plan optimisation.

Recreational interests include foreign languages, cooking, cricket and classical music.

**Jean-Claude Rosenwald** was born in 1945 in Neuilly, close to Paris. After earning an engineering degree in electronics, nuclear physics and computing sciences obtained in Nancy in 1967, he began his career as a computer scientist developing dose calculation programs in brachytherapy at the Institut Gustave Roussy in Villejuif, under the supervision of Andrée Dutreix. He obtained his PhD on this subject in 1976 from the University of Nancy.

He was appointed medical physicist at the Institut Gustave Roussy from 1971–1975 and then moved in 1976 to the Institut Curie in Paris, as head of the Physics Department. In 1996 he obtained an Habilitation à Diriger les Recherches from the Université Paul Sabatier in Toulouse in recognition of his capacity to coordinate research programmes. Altogether, more than 14 PhD and 60 master's students have undertaken research programmes under his supervision.

Dr. Rosenwald has a particular interest in the use of computers in radiation therapy, has participated in several international conferences, has been a co-author of several reports on this subject and was involved in the development of commercial solutions for treatment planning both for external-beam radiotherapy and brachytherapy. He has also promoted the use of proton beams in radiotherapy and played a major role in the development of the Centre de Protonthérapie d'Orsay. He has contributed to the expansion of the Radiotherapy Department at the Institut Curie, which is one of the leading centres in France, possessing modern equipment and practising modern radiotherapy techniques, based on advanced imaging devices and including intensity modulated radiotherapy, proton therapy and tomotherapy.

He served as president of the French Society for Medical Physics (today SFPM) from 1979–1982, as chairman of the Scientific Committee of the European Federation of Medical Physics (EFOMP) from 1990–1993 and chaired the Scientific Committee for Medical Physics at the International Conference of Bioengineering and Medical Physics held in Nice in 1997. He is a member of the editorial board of *Radiotherapy and Oncology*.

# TABLE OF CONTENTS

## Part A: Fundamentals

Chapter 1 <b>Structure of Matter</b> . . . . .	5
<i>Jean Chavaudra</i>	
Chapter 2 <b>Radioactivity</b> . . . . .	19
<i>Jean Chavaudra</i>	
Chapter 3 <b>Interactions of Charged Particles with Matter</b> . . . . .	35
<i>Alan Nahum</i>	
Chapter 4 <b>Interactions of Photons with Matter</b> . . . . .	57
<i>David Dance and Gudrun Alm Carlsson</i>	
Chapter 5 <b>The Monte Carlo Simulation of Radiation Transport</b> . . . . .	75
<i>Alex Bielajew</i>	
Chapter 6 <b>Principles and Basic Concepts in Radiation Dosimetry</b> . . . . .	89
<i>Alan Nahum</i>	
<b>References</b> . . . . .	117

## Part B: Radiobiology

Chapter 7 <b>Radiobiology of Tumours</b> . . . . .	127
<i>Gordon Steel (with Don Chapman and Alan Nahum)</i>	
Chapter 8 <b>Radiobiology of Normal Tissues</b> . . . . .	149
<i>Gordon Steel</i>	
Chapter 9 <b>Dose Fractionation in Radiotherapy</b> . . . . .	163
<i>Gordon Steel (with Alan Nahum)</i>	
<b>References</b> . . . . .	179

## Part C: Equipment

Chapter 10 <b>Kilovoltage X-Ray Units</b> . . . . .	187
<i>Tony Greener</i>	
Chapter 11 <b>Linear Accelerators</b> . . . . .	197
<i>Les Loverock (with Philip Mayles, Alan McKenzie, David Thwaites and Peter Williams)</i>	
Chapter 12 <b>Cobalt Machines</b> . . . . .	241
<i>John Saunders</i>	
Chapter 13 <b>Simulators</b> . . . . .	251
<i>Jean-Claude Rosenwald</i>

<b>Monte-Carlo Based Patient Dose Computation . . . . .</b>	603
<i>Alan Nahum</i>	
<b>References . . . . .</b>	621

#### **Part G: Treatment Planning**

Chapter 29	
<b>Target Definition . . . . .</b>	637
<i>Anthony Neal</i>	
Chapter 30	
<b>Patient Data Acquisition . . . . .</b>	647
<i>Anthony Neal</i>	
Chapter 31	
<b>Magnetic Resonance Imaging in Treatment Planning . . . . .</b>	657
<i>Vincent Khoo</i>	
Chapter 32	
<b>Beam Definition—Virtual Simulation . . . . .</b>	669
<i>Vibeke Nordmark Hansen</i>	

<b>Chapter 33</b>	
<b>Photon-Beam Treatment Planning Techniques</b>	681
<i>Peter Childs and Christine Lord</i>	
<b>Chapter 34</b>	
<b>Electron-Beam Treatment Planning Techniques</b>	701
<i>Alan McKenzie and David Thwaites</i>	
<b>Chapter 35</b>	
<b>Dose Evaluation of Treatment Plans</b>	719
<i>Margaret Bidmead and Jean-Claude Rosenwald</i>	
<b>Chapter 36</b>	
<b>Biological Evaluation of Treatment Plans</b>	731
<i>Alan Nahum and Gerald Kutcher</i>	
<b>References</b>	773

#### **Part H: Quality Assurance**

<b>Chapter 37</b>	
<b>Rationale and Management of the Quality System</b>	793
<i>Philip Mayles and David Thwaites (with Jean-Claude Rosenwald)</i>	
<b>Chapter 38</b>	
<b>Quality Control of Megavoltage Equipment</b>	809
<i>Edwin Aird, Philip Mayles, and Cephas Mubata</i>	
<b>Chapter 39</b>	
<b>Quality Assurance of the Treatment Planning Process</b>	841
<i>Jean-Claude Rosenwald</i>	
<b>Chapter 40</b>	
<b>Quality Control of Treatment Delivery</b>	867
<i>Philip Evans and Ginette Marinello</i>	
<b>Chapter 41</b>	
<b>Recording and Verification—Networking</b>	897
<i>Margaret Bidmead</i>	
<b>Chapter 42</b>	
<b>Data Communication with DICOM</b>	909

## INTRODUCTION

This Part introduces the fundamental concepts underlying radiotherapy physics. It moves from the structure of matter and radioactivity ([Chapter 1](#) and [Chapter 2](#)) to an explanation of the various interactions between radiation and matter ([Chapter 3](#) and [Chapter 4](#)). A description of the Monte Carlo method is given in [Chapter 5](#), as it illustrates the way in which knowledge of the detailed interactions can lead to an understanding of the transport of radiation in matter. Finally, in [Chapter 6](#), the main dosimetric quantities are defined and their relationship is discussed in order to provide a more thorough understanding of dose-measurement methods presented in [Part D](#) and dose-calculation methods presented in [Part E](#) and [Part F](#). Numerical values of many useful quantities are given in [Part M](#). For complementary data on fundamental radiation physics used for medical applications the reader can refer to other more detailed textbooks (Goodwin and Rao 1977; Halliday and Resnic 1988; Bushberg et al. 1994; Cherry, Sorenson and Phelps 2003).

## 1.1 THE CONCEPT OF THE ATOM

The concept of matter composed of empty space filled with small indivisible particles had been proposed as early as several centuries BC, in particular by the Greek Demokritos. However, the Aristotelean concept of continuous matter prevailed for centuries until the development, circa 1800, of modern quantitative chemistry by scientists including A.L. de Lavoisier, J. Dalton, J.L. Gay-Lussac, A. Avogadro, and L.J. Proust. Their work developed the principle of the composition of compound materials from well-defined proportions of chemical elements.

Nevertheless, the most convincing evidence of the structure of matter was associated with the discovery of radioactivity, which revealed valuable information about the atomic structure.

---

## 1.2 THE ATOMIC STRUCTURE

### 1.2.1 BUILDING UP THE MODELS

The discovery of the electron and the ratio of its electric charge to its mass by J.J. Thomson in 1897 not only explained the nature of electric current, but also provided a basis for J. Perrin and J.J. Thomson's first hypothesis in 1901–1902 that atoms were made of negative and positive charges, globally neutral and structured according to some kind of planetary system.

The confirmation of this hypothesis was obtained through experiments done by E. Rutherford, and by H. Geiger and E. Marsden using  $\alpha$  particle scattering in gold leaf. The results suggested that atoms were made of a heavy nucleus exhibiting a positive electric charge, surrounded by orbiting electrons bound to the nucleus by the electrostatic force of attraction, and exhibiting an equivalent negative charge.

This model was not satisfactory, as it could not explain how the electrons could avoid losing radiant energy and consequently, following the classical physics rules, being at last captured by the nucleus.

The currently accepted model for the description of atoms relies on the 1913 Bohr model. This model adds two postulates that contradict principles of classical physics, but it is further reinforced by the contributions of the pioneers of quantum-wave-mechanics, especially those of M. Planck, A. Sommerfeld, W. Pauli, P.A.M. Dirac, M. Born, W. Heisenberg, E. Schrödinger, and L. de Broglie.

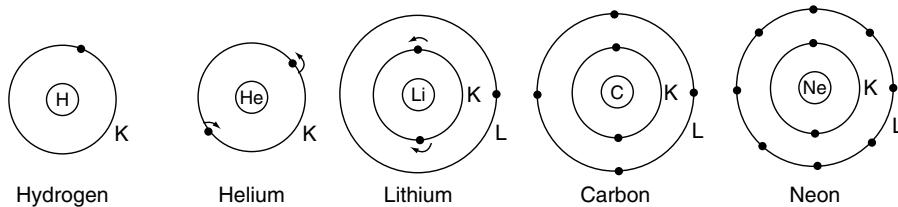

The classical rules of mechanics and electricity could not explain atomic stability or the discontinuities observed in the results of early experiments on light emission and absorption by atoms. Explaining these phenomena required the adoption of Planck's quantum mechanical principles:

- Electrons revolve about the nucleus only in orbits with radii such that the relationship  $M = nh/2\pi$  is satisfied, in which  $M$  is the angular momentum of the electron,  $h$  is Planck's constant and  $n$  is an integer. This means that the angular momentum (electron-mass  $\times$  speed-along-orbit  $\times$  radius) must be a multiple of  $nh/2\pi$ , and that only well defined orbits are possible
- Electrons do not gain or lose energy when they remain in a given orbit. They only exchange energy when they move from one orbit to another.

### 1.2.2 SCHEMATIC DESCRIPTION OF THE ATOMIC STRUCTURE

#### 1.2.2.1 *The Nucleus*

Most of the mass of the atom is concentrated in the nucleus, which has a very high density (diameter on the order of a few fermis, or about  $10^{-4} \times$  the atom's diameter).

**FIGURE 1.1**

Schematic diagram showing the electron structure for hydrogen, helium, lithium, carbon and neon. (From Johns, H. E. and Cunningham, J. R., *The Physics of Radiology*, Charles C. Thomas., 4th Ed., Springfield, IL, 1983.)

The nucleus may be considered as made up of  $Z$  protons and  $N$  neutrons (nucleons).

The *protons* are responsible for the positive electric charge of the nucleus. Their electric charge has the same absolute value as the charge of the electron,  $e = 1.602\ 176\ 53(14) \times 10^{-19}\ \text{C}$ <sup>\*</sup> and a rest mass  $m_p = 1.672\ 621\ 71(29) \times 10^{-27}\ \text{kg}$  (Mohr and Taylor 2005).

To compensate for the  $Z$  *electric charges* of the nucleus,  $Z$  electrons should be present in the atom;  $Z$  is called the *atomic number* of the atom. The atoms classically considered as *natural* have atomic numbers ranging from 1 (hydrogen) to 92 (uranium).

The *neutrons* have no electric charge. Their rest mass is very close to the proton mass. The number of neutrons in a nucleus is close to the number of protons. Outside the nucleus, neutrons are unstable, dividing into protons, electrons and antineutrinos.

The mass of the nucleus is slightly smaller than the sum of the masses of the  $Z$  protons and  $N$  neutrons, due to their nuclear bonding energy corresponding, according to Einstein, to the use of a tiny proportion of the nuclear mass, called the mass defect (see [Section 1.3.2.1](#)).

### 1.2.2.2 The Peripheral Electrons/Electronic Shells

The *electrons* have a negative electric charge  $e = 1.602\ 176\ 53(14) \times 10^{-19}\ \text{C}$  and a rest mass  $m_e = 9.109\ 3826(16) \times 10^{-31}\ \text{kg}$ .

The  $Z$  peripheral electrons revolve about the nucleus in well defined orbits, called electronic K, L, M, N,...shells according to their rank, from the nucleus to the periphery of the atom.

According to the principles of the atomic model, the number of electrons present in a given shell is limited. The innermost shell, called the K shell, has the rank of 1. Any shell with a rank  $n$  has a maximum allowed number of electrons of  $2n^2$ .

Hydrogen is the simplest atom, consisting of one electron revolving about one proton on the K shell (Figure 1.1). The next simplest atom, helium, has two electrons, saturating the K shell, and spinning in opposite directions. The next atom, lithium, has 3 electrons and the additional electron is alone on the L shell. The same evolution can be observed from carbon to neon atoms, the latter presenting a saturated L shell.

The most peripheral electrons, those belonging to the outermost shell (valence electrons), are directly linked to the chemical properties of atoms and molecules, and so determine the chemical elements or nuclides reported in the Mendeleyev table. Helium and neon atoms, presenting a saturated outer shell, are remarkably chemically stable.

\* These values are given in the so-called *concise form* in which the number in brackets is the *standard uncertainty*.

### 1.2.2.3 The Global Atom

**Mass Number:** The mass number  $A$  is defined as the total number of nucleons in the atom. It ranges from 1 (hydrogen) to more than 200 for the heaviest nuclei.

**Atomic Mass:** As seen previously, the mass of a given atom is close to the sum of the masses of the nucleons and the electrons. Remember that the mass of an electron is about 1840 times smaller than the mass of a nuclear particle. The actual mass of an atom X,  $m(X)$ , expressed in terms of kilograms, the international unit of mass, is very small and not of much practical use. Consequently, another approach is often used, by defining a special unit of *atomic mass* (a.m.u. or u).

The international unit of *atomic mass* is approximately the mass of a nuclear particle, permitting the atomic mass of an atom to be expressed with numbers close to the mass number. The official definition of the atomic mass unit (unified atomic mass  $m_u$ ) is related to 1/12 of the mass of the carbon atom with 6 protons and 6 neutrons, i.e.  $1\text{ u} = 1.660\,538\,86(28) \times 10^{-27}\text{ kg}$ . Because the mass number of a carbon atom is exactly 12, its atomic mass is also 12 u. However, for oxygen 16, for example, 1 atom corresponds to 15.9991 u. Atomic masses range from 1 u (hydrogen) to more than 200 u for the heaviest nuclei.

Another definition of atomic mass is used in chemistry, with the same symbol A, but in this case, it refers to the so-called atomic weights. The difference from the definition above is that, for a given element, this definition takes the naturally occurring mixture of nuclides into account (with the isotopes) so the value of A may be different from the mass number. We may also refer to molar masses, so that if, for instance, a mole (mol) of carbon atoms is made of  $N_A$  (Avogadro's number =  $6.022\,1415(10) \times 10^{23}\text{ mol}^{-1}$ ) atoms, a mole of carbon atoms has a mass of exactly 12 g. Thus, the molar mass  $M(X)$  of any other element X can be derived from the carbon molar mass, in the same way as the atomic masses\*.

## 1.2.3 ATOMIC STRUCTURE INTERPRETATION ACCORDING TO THE WAVE-MECHANICAL MODEL

In this model, the classical fundamental law,  $\vec{F} = m\vec{\gamma}$  in which the acceleration  $\gamma$  of a particle with mass  $m$  is obtained by applying a force  $\vec{F}$  to the particle, is replaced by the Schrödinger equation in which the particle is associated with a probability of presence at a given place, at a given time, thus extending the meaning of electron orbits or shells. Furthermore, in addition to the classical parameters qualifying the behaviour of a particle (mass, 3D coordinates and speed components) an intrinsic angular momentum, the spin, is added. Particles with spins that are odd multiples of  $\frac{1}{2}\hbar/2\pi$  are called fermions and include in particular the *classical* components of matter (electrons and nucleons), also called leptons. Particles with spins that are multiples of  $\hbar/2\pi$  are called bosons and include photons.

---

\* “The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kg of carbon 12; its symbol is “mol”. When the mole is used, the elementary entities must be specified, and may be atoms, molecules, ions, electrons, other particles or specified groups of such particles.” (Bureau International des Poids et Mesures 1998).

### 1.2.3.1 Peripheral Electrons

According to the model, the peripheral electrons of the atoms are each characterised by four quantum numbers:

The *principal quantum number*,  $n$ , defines the shell within which the electron resides. As stated above,  $n$  can have the values 1, 2, 3... corresponding to K, L, M ... shells.

The *azimuthal quantum number*,  $l$ , describes the electron's angular momentum and provides information on the elliptical characteristics of the orbit.  $l$  can have integer values ranging from 0 to  $n - 1$ .

The *magnetic quantum number*,  $m_e$ , represents the orientation of the electron's magnetic moment in a magnetic field and provides information on the orbit orientation with respect to a given reference direction. The values of this quantum number, for a given orbit  $l$ , are the integer values in the range  $-l \leq m_e \leq l$ .

The *spin quantum number*,  $m_s$ , defines the direction of the electron's spin upon its own axis with respect to a given reference direction, and can have two values,  $+1/2$  and  $-1/2$ .

### 1.2.3.2 Electronic Status

The Pauli exclusion principle states that a given set of quantum numbers can characterise only one electron.

This allows us to derive the maximum number of electrons in a given shell. For example:

In the K shell,  $n = 1$ ,

therefore  $l = 0$  and  $m_e = 0$ .

$m_s$  can have values of  $+1/2$  or  $-1/2$ .

Only 2 electrons can reside in the K shell.

The same rule leads to 8 possibilities for the L shell, 18 for the M shell, etc.

### 1.2.3.3 The Nucleus

Two main models have been proposed for the nucleus. The *liquid drop model* assumes that the nucleus is made up of closely packed nucleons in constant motion. This model is compatible with the explanation of interactions of heavy particles with the nucleus, but is not compatible with the explanation for discrete nuclear energy states revealed in interactions with light particles. Because of this, a shell model of the nucleus has been proposed, which is similar to the shell model for the peripheral electrons. In this model, each nucleon is characterised by four quantum numbers, with the same meanings, replacing *electron* with *nucleon*:

The *principal quantum number*,  $n$ , related to each nucleon shell (protons or neutrons);

The *orbital quantum number*,  $l$ , characterising the orbital motion of the nucleons inside the nucleus (from 0 to  $n - 1$ );

The *spin quantum number*,  $m_s$ , equal to  $\pm 1/2$ ;

The *magnetic quantum number*,  $m_e$  (from  $-l$  to  $l$ ).

More elaborate models have been proposed in order to fit better with the latest experimental data, but they will not be considered here.

## 1.2.4 NOMENCLATURE

To characterise a given nuclide, the following symbolism is used:  ${}^A_Z X$ , in which  $X$  is the element nuclide symbol,  $Z$  the atomic number and  $A$  the mass number.

*Isotones* are atoms that have the same number of neutrons, such as  ${}^{51}_{23} V$ ,  ${}^{52}_{24} Cr$ ,  ${}^{54}_{26} Fe$ .

*Isotopes* are atoms that have the same number of protons ( $Z$ ) with different number of neutrons. They are therefore different versions of the same element. Many elements are made of a mixture of several isotopes, with a fairly stable composition. The atomic mass  $A$  for such elements may then be calculated and is not necessarily an integer.

*Isobars* are atoms that have the same number of nucleons (value of  $A$ ). They belong to different elements as they have different values of  $Z$  (e.g.  ${}^{40}_{18} Ar$ ,  ${}^{40}_{19} K$ ,  ${}^{40}_{20} Ca$ ). For the so-called natural nuclides,  $A$  ranges from 1 to 238 ( ${}^{238}_{92} U$ ).

## 1.3 BINDING ENERGIES IN ATOMS AND MOLECULES

### 1.3.1 ENERGY AND MATTER

There are various forms of energy, mechanical, kinetic, and electrical. The fundamental laws of physics include the conservation of the total energy of a given system, whatever the transformations in it. The energy unit, in the International System of Units is the joule (J), but because this quantity is too large when applied to particle energies, the electron volt (eV) is often used instead.

This unit, representing the energy acquired by an electron accelerated through a potential difference of 1 V, is such that:

$$1 \text{ eV} \approx 1.6 \times 10^{-19} \text{ J}$$

$$1 \text{ keV} \approx 1.6 \times 10^{-16} \text{ J}$$

$$1 \text{ MeV} \approx 1.6 \times 10^{-13} \text{ J}$$

#### 1.3.1.1 Energy of Photons

Photons have no rest mass. Considering the frequency  $\nu$  of the electromagnetic wave associated with a given photon (behaving as a particle in the energy range of radiotherapy-i.e. above tens of keV), the amount of energy  $E$  carried by the photon can be obtained, according to Einstein, from the equation:

$$E = h\nu \quad \text{or} \quad E = \frac{hc}{\lambda}$$

where  $E$  is given in eV, Planck's constant  $h$  is given as  $4.135\ 667\ 43 \times 10^{-15}$  eVs,  $\nu$  is in Hz,  $c$  is the velocity of light in vacuo\* ( $299\ 792\ 458\ ms^{-1}$ ) and  $\lambda$  is the wavelength in m.

After Duane and Hunt, a numerical value of  $E$  can be obtained from:

$$E(\text{eV}) = \frac{1240}{\lambda(\text{nm})}$$

It will be seen that photon energies increase when their wavelength decreases. Also, although photons have no rest mass, they have a momentum equal to  $h\nu/c$  and a virtual dynamic mass  $m = h/\lambda c$

\* In fact the symbol should in principle be written  $c_0$  (to refer to velocity *in vacuo*).

**TABLE 1.1**

Relationship between Kinetic Energy, Relative Mass and Relative Velocity for Electrons

T Kinetic Energy (MeV)	$m/m_0$	Relative Velocity
0	1	0
0.051	1.1	0.416
0.511	2	0.866
1.022	3	0.942
5.11	11	0.996
51.1	101	0.99995

Source: From Dutreix, J. et al., *Biophysique des Radiations et Imagerie Médicale*, 3rd Ed., Masson, Paris, France, 1993.

### 1.3.1.2 Energy of Particles with Mass

According to the relativity principle, the mass defined above from classical physics principles is not constant when the particle velocity  $v$  varies. It is given by:

$$m = \frac{m_0}{\sqrt{1 - \frac{v^2}{c^2}}}$$

where  $m_0$  is the rest mass ( $v=0$ ), and  $c$  is the velocity of light in vacuo.

The particle momentum is given by  $\overrightarrow{m} \cdot \overrightarrow{v} = \overrightarrow{m_0} \cdot \overrightarrow{v_0} / \sqrt{1 - (v^2/c^2)}$

Also, the rest mass  $m_0$  is considered as a particular form of energy, according to the Einstein equation:

$$E = m_0 c^2$$

For example, the energy corresponding to one u is 931 MeV, and the energy corresponding to the rest mass of an electron is 511 keV.

When a particle is moving, its total energy is the sum of the energy corresponding to its rest mass, and of the translation kinetic energy. So, the total energy of the particle becomes  $E = mc^2$ , according to Einstein, in such a way that  $mc^2 = m_0 c^2 + T$ , where  $T$  is the translation kinetic energy, i.e. the additional energy due to the particle movement.  $T$  can also be expressed as equal to  $m_0 c^2 ((1/\sqrt{1 - v^2/c^2}) - 1)$ . When the particle velocity becomes small, the above equation becomes close to the classical value of  $T = \frac{1}{2}mv^2$ .

This theory shows that, for instance, in the energy range of the electrons considered in medical radiological physics, their very small rest mass can nevertheless allow large kinetic energies obtained with large velocities approaching the light velocity in vacuo (Table 1.1).

### 1.3.2 BINDING ENERGIES IN ATOMS

Matter appears to be made of large numbers of particles associated through bonds resulting from forces with a wide range of intensity. The nature of these forces is not yet fully understood. Four kinds of interactions have been considered to explain such remote interactions, involving quantum energy exchanges between elementary particles: gravity, electromagnetic interactions, weak interactions and strong interactions. For example, in the nucleus, the strong interactions are believed to be between the elementary particles called quarks; nucleons are believed to be made up of three quarks. The quantum exchanged in such interactions is called the gluon, which has no mass.

The strength of the bonds existing between subgroups of particles depends upon whether the forces are within the nucleus, inside the atom, between atoms or between molecules. The rest of this Chapter will deal with atomic and molecular structures. The structure of the nucleus will be considered in [Chapter 2](#).

The bonds associated with different matter structures can be quantified with the definition of *binding energy*: the energy required to dissociate a given structure or substructure. It is usually denoted by  $W$ . Table 1.2 provides examples of binding energies corresponding to various structures.

### 1.3.2.1 Mass Defect

The energy required to create a bond in a system is lost by the system and induces a mass decrease. So, the total mass of the system is smaller than the sum of the masses of its individual components. This is called the *mass defect* and is about 7 MeV per nucleon in the helium atom.

### 1.3.2.2 Electron Binding Energy and Energy Levels of the Atomic Shells

According to the models above, an electron of an inner shell of an atom is attracted by the nucleus with an electrostatic force greater than the force applied by the nucleus to an electron of an outer shell. The binding energy required to extract a given electron from an atom depends on the shell considered and the electric charge  $Z$  of the nucleus, according to the approximate Moseley rule:

$$W = 13.6 \frac{(Z - b)^2}{n^2}$$

in which  $W$  is the binding energy of the electron (in eV),  $Z$  is the atomic number of the atom,  $n$  is the electron shell number and  $b$  is a constant used to correct for the electrostatic *screening effect* due to electrons situated between the nucleus and the electron considered.

Obviously, the outer shells are less dependent on the  $Z$  number of the atoms, due to increasing values of  $b$ . Consequently the outer shells correspond to a binding energy ranging from 1 to 16 eV, whatever the value of  $Z$ . This corresponds to the first ionisation energy of the atoms.

Note that the value of  $n$  is related to the principal energy level of a given shell (usually  $n=1$  means the K shell,  $n=2$  the L shell etc). The binding energies of sublevels are close to the binding energy of the principal energy level, but cannot be calculated with the empirical Moseley formula.

**TABLE 1.2**

Orders of Magnitude of Various Binding Energies

Action	Energy Required (eV)
To extract one alcohol molecule from a water solution through distillation	13
To break the covalent link between H and O in $\text{H}_2\text{O}$ using electrolysis	5
To extract one electron from	
A hydrogen atom	13
Molecules of biological materials	15
The M shell of a tungsten atom	2500
The K shell of a tungsten atom	70 000
To dissociate the helium nucleus into 4 nucleons, for each nucleon	7 000 000

Source: From Dutreix, J. et al., *Biophysique des Radiations et Imagerie Médicale*, 3rd Ed., Masson, Paris, France, 1993.

Also, when all electrons belong to shells in such a way that all binding energies are at the maximum value, the atom is said to be in the fundamental state. This state also corresponds to the minimum internal energy.

### 1.3.3 BINDING ENERGIES IN MOLECULES

In molecules, the links between atoms rely on sharing outer shell electrons. Consequently, the binding energies of such electrons are changed. The magnitude of the changes depends on the molecules, and on the chemical species considered. The binding energies of electrons belonging to inner shells are less affected, or may remain unchanged.

In crystals, the situation is different, as the number of electrons shared is usually large, depending on the crystal structure and the atom. Consequently, electrons can be found at many different energy levels, in an energy range comparable to an energy band, called the *valence band*.

If, in the fundamental state, the crystal absorbs external energy, electrons can reach a higher energy level (an excited state), and behave as they do in conductors of electricity. The corresponding energy band is then the *conduction band*.

When the *conduction band* overlaps the *valence band*, the crystal is a conductor of electricity. If the bands do not overlap, a *forbidden band* of a few eV between the two bands ensures that the crystal behaves as an insulating material.

## 1.4 PERTURBATION OF BINDING ENERGIES

### 1.4.1 EXCITATION

If a given atom absorbs external energy at a level smaller than any electron binding energy, an electron may be moved from one shell to another, farther from the nucleus. This corresponds to a higher level of internal energy. The atom is then said to be excited.

One can assume that, if the electron moves, for example, from the L shell to the M shell, it is because the absorbed energy  $\Delta W$  is such that:

$$\Delta W = W_M - W_L$$

$W_M$  and  $W_L$  being binding energies of M and L shells, respectively.

If the energy given to the atom, increasing its internal energy, is defined as positive, then the binding energies should be considered as negative. For instance, for Tungsten:

$$W_L = -11\,280 \text{ eV} \quad \text{and} \quad W_M = -2\,810 \text{ eV}$$

$$\text{So : } \Delta W = -2\,810 + 11\,280 = 8\,470 \text{ eV.}$$

As in the fundamental state all inner shell electron positions are occupied, the electron transitions are most often observed between outer shells, involving the peripheral electrons, which are also responsible for the chemical characteristics of the atom. As such, peripheral electrons have a weak binding energy, and excitations can be produced with low energy photons (UV or visible). Conversely, excitations linked to internal shells require higher energy photons.

### 1.4.2 IONISATION

If a given atom absorbs external energy at a level equal to or higher than an electron binding energy, an electron becomes free because its link with the atom has been broken. As a result, the electrical equilibrium in the atom is no longer maintained, and the atom

becomes a *positive ion*. For a given electron to be removed from the atom, the energy transfer must be higher than the binding energy of this electron. The excess of energy is, in principle, shared between the ionised atom and the electron as kinetic energy. Since particle momentum is conserved, most of the kinetic energy is given to the electron, because of the very large difference in masses.

### 1.4.3 EQUILIBRIUM RECOVERY: FLUORESCENCE

After receiving a given amount of energy, leading to excitation or ionisation, an atom has an excess of internal energy, becomes unstable, and tends to return to its fundamental state. This recovery of the fundamental state is associated with re-emission of energy. In the *fluorescence* process, the energy re-emission is made through prompt emission of one or several photons (after a delay of the order of  $10^{-6}$  s).

The mechanism of this process is described as follows: after excitation or ionisation, vacancies or *holes* appear in electron shells, and are promptly filled by electrons cascading from energy levels corresponding to shells farther from the nucleus. As the vacancies are filled, energy is released (for instance through photon emission) and the internal energy of the atom is reduced.

A single photon is emitted if the original event is a single ionisation and if the position of the electron removed from the atom is re-occupied by an external free electron. The photon energy is then equal to the binding energy of the electron removed by ionisation ( $W$ ).

Several photons are emitted if the return to the fundamental state is made through successive transitions of different electrons, from the inner part of the atom to the peripheral shell, where a free external electron can be captured. The global energy emitted through the photons is still equal to  $W$ , the binding energy of the electron initially removed by the ionisation.

If the original event is an excitation, the energy available is the difference in the binding energies corresponding to the shells involved in the electron transition (Figure 1.2a and Figure 1.2b).

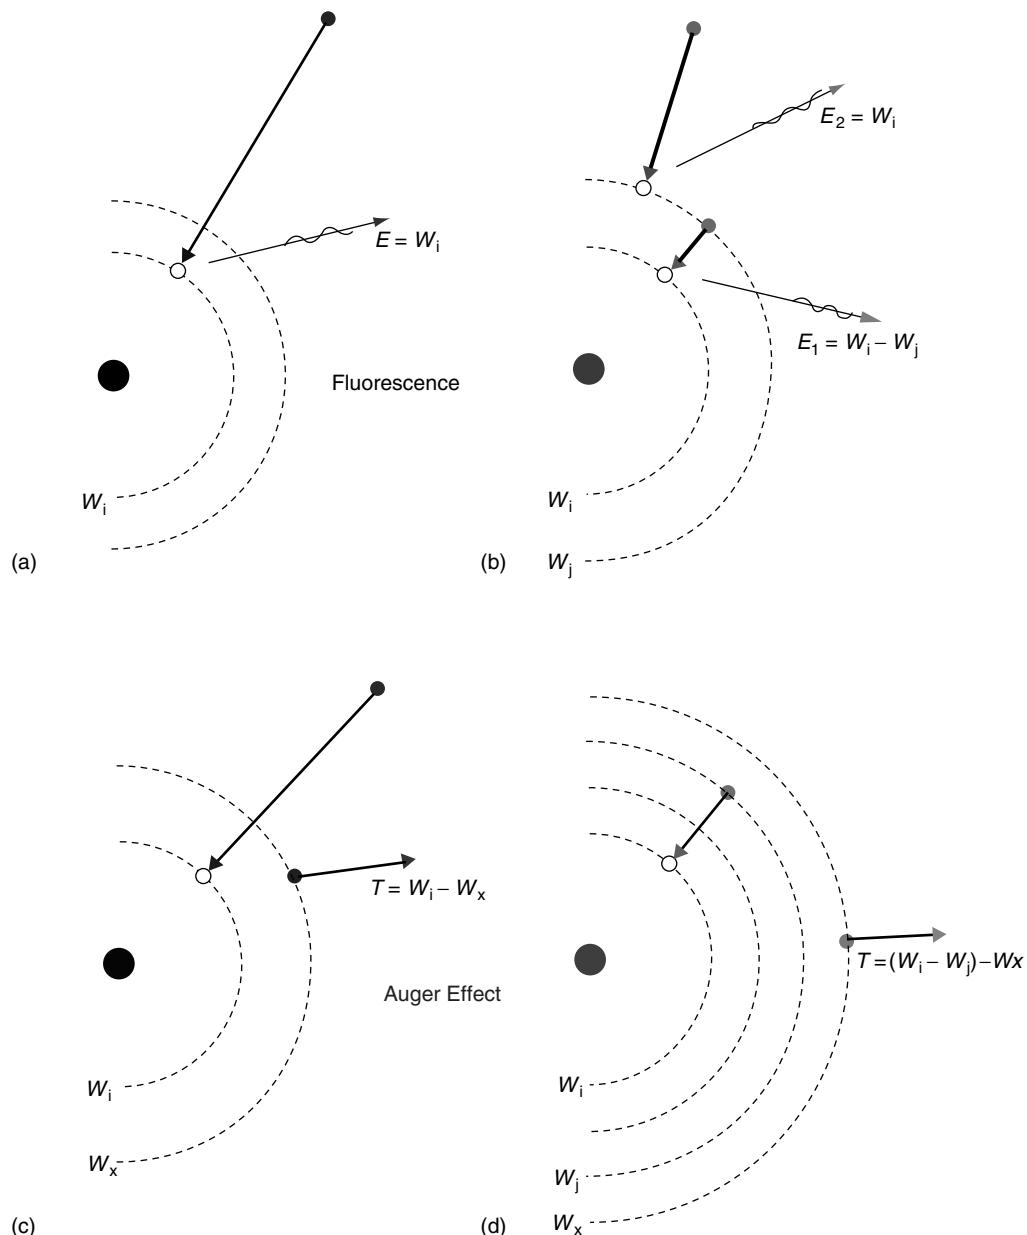

The energy of the emitted fluorescence photons is closely related to the mechanism of their production. This energy is therefore characteristic of the energy structure of the atoms and molecules involved in the production process and the emitted photons are called *characteristic x-rays*. The fluorescence spectrum is made up of lines allowing the characteristic radiation to be identified and associated with a specific atom. Fluorescence emission is usually described according to the destination of the cascading electron, as, for instance, K characteristic radiation, or K fluorescence.

*K shell* is a general name for a family of sub-shells with close energy levels, in such a way that the K characteristic radiation is made of a number of lines with close energies, with sub-families described as  $K\alpha$ ,  $K\beta\dots$  according to the original energy level of the electron (an example is given for tungsten in Figure 1.3). Depending on the energy levels in the atoms, the fluorescence photons can belong to the infrared, visible, UV or x-ray part of the electromagnetic spectrum.

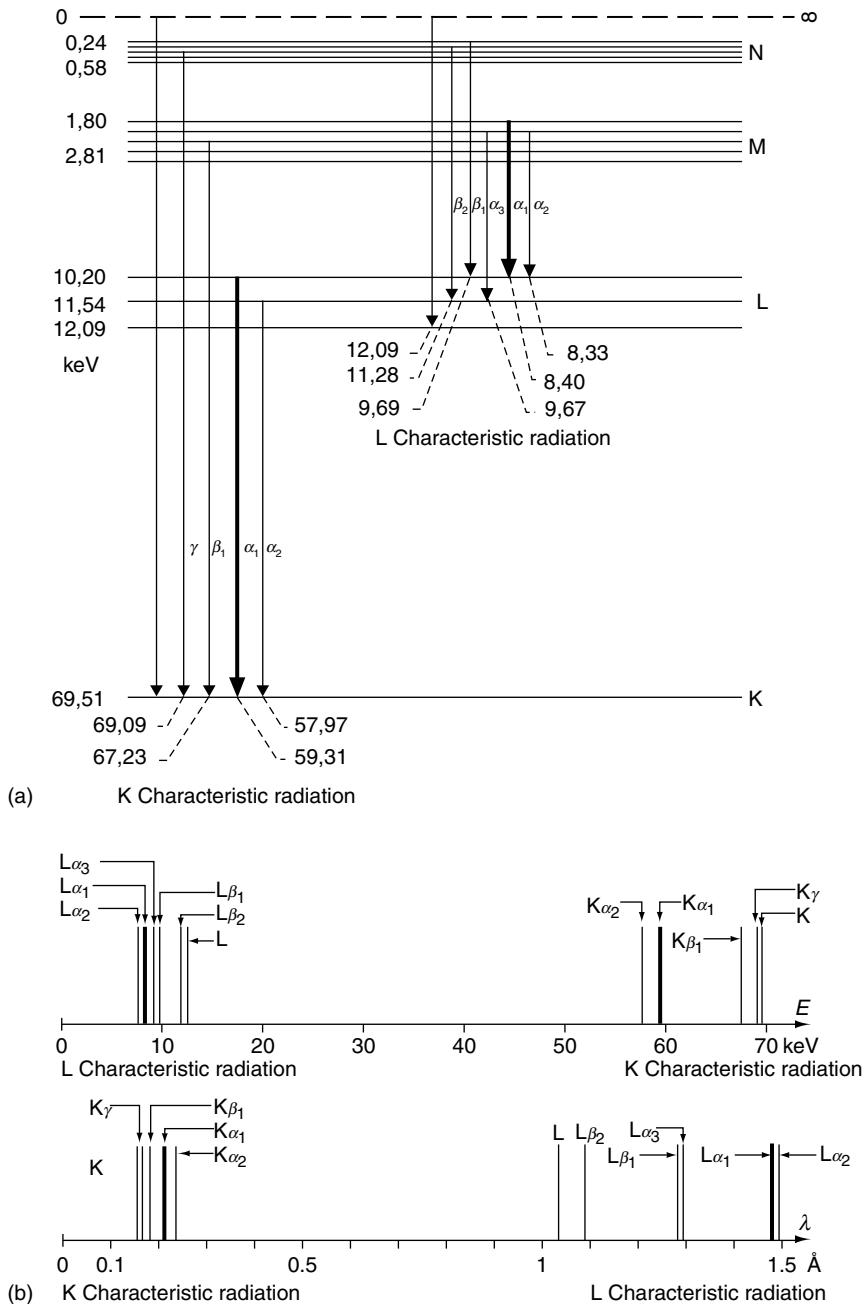

### 1.4.4 EQUILIBRIUM RECOVERY: AUGER EFFECT

Occasionally, the recovery energy may be used to eject a second electron instead of a photon. This ejected electron is called an Auger electron. Like fluorescence photons, Auger electrons have well-defined energies, depending on whether the energy is effectively transferred to more external electrons or whether the emission of the Auger electron is due to a free electron filling the initial vacancy (Figure 1.2c and Figure 1.2d).

The probability of the Auger effect is higher for low-Z biological media than the probability of fluorescence, close to 1 for  $Z < 10$  and about 0.1 for  $Z > 80$ .

**FIGURE 1.2**

Description of the mechanisms of fluorescence and the Auger Effect: (a) an i shell vacancy is filled with a free external electron, (b) an i shell vacancy is filled through two successive transitions involving the j shell, (c) after an i shell vacancy is filled with an external electron, an electron of the x-shell is ejected as an Auger electron, (d) similar to c, but the vacancy filling is due to a transition between the j and i shells. (From Dutreix, J. et al., *Biophysique des Radiations et Imagerie Médicale*, 3rd Ed., Masson, Paris, France, 1993.)

**FIGURE 1.3**

Fluorescence in Tungsten (a) Schematic description of the electron energy levels in tungsten atoms: The thick lines correspond to the highest probabilities of emission. The M fluorescence has an energy of a few keV and is usually not visible in the spectra from x-ray tubes, (b) Spectral distributions of fluorescence lines for tungsten atoms: Families of lines can be shown as a function of energy or of wavelength. (From Dutreix, J. et al., *Biophysique des Radiations et Imagerie Médicale*, 3rd Ed., Masson, Paris, France, 1993.)

After an Auger effect transition, the atom is still ionised, and another process can occur, leading to fluorescence or to a new Auger electron.

## 2.1 STABLE NUCLEUS: NUCLEAR ENERGY STRUCTURE

### 2.1.1 NUCLEAR ENERGY LEVELS

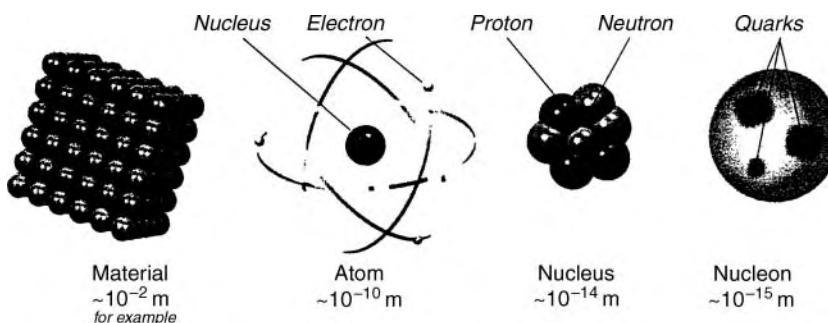

According to the shell model of the nucleus, the forces existing between nucleons determine a structure supported by discrete strong binding energies as illustrated in Figure 2.1.

This could appear paradoxical because the nucleus is made up of a mixture of protons and neutrons despite the repulsive electrostatic forces between protons. In fact, the nuclear energy structure can be explained by considering the following principal forces between the nucleons:

- The postulated attractive force ensuring the cohesion of the nucleus is called the *nuclear force* or *strong force*. It is supposed to be effective when the distance between nucleons is smaller than the diameter of the nucleus, and it is associated with the exchange of gluons between the quarks constituting the nucleons.
- The *electrostatic repulsive force* expected to take place between the protons is effective when the distance between the protons is greater than the diameter of the nucleus. Its strength is much smaller than the strength of the nuclear force ( $10^{-2}$  to  $10^{-6}$ ), and it is believed to be associated with the exchange of photons.
- The *weak force* is a very weak force, about  $10^{-10}$  times smaller than the nuclear force, believed to explain some  $\beta$  disintegrations, and it also involves electrons and neutrinos. It is associated with the exchange of bosons (so called W and Z particles which have large mass but cannot be observed directly).
- The *gravitational force* is a general component of the universe, but it is very tiny when small masses are considered, of the order of  $10^{-40}$  times smaller than the nuclear force, in relation to both protons and neutrons.

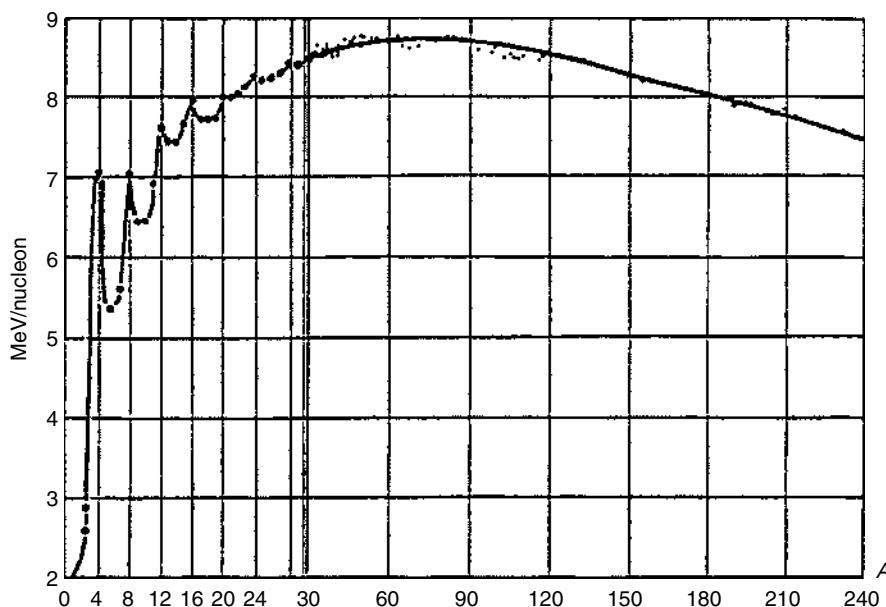

The binding energy of nucleons can be considered similarly to the principles presented for the peripheral electrons. The major difference is the magnitude of this binding energy that is of the order of 1 MeV per nucleon, i.e. about  $10^6$  times the binding energy of the peripheral electrons. This binding energy is obviously linked to the content of the nucleus, and it is the result of the combination of the different forces described above. Figure 2.2 shows the variation of the mean nuclear binding energy per nucleon as a function of the total number of nucleons  $A$ .

It appears that the maximum binding energy per nucleon (about 9 MeV per nucleon) occurs for values of  $A$  around 60 to 70 (Fe, Ni, Co, Ca, etc.), corresponding to very stable nuclei. When the number of nucleons,  $A$ , becomes higher, the binding energy decreases

**FIGURE 2.1**

The different components of the structure of matter, progressively magnified. (From Gambini, D. J. and Granier, R., *Manuel Pratique de Radioprotection*, Technique & Documentation collection, Lavoisier Editions, Cachan, France, 1997.)

**FIGURE 2.2**

Mean nuclear binding energy per nucleon as a function of the mass number (also the total number of nucleons  $A$ ). (From Gambini, D. J. and Granier, R., *Manuel Pratique de Radioprotection*, Technique & Documentation collection, Lavoisier Editions, Cachan, France, 1997.)

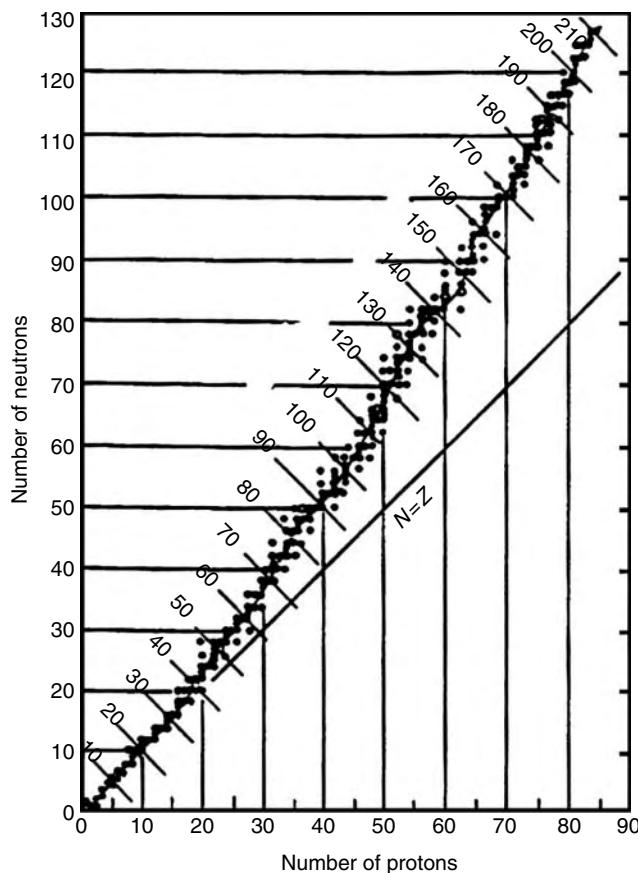

because of the larger distances between nucleons and the increasing influence of Coulomb forces. Discontinuities can be observed for a number of atoms where the saturation of nuclear shells (according to the shell model of the nucleus) is associated with a remarkable atomic stability (e.g.  ${}^4_2\text{He}$ ,  ${}^{12}_6\text{C}$ , and  ${}^{16}_8\text{O}$ ).

It can be predicted that the fusion of two light-nuclei, resulting in a heavier one, or the fission of a very heavy nucleus into lighter ones will allow the mean binding energy per nucleon to increase, leading to more stable atoms. This is associated with the release of energy and a greater global mass defect. This energy release can be very high. For example,  ${}^{235}_{92}\text{U}$  fission produces near  $10^{11}$  J/g, whereas, the fusion of  ${}^3_1\text{H}$  and  ${}^2_1\text{H}$  produces 3.1011 J/g.

### 2.1.2 ABUNDANCE OF STABLE NUCLEI AS A FUNCTION OF THE NUMBER OF PROTONS AND NEUTRONS

The possible number of nuclear configurations leading to stable atoms is only a small fraction of all possible configurations for a given set of nucleons. Approximately 300 different stable atoms naturally exist on earth, but more than 2000 other atoms have already been observed, at least for very short times during the many experiments that have taken place over recent years.

Figure 2.3 is interesting to consider as it shows the number of neutrons as a function of the number of protons for a wide range of existing atomic mass numbers. It appears that, for light atoms, the number of neutrons is about equal to the number of protons. For mass numbers above approximately 40, the number of neutrons becomes higher than the number of protons to allow these existing elements to remain stable for a significant time. If a given nucleus has a neutron or a proton content differing from the optimal structure, it would be expected that unstable configurations will arise during the constant changes linked to the orbits of the nucleons. Most of the nuclei with atomic numbers greater than approximately 80 are unstable, but unstable nuclei also exist with smaller atomic numbers.

**FIGURE 2.3**

Number of neutrons as a function of the number of protons for existing atoms for mass numbers  $A$  in the range 0–210. (From Dutreix, J. et al., *Biophysique des Radiations et Imagerie Médicale*, 3rd Ed., Masson, Paris, France, 1993.)

### 2.1.3 INFLUENCE OF $N/Z$ ON STABILITY

Excepting catastrophic events such as fusion or fission, more stable structures can be obtained through changes in the number or in the nature of nucleons for a given nucleus. For instance, a nucleus with an excess of neutrons can eject a negative charge, changing a neutron into a proton ( $\beta^-$  emission), whereas, a nucleus with an excess of protons can eject a positive charge, changing a proton into a neutron ( $\beta^+$  emission). Very heavy nuclei that contain too many protons and neutrons can eject a group of two protons and two neutrons (i.e. a helium nucleus) which forms one of the most stable structures ( $\alpha$  emission).

---

## 2.2 NUCLEAR INSTABILITY: RADIOACTIVITY

### 2.2.1 DEFINITION OF RADIOACTIVITY

Discovered by Henri Becquerel in 1896 in the form of emissions from uranium, radioactivity is commonly described as the possibility that a given atomic nucleus will spontaneously emit particles through disintegration, leading to possible change in its physical and chemical properties. In 1898 Pierre and Marie Curie announced that they had identified two hitherto unknown elements, polonium and radium. These elements were much more radioactive than uranium and formed a very small fraction of the uranium ore, pitchblende.

The complex phenomena involved in the radioactivity process required at least ten years to be properly explained with the initial work made by Henri Becquerel, Pierre and Marie Curie, Ernest Rutherford, and Frederick Soddy at the beginning of the twentieth century. Another main step was the discovery of *artificial* radioactivity by Irène and Frédéric Joliot in 1934, introducing the production of a great number of *radionuclides* and the world of nuclear energy. The process involved in the radioactivity phenomenon is the same for natural and artificial radionuclides.

Based on the current view of the energy structure of the atomic nucleus (Blanc and Portal 1999) the principal different, spontaneous radioactive transformations can be categorised according to whether they are associated with strong interactions, electrostatic interactions or weak interactions. They are described in Section 2.2.2 through [Section 2.2.4](#) according to these classifications.

## 2.2.2 RADIOACTIVE TRANSFORMATIONS ASSOCIATED WITH STRONG INTERACTIONS

### 2.2.2.1 $\alpha$ Radioactivity

As previously stated, one of the most strongly bound structures is the helium nucleus  ${}^4_2\text{He}$ . It is emitted as alpha particles by a number of nuclei with high atomic numbers ( $> 80$ ), and it was first observed by H. Becquerel and described by E. Rutherford around 1900.

An alpha transition can be described as follows:

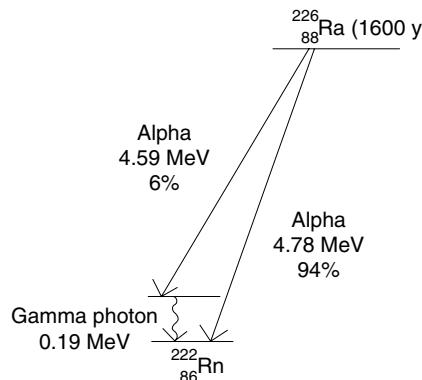

where the nuclide, X, changes into another nuclide, Y. The daughter nuclide frequently is in an excited energy state, leading to a gamma photon emission associated with the return to the basic energy state.

It can be observed that the sums of the mass numbers and the atomic numbers of the daughter nuclide and the alpha particle equal the mass number and the atomic number, respectively, of the parent nuclide. The discrete transition energy is usually shared between the alpha particle kinetic energy and the gamma photon. For this reason, alpha particles are emitted with discrete energies.

A classical alpha decay is the decay of  ${}^{226}_{88}\text{Ra}$ :

The corresponding radioactive decay scheme is represented in Figure 2.4.

**FIGURE 2.4**

Radioactive-decay scheme for alpha decay of  ${}^{226}\text{Ra}$ . (From Hendee, W. R., *Medical Radiation Physics*, 2nd Ed., Yearbook Medical Publishers, Inc., Chicago, IL, 1979.)

### 2.2.2.2 Spontaneous Fission

In spontaneous fission, the nucleus splits into two or more pieces with the simultaneous emission of fast neutrons. This phenomenon happens with the heaviest nuclei, and it seems to be the reason for an upper limit of the atomic numbers of approximately 110. An example of such radioactive sources used in radiation therapy is  $^{252}_{98}\text{Cf}$  that produces  $\alpha$  and  $\gamma$  particles, and neutrons with a mean energy of 2.35 MeV.

## 2.2.3 RADIOACTIVE TRANSFORMATIONS ASSOCIATED WITH THE ELECTROSTATIC FORCE

### 2.2.3.1 Nuclear Isomerism (or $\gamma$ Radioactivity)

So-called *pure gamma radioactivity*\* is really nuclear isomerism. A nucleus is artificially elevated to an excited energy state, and it then returns to the fundamental state through well-defined gamma emissions. This may be represented by:

A classical example in the medical field of this type of decay is

that results in gamma photons of 140 keV.

### 2.2.3.2 $\gamma$ Emission and Internal Conversion

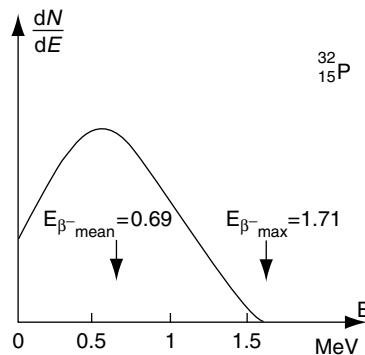

$\gamma$  photon emission is often observed during radioactive transformations as the daughter nucleus is formed in an excited, metastable state. The  $\gamma$  photons, first observed by Villard in 1900, directly result from the return of the daughter nucleus to ground energy state, and they are produced according to the discrete energies available, corresponding to characteristic lines in the energy spectrum. As a result, a large number of radionuclides with different decay schemes include  $\gamma$  emissions in the resulting emission spectrum. When the nuclear transition energy available is sufficiently high, the return to ground energy level may require several steps with cascades of  $\gamma$ -rays and  $\beta$  particles.

Sometimes, the energy release is produced by internal conversion, corresponding to an electron being ejected from the shells close to the nucleus. This electron receives kinetic energy equal to the energy released minus the binding energy of the electron. This process could appear as an interaction of a  $\gamma$  photon with the electronic shells. The result of such a vacancy in an electronic shell is a cascade of electron transitions to fill the vacancy with emission of characteristic x-rays and Auger electrons.

The probability of internal conversion increases rapidly with atomic number and with the lifetime of the metastable state of the nucleus.

---

\* Photons emitted from the nucleus are called  $\gamma$  photons, whereas, the photons produced outside the nucleus are called x-rays.

**FIGURE 2.5**

$\beta^-$  spectrum of  $^{32}_{15}\text{P}$ . (From Gambini, D. J. and Granier, R., *Manuel Pratique de Radioprotection*, Technique & Documentation collection, Lavoisier Editions, Cachan, France, 1997.)

## 2.2.4 RADIOACTIVE TRANSFORMATIONS ASSOCIATED WITH THE WEAK INTERACTION

### 2.2.4.1 $\beta^-$ Radioactivity

$\beta^-$  radioactivity\* can be observed when neutrons are in excess in the nucleus. The following process occurs through weak interactions where a neutron becomes a proton with the release of a negative electron (*negatron*) and of an electronic antineutrino (no electric charge and rest mass  $< 15 \text{ eV}/c^2$ ):

Generally, the transition energy is equally shared between the electron ( $\beta^-$  particle) and the neutrino, according to probabilities leading to a continuous energy spectrum as shown on the Figure 2.5 for  $^{32}_{15}\text{P}$ , even though the transition energies are discrete. The energy transmitted to the nucleus is negligible.

The result for the atom is as follows:

As the atomic number  $A$  does not change, this transition is called *isobaric*.

$\beta^-$  decay is possible whatever the atomic mass as is also the case for  $\beta^+$  decay below.

### 2.2.4.2 $\beta^+$ Radioactivity

$\beta^+$  decay can be observed when protons are in excess in the nucleus. The same type of process as shown above is produced with

\* Electrons emitted from the nucleus are called  $\beta$  particles, whereas, electrons arising from the electron shells are not  $\beta$  particles (they can, for instance, be Auger electrons).

where  ${}_{+1}^0 e$  is an antielectron, called a *positron*.  $\nu_e$  is an electron-neutrino. Again, the transition energy is shared between the  $\beta^+$  particles and the neutrinos in such a way that a continuous energy spectrum is observed for the  $\beta^+$  particles.

The  $\beta^+$  particles do not permanently exist, and they initially behave like the  $\beta^-$  particles with respect to interactions with matter. Eventually, when they have almost reached rest energy, a recombination of the positron and a negatron of the matter takes place.

This means that nuclei that cannot produce at least 1.02 MeV for a given transition do not decay through positron emission.

With this kind of radioactivity, the result for the atom is

This transition is also isobaric.

#### 2.2.4.3 General Aspects of $\beta$ Decay

There are a large number of radionuclides that are  $\beta$  emitters. The energy spectrum of  $\beta$  radioactivity is such that the mean energy of the  $\beta$  particles is of the order of one third of the maximum energy, with differences from one nucleus to another, and between  $\beta^-$  and  $\beta^+$ . It is possible for a number of radionuclides to be simultaneously  $\beta^-$  and  $\beta^+$  emitters with a well-defined ratio between both emission probabilities.

#### 2.2.4.4 Electron Capture

This process is another way for a given atom to increase its n/p ratio, especially when the transition energy is not high enough to allow a  $\beta^+$  decay. It can be described as a *capture* by the nucleus of an electron belonging to the shells, leading to:

The result for the atom is;

In this case, the neutrinos produced are monoenergetic. After such a capture, most often of a K shell electron, a vacancy is produced. This is then filled by an electron cascading from an energy level farther from the nucleus with emission of characteristic x-rays. The energy spectrum of such x-rays is then made up of well-defined lines.

A typical radionuclide used in Brachytherapy and that decays through electron capture is  ${}^{125}\text{I}$  with photon emissions corresponding to the characteristic x-rays of the Iodine atom.

#### 2.2.5 ARTIFICIAL RADIOACTIVITY

Unstable nuclei, leading to radioactive transformations, can be obtained by bombarding stable nuclei with a number of particles such as neutrons, high energy protons, deuterons,

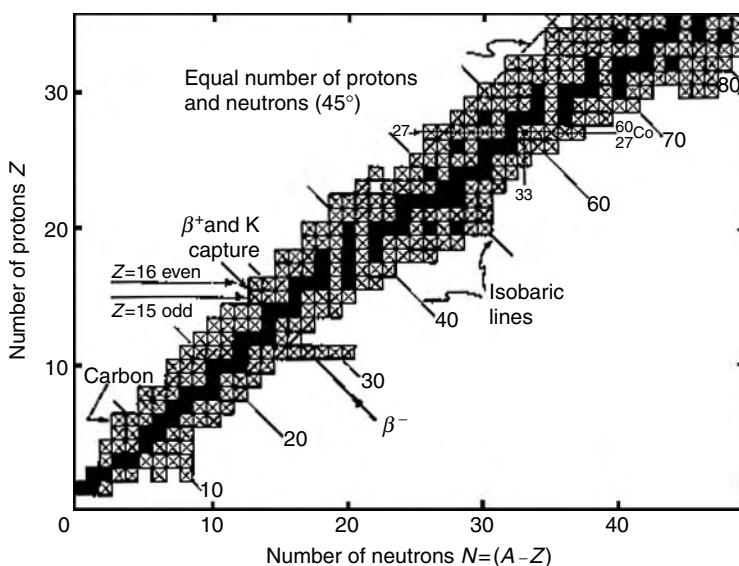

**FIGURE 2.6**

Chart showing the proportions of protons and neutrons in nuclei. Stable nuclei are represented by solid squares; radioactive nuclei by crosses. Nuclei with equal numbers of neutrons and protons lie along the line  $N=Z$ . Isotopes appear along horizontal lines and isobars along lines at  $45^\circ$ . (From Johns, H. E. and Cunningham, J. R., *The Physics of Radiology*, 4th Ed., Charles C. Thomas, Springfield, IL, 1983.)

$\alpha$  particles or  $\gamma$ -rays. During a collision of the particles with the nucleus, the particles can either be absorbed or they can eject a nucleon from the nucleus. The result is the production of a new nuclide with a nuclear content that may allow radioactive transformations. A very large number of artificial radioactive isotopes\* have been produced with the wide range of high-energy particle-accelerators now available, and most of the radionuclides used in medicine are man-made (Figure 2.6).

The classical example of the production of artificial radioactivity is the experiment that allowed Frédéric and Irène Joliot-Curie to discover this process. They bombarded aluminium foil with  $\alpha$  particles produced by a  $^{210}\text{Po}$  source (5.3 MeV). Aluminium produced positrons with an exponential decay, suggesting a radioactive process. In fact, the following processes were involved:

Through chemical analysis, they were able to confirm that phosphorus had actually been produced. A number of radionuclides are also produced through the fission process, the fission fragments corresponding to nuclei situated outside the stability conditions. The mathematical description of radioactive decay is considered in [Section 2.3](#) and the artificial production of radionuclides in [Section 2.4](#).

\* The term *isotopes* is frequently used to designate *radionuclides* (i.e. radioactive nuclides)

## 2.3 QUANTIFICATION OF RADIOACTIVITY

### 2.3.1 ACTIVITY: QUANTITY AND UNIT

According to ICRU (ICRU 1998): “the activity  $A$  of an amount of radioactive nuclide in a particular energy state at a given time is the quotient of  $dN/dt$ , where  $dN$  is the expectation value of the number of spontaneous nuclear transitions from that energy state in the time interval  $dt$ ”.

$$A = \frac{dN}{dt}$$

The unit of activity is  $s^{-1}$ . The special name for the unit of activity is becquerel (Bq)

$$1 \text{ Bq} = 1 \text{ s}^{-1}$$

This unit replaces the former curie (Ci) such that

$$1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq} \text{ (exactly)}$$

### 2.3.2 RADIOACTIVE DISINTEGRATION AND DECAY

The principles of radioactive decay are discussed here. Examples of decay characteristics for radionuclides of interest in radiotherapy will be found in [Table M.4](#).

#### 2.3.2.1 Law of Radioactive Decay

The radioactive decay law was experimentally established in 1902 by Rutherford and Soddy in Great Britain. According to this law, the number  $dN$  of spontaneous disintegrations happening in a given amount of radioactive material during an infinitesimal time interval  $dt$  is proportional to:

- The number of radioactive atoms included in this amount of material at the time considered
- The time interval  $dt$
- A constant  $\lambda$ , called the decay constant. It represents, for a given nucleus of a given radio-nuclide, the quotient,  $dP/dt$ , where  $dP$  is the probability that the nucleus will undergo a spontaneous nuclear transition from the original energy state during the time interval  $dt$ . This constant is a specific characteristic of the nuclide and is not influenced by its physico-chemical status.

So,

$$dN = -\lambda N dt \quad (2.1)$$

Starting with an initial number  $N_0$  of radioactive atoms, the number,  $N_t$ , of atoms present at time  $t$  will be

$$N_t = N_0 \exp(-\lambda t) = N_0 e^{-\lambda t} \quad (2.2)$$

From the above definition, it follows that the activity  $A$  is represented by:

$$A = \left| \frac{dN}{dt} \right| = \lambda N \quad (2.3)$$

and by following a similar argument to the derivation of  $N_t$ :

$$A_t = A_0 \exp(-\lambda t) = A_0 e^{-\lambda t} \quad (2.4)$$

### 2.3.2.2 Half-Life of a Radioactive Nuclide

The principles of exponential decay lead to the fact that, in a given time interval, a given proportion of radioactive atoms disintegrate.

To illustrate the decay rate of a given radionuclide, the time required for half of the existing radioactive atoms to disintegrate has been chosen as a reference and is called the half-life,  $T^*$ . The *half-life* can be introduced into the above equations as follows:

$$0.5 = \frac{N}{N_0} = \exp(-\lambda T) = e^{-\lambda T}$$

hence:

$$T = \frac{\ln 2}{\lambda} \approx \frac{0.693}{\lambda} \quad (2.5)$$

$$A_t = A_0 \exp\left(-\frac{\ln 2 \times t}{T}\right) \quad (2.6)$$

Sometimes, the *mean life*,  $\tau$ , is used instead of the half-life  $T$ .

$$\tau = \frac{1}{\lambda} = \frac{T}{\ln 2} \approx 1.44T$$

### 2.3.2.3 Specific Activity

When, in a given amount of material, stable and radioactive atoms of the same element are present, the *specific activity* of this radionuclide is given by:

$$A_{\text{spec}} = \frac{N_{\text{ra}}}{N_{\text{st}} + N_{\text{ra}}} \quad (2.7)$$

where  $N_{\text{ra}}$  is the number of radioactive atoms, and  $N_{\text{st}}$  the number of stable atoms. It represents the activity per unit mass of that radionuclide. It is different from the *mass specific activity* that, in a material containing a radionuclide, is the activity per unit mass of that material.

### 2.3.2.4 Equilibrium with Radioactive Daughter Products

When daughter nuclides produced by a radioactive process are also radioactive, the decay of the daughter nuclides in a mixture of original/daughter nuclides may appear different from the decay expected for the daughter nuclides alone.

A radionuclide with a decay constant  $\lambda_1$ , and the daughter with a decay constant  $\lambda_2$ , larger than  $\lambda_1$  (shorter half-life) is now considered. According to the above equations,

$$dN_1 = -\lambda_1 N_1 dt$$

---

\* The symbol for the half life is sometimes written as  $T_{1/2}$ .

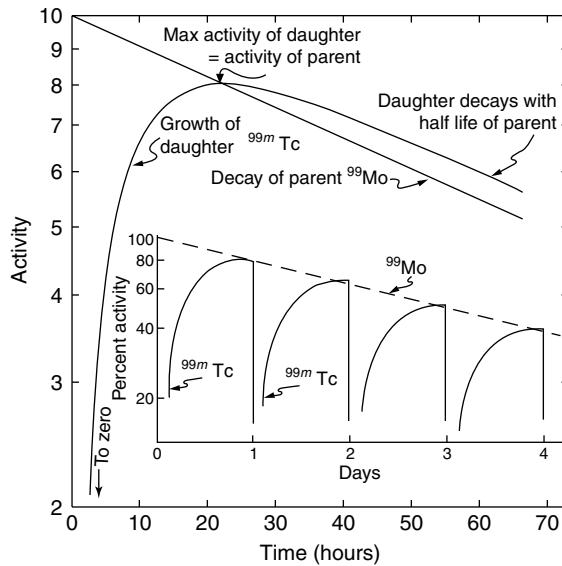

**FIGURE 2.7**

Illustration of activity decay of parent  $^{99}\text{Mo}$  and activity growth of daughter  $^{99m}\text{Tc}$  as a function of time, assuming that it is started from a pure source of parent. The figure insert shows the same data when the daughter is *milked* from the parent once every day. The actual situation is somewhat more complicated because only about 86% of the parent  $^{99}\text{Mo}$  nuclei decay to the daughter  $^{99m}\text{Tc}$ . This means that the activity of the  $^{99m}\text{Tc}$  is about 14% less than indicated on the graph. (From Johns, H. E. and Cunningham, J. R., *The Physics of Radiology*, 4th Ed., Charles C. Thomas, Springfield, IL, 1983. With permission.)

$$dN_2 = \lambda_1 N_1 dt - \lambda_2 N_2 dt \quad (2.8)$$

The corresponding activities are then

$$A_{1t} = A_{1t_0} e^{-\lambda_1 t} \\ A_{2t} = \frac{\lambda_2}{\lambda_2 - \lambda_1} A_{1t_0} \left[ e^{-\lambda_1 t} - e^{-\lambda_2 t} \right] = \frac{\lambda_2}{\lambda_2 - \lambda_1} A_{1t_0} \left( 1 - e^{-(\lambda_2 - \lambda_1)t} \right) \quad (2.9)$$

$A_1$  decays exponentially, whereas,  $A_2$  increases then decays after a maximum value  $t_m$  such that

$$t_m = \frac{\ln(\lambda_2/\lambda_1)}{\lambda_2 - \lambda_1} \quad (2.10)$$

For this example where  $T_1 > T_2$ , after a long time, a *transient equilibrium*\* is obtained as the daughter nuclide decreases with an apparent half-life equal to the half-life of the parent. The production of daughter atoms is slower than the disintegration rate of the daughter itself. At

\* *Editors note:* The use of the terms *transient* and *secular* (which means “very long lasting”) equilibrium is controversial (Hendee and Bednarek 2004). The *equilibrium* usually described in textbooks is equilibrium between the activity of the daughter and the parent. This ratio becomes constant as in Equation 2.11 so this *equilibrium* is *secular* whether  $T_1 \gg T_2$  or not. We could also consider the equilibrium in the balance between rate of increase in activity of the daughter and its rate of decay which occurs when  $dN_2/dt = 0$ , i.e. when  $\lambda_1 N_1$  is equal to  $\lambda_2 N_2$  as can be seen from Equation 2.8. This is transient in both cases, but if  $T_1$  is very large the situation may *appear* secular. More obviously, the *equality* of activity between daughter and parent is *transient* unless  $T_1 \gg T_2$ .

this point, the exponential term in Equation 2.9 tends to zero and:

$$\frac{A_1}{A_2} = \frac{\lambda_2 - \lambda_1}{\lambda_2} \quad (2.11)$$

The ratio between the activities of parent and daughter remains constant. This principle is used in generators for radioactive nuclides used in nuclear medicine. For instance, for the production of  $^{99m}\text{Tc}$  ( $T=6.03$  h) from  $^{99}\text{Mo}$  ( $T=66.7$  h), a quasi-transient equilibrium can be obtained after less than one day (Figure 2.7).

If  $T_1 \gg T_2$ , a *secular equilibrium* is obtained, and the activities of the parent and daughter radionuclides become equal after several half-lives of the daughter.

On the other hand, if  $T_1 \ll T_2$ , the production of daughter atoms is faster than the daughter decay, and the daughter activity increases and, after a long delay, the parent has decayed to a negligible activity so that the daughter decay can be observed alone.

In practice, since the situation depends upon the individual half-life of the parent and daughter radionuclide, it becomes much more complex if the decay scheme involves several successive daughter radionuclides.

## 2.4 PRODUCTION OF RADIOACTIVE SOURCES THROUGH THE ACTIVATION PROCESS

As previously stated, artificial radioactivity can be induced by bombarding stable nuclei with various particles, including neutrons, protons,  $\alpha$  particles or  $\gamma$ -rays, with appropriate energy.

### 2.4.1 STANDARD PRODUCTION OF ARTIFICIAL RADIONUCLIDES

Production of artificial radionuclides takes place in nuclear reactors, either as by-products of nuclear fission (e.g.  $^{137}\text{Cs}$ ,  $^{90}\text{Sr}$ ,  $^{131}\text{I}$ ) or by neutron bombardment, through  $(n, \gamma)$  reactions (e.g.  $^{60}\text{Co}$ ,  $^{198}\text{Au}$ ,  $^{192}\text{Ir}$ ). Cyclotrons are also used for the production of radionuclides used in nuclear medicine.

The principles and the quantitative aspects of the production of radioactive atoms can be summarised as follows:

A thin target (thickness  $dx$ ) with an area being equal to  $1 \text{ cm}^2$  is considered. This target contains  $n$  atoms involved in the activation process.

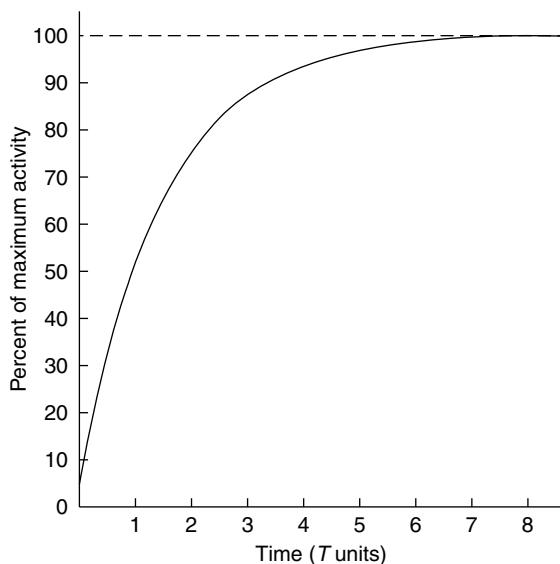

The production of radioactive atoms is a function of the following parameters:

- The duration  $dt$  of the bombardment
- The number of atoms under bombardment. ( $n dx$  for this target)
- The neutron fluence rate  $\dot{\Phi}$
- The cross section  $\sigma$  of the nuclear reactions, leading to neutron capture in the target material. This cross section depends on the material and on the neutron energy. It is expressed in  $\text{cm}^2$  per atom.

So, if the activation process starts at  $t_0$ , with  $n$  initial number  $N_0$  of radioactive atoms in the target equal to zero, during  $dt$ , the following can be observed:

$$\frac{dN}{dt} = \sigma \dot{\Phi} n dx - \lambda N \quad (2.12)$$

$\lambda$  being the decay constant of the radionuclide produced, decaying during  $dt$ .

**FIGURE 2.8**

Production of artificial radionuclides: Variation of activity in the target as a function of time expressed in half-life units.

Hence, the total number of radioactive atoms at time  $t$  is:

$$N_t = \sigma \dot{\Phi} n dx \frac{(1 - e^{-\lambda t})}{\lambda} \quad (2.13)$$

The radionuclide activity after a bombarding time  $t$  is:

$$A_t = \lambda N_t = \sigma \dot{\Phi} n dx (1 - e^{-\lambda t}) \quad (2.14)$$

This increase of activity in the target as a function of time is represented on Figure 2.8.

It appears that, for a given neutron fluence rate, the activity reaches a limit value even for an infinite bombarding time. It is called saturation activity and given by:

$$A_s = \sigma \dot{\Phi} n dx \quad (2.15)$$

In this situation, the atom disintegration rate is equal to the atom production rate.

As higher activities are required (i.e. for radiotherapy), the target mass or the neutron fluence rate must increase. Because the source size is usually constrained by the application, an increase in activity can only be achieved by increasing the neutron fluence rate.

For the production of cobalt-60, the  $(n, \gamma)$  reaction transforms an atom of atomic mass  $A$  into an isotope of atomic mass  $A + 1$ :

The neutron spectrum should, of course, be optimised in order to get the highest value possible for  $\sigma$ .

To reach 75% of the saturation activity in a given reactor neutron fluence rate, it is necessary to wait for two times the half-life. In the case of the production of  ${}^{60}\text{Co}$  ( $T = 5.271$  years), this would represent more than ten years, which is not practically possible.

**TABLE 2.1**Examples of Radionuclides Possibly Produced in Linear Accelerators by a ( $\gamma$ , n) Reaction

## 2.4.2 UNINTENTIONAL ACTIVATION

Unintentional activation can occur in high energy accelerators, and this activation should be taken into consideration for radiation protection. For electron accelerators, the process first involves the production of photons in the target or in various parts of the unit (contributing to photon leakage around the machine). It then involves the production of neutrons through a photonuclear interaction. This photonuclear interaction occurs when the photon energy has the same order of magnitude as the binding energy of the nucleons. When the photon is absorbed by the nucleus, the additional internal energy is generally lost through a neutron or a proton emission (usually presented as ( $\gamma$ , n) or ( $\gamma$ , p) reactions). Except for light atoms, the most common reaction is ( $\gamma$ , n).

Such a reaction appears only above a given energy threshold that depends on the material. The induced activity depends on the material (cross-section value) and on the irradiation conditions (energy, dose rate, and irradiation time).

A few examples of activation reactions are given in Table 2.1. This table shows that there are parts of the linac made of copper that can be activated when the electron/photon energies are higher than approximately 10 MeV. For higher energies, some activation occurs in air (and in the patient). Therefore, the global radiation protection problem for the higher energy range used in radiotherapy is linked to both the neutron production during irradiation (suitable absorbing materials must be present in the walls and in the door of treatment rooms) and the photons emitted during, and even some time after, irradiation. The latter are due to activation and must be taken into consideration for maintenance and repair activities. More severe radiation protection problems may occur in the use of protons, neutrons or heavy ions in radiation therapy (see [Chapter 46](#) and [Chapter 49](#)).

## 3.1 INTRODUCTION

Charged particles are fundamental to the medical use of radiation. Even if the primary radiation is a photon beam, it is the charged particles, known as secondary radiation in such cases, that cause the biological effect, whether it be cell killing or other changes that may eventually induce cancer. In fact, charged particles are often termed *ionising* radiation, and photons (and neutrons) termed *non-ionising* or *indirectly ionising*. Furthermore, a precise knowledge of the *spatial* distribution of the absorbed dose is crucial to radiotherapy treatment planning and delivery (and in certain cases, to radiation protection considerations), and this can only be obtained if the transport of the energy by the charged particles (overwhelmingly electrons) can be modelled. In many cases, the ranges of, for example, the Compton electrons (see [Section 4.3.2](#)) generated by megavoltage x-ray beams are appreciable (up to several cm) and must, therefore, be accurately modelled. The generation of x-rays, i.e. bremsstrahlung, is a charged-particle interaction. Alternatively, radiotherapy is sometimes delivered by primary charged particle beams, usually megavoltage electrons, where electron interactions with matter are obviously crucial. However, increasingly, proton beams are coming into therapeutic use (see [Chapter 46](#)), and even so-called heavy ions such as carbon are used (see [Chapter 49](#)). Mention can also be made of unsealed source therapy (Part K) with, for example,  $\beta$ -emitting radionuclides; these electrons (or positrons) can also have ranges up to a centimetre. The subject of radiation dosimetry (see [Chapter 6](#) and [Part D](#)) depends on an intimate knowledge of the interactions of both non-ionising and directly ionising (i.e. charged) particles (e.g. the Bragg–Gray cavity principle) as will be made clear in Chapter 6. At the microdosimetric level, a fundamental understanding of the action of radiation on cells can only come through studying the track structure of particle tracks in relation to the relevant targets (i.e. the DNA in the cell nucleus). Again, this requires knowledge of the charged-particle interactions. Perhaps the only use of radiation in radiotherapy that does not rely heavily on charged particle interactions is imaging by diagnostic x-rays.

In this chapter, the emphasis is on electrons. However, much of the material applies with little modification to protons and other ions, and this will be indicated where appropriate. There are primarily three interaction mechanisms of importance for electrons in the energy range from a few hundred eV up to 50 MeV\*: first, *collisions* with bound atomic electrons (Møller scattering); second, *bremsstrahlung* or radiative losses; and third, *elastic scattering* largely because of the heavy, positively charged nucleus. For heavy particles only (inelastic) collision losses and elastic scattering are important (see [Chapter 47](#) and [Chapter 49](#)). In all cases, the consequences of the interactions are twofold: modifications of the incident (direct or secondary) charged particles in terms of energy loss and direction, and transfer of energy to matter, resulting in energy absorption and dose deposition. This second issue will be considered in more detail in Chapter 6.

---

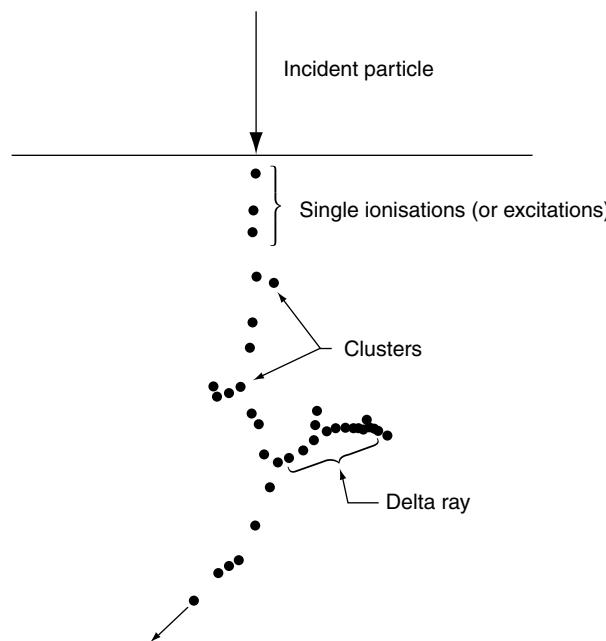

## 3.2 COLLISION LOSSES

### 3.2.1 THEORY

Coulomb interactions with the bound atomic electrons are the principal way that charged particles (electrons, protons, etc.) lose energy in the materials and energies of interest in radiotherapy. The particle creates a trail of ionisations and excitations along its path. Occasionally, the energy transfer to the atomic electron is sufficient to create a so-called *delta ray* (or  $\delta$ -ray)

---

\* See [Section 5.4](#) for some historical references related to the fundamental electrons and positrons interaction processes.

**FIGURE 3.1**

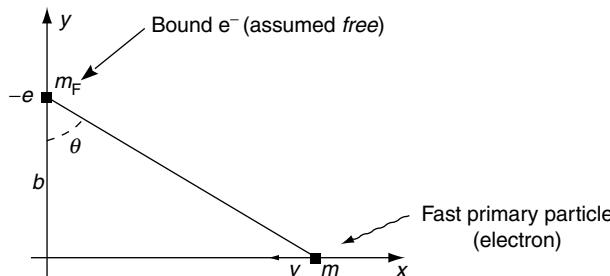

Diagrammatic representation of the track of a charged particle in matter. (From ICRU, *Linear Energy Transfer, Report 16*, ICRU, Bethesda, MD, 1970.)

which is a (secondary) electron with an appreciable range of its own. This is schematically illustrated in Figure 3.1. A fuller and very readable account of the theory of inelastic collisions between fast charged particles and atomic electrons can be found in Evans (1955).

The physical model of the Coulomb interaction between the fast charged particle and a bound electron in the medium is shown in Figure 3.2. The electron is assumed to be free, and its binding energy assumed to be negligible compared to the energy it receives. The primary particle imparts a net impulse to the bound electron in a direction perpendicular to its path.

Using classical, non-relativistic collision theory, as Bohr once did, from Newton's second law, (i.e. the change in momentum is equal to the impulse [the time integral of the force]) and from the Coulomb law for the force between charged particles, it can be shown that the energy transfer  $Q$  is given by:

$$Q = \frac{2k^2 z^2 e^4}{mb^2 v^2} \quad (3.1)$$

**FIGURE 3.2**

Interaction between a fast primary charged particle and a bound electron. The incoming electron is moving at a speed  $v$  in a direction opposite to axis  $x$ . (From Nahum, A. E., *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Medical Physics Publishing, Madison, WI, 1985.)

where  $b$ , the distance of closest approach, is known as the *impact parameter*;  $m$  is the mass of the electron;  $z$  is the charge on the primary particle (in units of the electronic charge  $e$ );  $v$  is the velocity of the primary particle; and the constant,  $k$ , is defined below. It should be noted that the mass of the primary particle does not enter into Equation 3.1, which equally applies to electrons, protons (that both have  $z=1$ ), and other heavier charged particles (see Chapter 46 and Chapter 49). Equation 3.1 leads to the following classical expression for the cross-section per electron, differential in the energy transfer  $Q$ :

$$\frac{d\sigma}{dQ} = \frac{2\pi z^2 e^4 k^2}{mv^2} \frac{1}{Q^2} \quad (3.2)$$

The full relativistic, quantum-mechanical cross-section for Coulomb interactions between free electrons, due to Møller (1932), is:

$$\frac{d\sigma}{d\varepsilon} = \frac{2\pi e^4 k^2}{Tm_e v^2} \left[ \frac{1}{\varepsilon^2} + \frac{1}{(1-\varepsilon)^2} + \left( \frac{\tau}{\tau+1} \right)^2 - \frac{2\tau+1}{(\tau+1)^2} \frac{1}{\varepsilon(1-\varepsilon)} \right] \quad (3.3)$$

where

$T$  is the electron kinetic energy (k.e.)

$\varepsilon = Q/T$  is the energy transfer in units of the electron k.e.

$\tau = T/m_e c^2$  is the k.e. in units of the electron rest mass

$v$  is the electron velocity

$k = 8.9875 \times 10^9 \text{ N m}^2 \text{ C}^{-2}$  (constant appearing in the Coulomb-force expression)

The first term in Equation 3.3 dominates. Ignoring the remaining terms and changing the variable from  $\varepsilon$  to the energy transfer  $Q$ , the classical result given above (Equation 3.2) is obtained. The  $1/Q^2$  dependence clearly demonstrates that small losses predominate; the average energy loss in low atomic-number materials is of the order of 60 eV (ICRU 1970). The Møller expression (Equation 3.3) is valid provided that the electron energy is much greater than the binding energies of the atoms in the medium. The binding energies also set a lower limit to the energy transfer possible (see Section 3.2.2).

The terms *soft* and *hard* are often used to describe the different types of collisions. So-called *soft* collisions are said to occur when the fast particle passes an atom at a relatively large distance, and the Coulomb force field affects the atom as a whole, distorting it, with possibly an excitation or ionisation of a valence-shell (i.e. outer) electron. Only a small amount of energy can be transferred of the order of eV. These soft collisions are by far the most numerous type of collision. Cerenkov radiation can result from soft collisions (see Attix 1986); it is entirely negligible as a fraction of the total energy lost in soft collisions. The density or polarization effect is also concerned with soft or distant collisions (see Section 3.2.3).

When the fast particle passes relatively close to the atom (i.e. of the order of the atomic dimensions), then one can properly speak of an interaction with a single bound electron (Figure 3.2). Such hard collisions result in electrons being ejected with appreciable kinetic energy, and these are known as *knock-on* electrons or  $\delta$ -rays. Hard collisions are naturally much rarer than soft ones, but the contributions of hard and soft collisions to the total energy loss are comparable in magnitude.

If an inner-shell electron is ejected as a result of a hard collision, then the atom will return to its ground state either by the emission of characteristic x-rays or by Auger electrons in the same manner as for the photoelectric effect (see Section 4.3.1).

### 3.2.2 COLLISION STOPPING POWER

The occurrence of very frequent, small energy losses along the path of any charged particle in matter (in marked contrast to the way that photons transfer energy, see Chapter 4) leads

naturally to the concept of *stopping power*, defined as the average energy loss,  $dE$ , per unit distance,  $ds$ , along the track of the particle. This is usually expressed as the *mass* collision stopping power, written  $(1/\rho)(dE/ds)_{\text{col}}$  or  $S_{\text{col}}/\rho$ , which is calculated from

$$\frac{1}{\rho} \left( \frac{dE}{ds} \right)_{\text{col}} = N_A \left\langle \frac{Z}{A} \right\rangle \int_{Q_{\min}}^{Q_{\max}} Q \frac{d\sigma}{dQ} dQ \quad (3.4)$$

where  $N_A$  is Avogadro's number, and  $Z$  and  $A$  have their usual meaning (see Chapter 1).  $Q_{\max}$  for an electron with kinetic energy  $E_0$  is equal to  $E_0/2^*$ . Note that strictly  $(dE/ds)$  is a negative quantity as it expresses energy *loss* not energy *gain* as the distance  $s$  increases. However, this negative sign has generally been omitted in what follows.

The evaluation of the minimum energy transfer  $Q_{\min}$  represents a major difficulty. The integral for stopping power (Equation 3.4) can alternatively be cast in terms of the impact parameter  $b$  and then integrating out to  $b = \infty$  yields an infinite stopping power because of the large number of soft collisions at large distances. The first approximate solution to this far from trivial problem is due to Niels Bohr (1913, 1948). Bohr's first attempt at this was in 1913 before he had conceived of quantized energy levels for the atomic electrons. Bohr treated the problem in terms of the *time of collision*,  $\tau$ , and the natural frequency of the atomic electron,  $\nu$ , such that the electron, if displaced, oscillated about its natural equilibrium position with a period of  $1/\nu$ . If the collisions are such that  $\tau \approx b/\nu$  i.e. impact parameter/velocity) is short (i.e.  $\tau \ll 1/\nu$ ), then the electron would behave as though it were free and accept the impulse (corresponding to close collisions). If, on the other hand, the collision time was relatively long, such that  $\tau \gg 1/\nu$ , then the electron acts as though bound; its orbit is distorted or deformed by the passage of the charged particle, but no net energy transfer takes place. This is sometimes referred to as adiabatic behaviour. Bohr showed that the maximum impact parameter  $b_{\max} = 1.123\nu/2\pi\nu$  and, consequently, a finite energy loss per unit pathlength was obtained that included the geometric mean value  $\bar{\nu}$  of the  $Z$  individual atomic frequencies that are characteristic of different atoms

$$\left( \frac{dE}{ds} \right)_{\text{classical}}^{\text{Bohr}} = \frac{4\pi z^2 e^4}{m_e v^2} NZ \ln \frac{1.123 m_e v^3 M}{2\pi \bar{\nu} z e^2 (M + m_e)} \text{ ergs/cm}$$

where  $M$  is the mass of the fast charged particle and  $N$  is the number of atoms per unit volume.

The full quantum-mechanical expression for the electron mass collision stopping power (Berger and Seltzer 1964; ICRU 1984a, 1984b) is given by

$$\frac{1}{\rho} \left( \frac{dE}{ds} \right)_{\text{col}} = \frac{2\pi r_e^2 m_e c^2 N_A}{\beta^2} \left\langle \frac{Z}{A} \right\rangle \left\{ \ln \left[ \frac{\tau^2(\tau + 2)}{2(I/m_e c^2)^2} \right] + F(\tau) - \delta \right\} \quad (3.5)$$

where

$$F(\tau) = 1 - \beta^2 + [\tau^2/8 - (2\tau + 1)\ln 2]/(\tau + 1)^2 \quad (3.6)$$

and the extra quantities not defined so far are

$m_e c^2$ , rest mass energy of the electron

$\beta = \nu/c$

---

\* Two electrons are indistinguishable after the collision; therefore, it cannot be determined which was the incident electron. Arbitrarily, the faster electron after the collision is taken to be the incident one; this results in  $Q_{\max} = T/2$ . For heavy particles, it can be shown from kinematics that  $Q_{\max} = T\{1 + (2Mc^2/T)\}/\{1 + (M+m_0)^2c^2/2m_0T\}$  (e.g. Evans 1955).

$r_e$ , electron radius ( $=e^2/m_ec^2=2.818\times10^{-15}$  m)

$I$ , mean excitation energy

$\delta$ , density-effect correction (see [Section 3.2.3](#))

The above expression can be somewhat simplified if it is expressed in the virtually universally employed units of MeV cm<sup>2</sup> g<sup>-1</sup> (ICRU 1984a):

$$\frac{1}{\rho} \left( \frac{dE}{ds} \right)_{\text{col}} = 0.1535 \frac{1}{\beta^2} \left\langle \frac{Z}{A} \right\rangle \left\{ \ln \left[ \frac{\tau^2(\tau+2)}{2(I/m_ec^2)^2} \right] + F(\tau) - \delta \right\} \text{ MeV cm}^2 \text{ g}^{-1} \quad (3.7)$$

The mean excitation energy or potential,  $I$ , is an average of the transition energies  $E_i$  weighted by their oscillator strengths  $f_i$  according to the following:

$$Z \ln I = \sum_i f_i \ln E_i \quad (3.8)$$

It is effectively the geometric mean of all the ionisation and excitation potentials of the atoms in the absorbing medium; it is, of course, the more exact counterpart of Bohr's mean characteristic frequency that was discussed above. In general,  $I$  cannot be derived theoretically except in the simplest cases such as monoatomic gases. Instead, it must be derived from measurements of stopping power or range. The most recent values of  $I$ , based largely on experimental data, are given in ICRU (1984b). For example the best current estimate of the  $I$ -value for water is 75.0 eV. Generally, the  $I$ -value increases as  $Z$  increases (see [Table 3.1](#)).

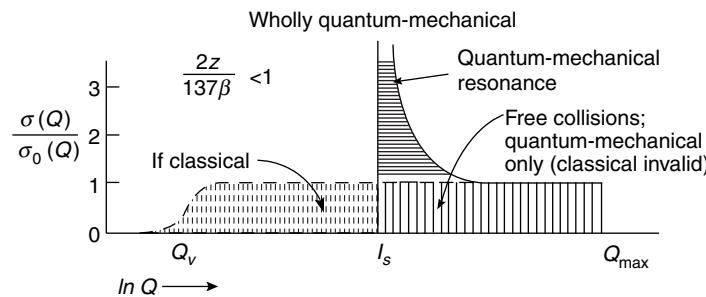

The correspondence between classical and quantum-mechanical treatments of the energy loss spectrum is illustrated in [Figure 3.3](#), taken from Evans (1955). The quantity  $\sigma(Q)/\sigma_0(Q)$  on the ordinate is the ratio of the effective cross-section to the classical one.  $I$  is the effective minimum excitation potential of the  $s$ th electron.  $Q$  is the adiabatic limit of minimum classical energy transfer to the  $s$ th electron when the impact parameter has its maximum effective value. In the quantum-mechanical treatment, the energy losses in soft collisions correspond to a type of resonance phenomenon. The fast incident particle has a finite probability of transferring energy to that particular atom. However, either the energy transferred is zero or it is equal to the

With permission.

**FIGURE 3.3**

The ratio of the effective cross-section  $\sigma(Q)$  to the classical one  $\sigma_0(Q)$  for high particle velocities. The classical theory predicts too large an energy loss as the adiabatic limit,  $Q_v$ , becomes much smaller than the allowed minimum energy loss,  $I_s$ , as  $\beta$  increases. (From Evans, R. D., *The Atomic Nucleus*, McGraw Hill, New York, 1955. With permission.)

excitation or ionisation energy of the atom. Therefore, quantum mechanics replaces the classical multitude of small losses to each of the atoms by larger losses to only a few of the atoms.

The essential features of the mass collision stopping power are retained in the following simplified expression:

$$\frac{S_{\text{col}}}{\rho} \propto \left\langle \frac{Z}{A} \right\rangle \frac{1}{v^2} [f(\tau) - 2 \ln I - \delta] \quad (3.9)$$

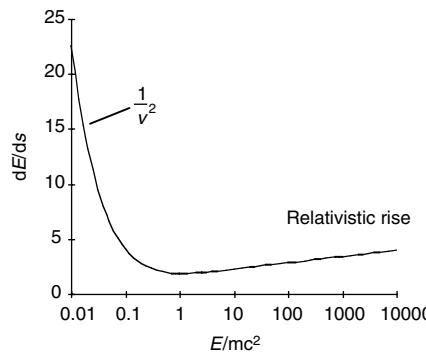

Comparing this expression with Equation 3.5 or Equation 3.7, the increase at decreasing sub-relativistic energies due to the  $(1/v^2)$  factor can be identified. This is simply explained by the fact that *slow* electrons spend more time going past an atom than do *fast* ones, and consequently the impulse (see above) is greater and thus more energy is lost. At relativistic energies, there is a more gradual increase in the stopping power which is known as the *relativistic rise*. Figure 3.4 illustrates these two main features.

The explanation for the relativistic rise in stopping power is as follows. The electric field of the moving primary particle undergoes a *Lorentz contraction* at relativistic energies. In the forward and backward directions the field is *weakened* by the factor  $\gamma$  whereas in the transverse directions it is *strengthened* by the factor  $\gamma$  (see footnote); the field-line pattern is changed from spherical to *pancake-shaped*. This *contraction* means that the field of the moving particle acts on the bound atomic electrons for a shorter time (i.e. the collision time,  $\tau$ , is reduced). Following Bohr's reasoning, this leads to an increase in  $b_{\max}$ \*. The net result of a decrease in  $\tau$ , a lateral broadening of the field, and an increase in the maximum impact parameter is an increase in the stopping power, approximately logarithmic with energy, as  $v$  approaches  $c$ , as illustrated in Figure 3.4.

### 3.2.3 DENSITY EFFECT

The density or polarization effect (Fermi 1940; Sternheimer 1961; ICRU 1984a) reduces the value of  $S_{\text{col}}$  at relativistic energies in condensed media via the term  $\delta$  in Equation 3.5 and Equation 3.9. It is connected to the relativistic rise in the stopping power. The increase in the maximum value of the impact parameter,  $b_{\max}$ , discussed in the previous section, implies an increase in the volume of the cylinder around the path of the fast charged particle where energy transfers are possible. However, if the stopping medium has a high density, (i.e. condensed media as opposed to gases) then the electric field seen by the atoms distant from the fast particle track is reduced due to the polarization of the intervening atoms (as illustrated in Figure 3.5). Consequently, the contribution of these distant collisions to the stopping power will be reduced.

\*  $b_{\max}$  increases by the factor  $\gamma = 1/\sqrt{1 - v^2/c^2}$ .

**FIGURE 3.4**

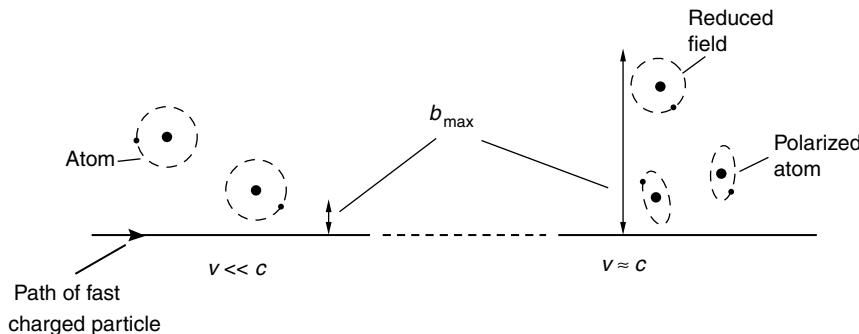

Collision energy loss as a function of (log) electron kinetic energy (in units of electron rest mass). (From Nahum, A. E., *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Medical Physics Publishing, Madison, WI, 1985.)

This reduction in collision stopping power is known as the *polarization* or *density effect*. Fermi (1940) gave the first theoretical treatment. Sternheimer (1961) subsequently worked out the theory in more detail and gave numerical recipes to calculate the correction factor  $\delta$  for a number of different materials.

The density effect is of particular importance in the dosimetry of megavoltage electron and photon beams as will become apparent when the water-to-air stopping-power ratio is discussed in [Section D.1](#) of [Appendix D](#). [Figure 3.6](#) shows the variation of  $S_{\text{col}}/\rho$  with energy for air and water, two substances with similar atomic compositions and similar  $I$ -values; note that the energy scale is linear, not logarithmic as in [Figure 3.4](#). The relativistic rise in the collision stopping power in the condensed medium is much less pronounced compared to that in the gas because of the density effect. Consequently, the ratio of mass stopping powers, water to air, is strongly energy dependent above around 0.5 MeV. It will be seen in [Section 6.7](#) and [Section 18.2.4](#) that it is precisely this ratio that determines the energy variation of the response (in terms of dose to water) of an ionisation chamber placed in water, and the energy region above 0.5 MeV is precisely the one that is relevant for the megavoltage photon and electron beams used in radiotherapy.

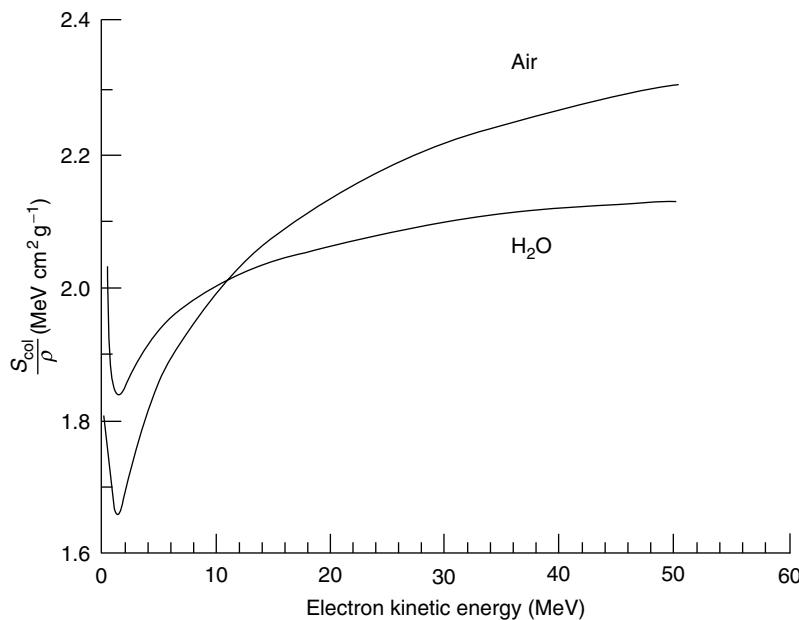

### 3.2.4 ELECTRON STOPPING-POWER DATA FOR SUBSTANCES OF MEDICAL INTEREST

The material-dependent terms in [Equation 3.5](#) are  $\langle Z/A \rangle$ , the mean excitation energy  $I$ , and the density-effect correction  $\delta$ . [Table 3.1](#) lists the relevant parameters for various human tissues

**FIGURE 3.5**

Schematic explanation of the mechanism of the density (or polarization) effect. (From Nahum, A. E., *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Medical Physics Publishing, Madison, WI, 1985.)

**FIGURE 3.6**

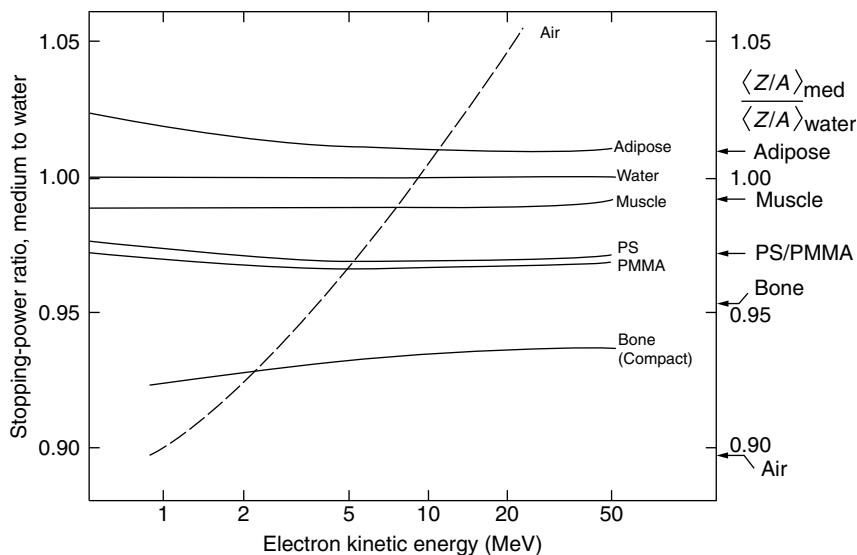

The variation of mass collision stopping power with electron kinetic energy for air and for water; note the linear energy scale. (From Nahum, A. E., Annual Meeting of the Canadian Association of Physicists, Quebec, 1983.)

and some other substances of dosimetric interest taken from ICRU (1984a) as well as for water as a comparison. It can be seen that the  $I$ -values all fall between 73 eV and 75 eV with the exception of adipose tissue (high hydrogen content) and bone with its high calcium content. In fact, the  $I$ -value is approximately proportional to the mean atomic number (e.g. the values for aluminium and lead are 166 eV and 823 eV, respectively). Given the similarity of the values of  $I$ ,  $\langle Z/A \rangle$ , and the (mass) density (the latter being involved in the density-effect correction  $\delta$ ) in the table, the values of  $(S_{\text{col}}/\rho)$  must also be very similar. This is very convenient, as it means that the electron energy loss over a given distance in the body can be derived from that in water by simply multiplying by the density, assuming that radiation losses are also very similar, which will generally be the case below around 20 MeV (see [Section 3.3.2](#)).

The values of the (mass) stopping-power ratio,  $s_{\text{med},\text{air}}$ , for various substances of interest in medical dosimetry, as a function of electron kinetic energy in the megavoltage region are shown in [Figure 3.7](#). The quantity  $\langle Z/A \rangle_{\text{med}}/\langle Z/A \rangle_{\text{water}}$  has been added along the right hand axis in order to show that for all these substances except bone, where the atomic number is appreciably higher, and air, where the density effect plays the dominant role (see [Section 3.2.3](#)),  $(S_{\text{col}}/\rho)_{\text{med}} \propto \langle Z/A \rangle_{\text{med}}$  (Equation 3.9). In fact, the curve labelled *Air* also follows this pattern at energies below about 1 MeV where the density effect is negligible. It can also be noted that the ratio is virtually independent of energy except for that of air; this is very convenient for dosimeter response evaluation and treatment planning purposes. These medium-to-water stopping-power ratios are likely to find direct application in the conversion of Monte-Carlo-derived dose distributions in patients (see [Chapter 28](#)) to *water-equivalent* doses (Siebers et al. 2000).

### 3.2.5 RESTRICTED STOPPING POWER

Use is frequently made of the *restricted stopping power*. This means that only energy transfers below a certain value  $\Delta$  are included; it is calculated by setting  $Q_{\max}$  equal to  $\Delta$  in Equation 3.4. The full expression is again given by Equation 3.5 and Equation 3.6, but with the  $F(\tau)$  term now modified to:

**FIGURE 3.7**

Ratios of mass collision stopping powers, medium to water, for various substances of medical and dosimetric interest. PS stands for polystyrene and PMMA for polymethyl methacrylate (perspex). The quantity  $\langle Z/A \rangle_{\text{med}} / \langle Z/A \rangle_{\text{water}}$  for the various media is given on the right-hand axis. (From Nahum, A. E., *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Medical Physics Publishing, Madison, WI, 1985.)

$$F(\tau, \Delta) = -1 - \beta^2 + \ln\{4\Delta(\tau - \Delta)\tau^{-2}\} + \tau/(\tau - \Delta) + \{\Delta^2/2 + (2\tau + 1) \ln(1 - \Delta/\tau)\}(\tau + 1)^{-2} \quad (3.10)$$

It should be noted that the expression for the restricted stopping power still includes the density-effect correction factor  $\delta$  (i.e. it is implicitly assumed that all the losses that do not appear because of the density effect are below  $\Delta$  in energy). This is reasonable as it is precisely the so-called distant (i.e. soft) collisions that are affected by the density effect.

The restricted stopping power is often written  $L_\Delta$ ; it is required in the evaluation of the Spencer–Attix form of the (mass) stopping-power ratio (see [Section 6.7.4](#)). The ratio  $L_\Delta/S_{\text{col}}$  as a function of  $\Delta$  is plotted in [Figure 3.8](#) for 1 MeV and 10 MeV electrons in water; very similar plots would have been obtained for other low- $Z$  substances. The slow decrease from unity with decreasing  $\Delta$  demonstrates that small energy transfers dominate in the overall energy transfer process as has been previously emphasised.

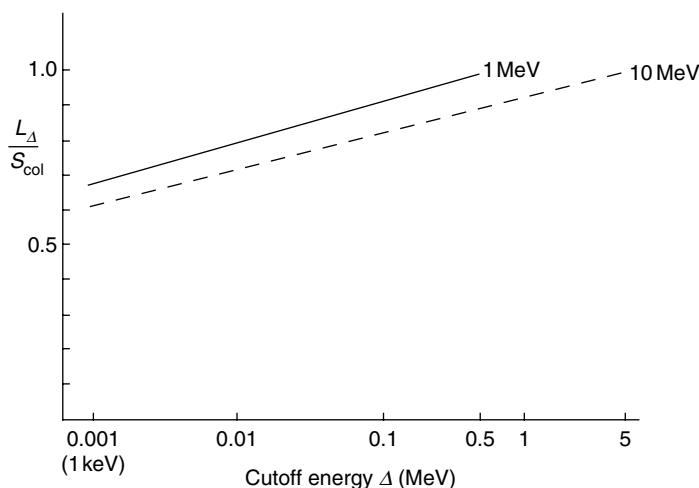

### 3.2.6 COLLISION STOPPING POWER FOR HEAVY CHARGED PARTICLES

The stopping-power formula for a singly charged particle heavier than an electron is (Attix 1986; ICRU 1984a)

$$\frac{1}{\rho} \left( \frac{dE}{ds} \right)_{\text{col}} = \frac{2\pi N_A r_c^2 m_e c^2 z^2}{\beta^2} \left\langle \frac{Z}{A} \right\rangle \left\{ \left\{ \ln \left( \frac{2m_e c^2 \beta^2 T'_{\max}}{I^2(1-\beta^2)} \right) \right\} - 2\beta^2 - 2 \frac{C}{Z} - \delta \right\} \quad (3.11)$$

where  $T'_{\max}$  is the maximum energy that can be transferred in a head-on collision with an (unbound) atomic electron (see footnote). For kinetic energy  $T < M_0 c^2$ ,  $T'_{\max} \approx 2m_0 c^2 (\beta^2 / 1 - \beta^2)^*$ . Following Attix (1986), the above expression can then be

\* For a 10 MeV proton,  $T'_{\max} = 20 \text{ keV}$ ; this can be contrasted with a maximum delta ray energy of 5 MeV for a 10 MeV electron.

**FIGURE 3.8**

The ratio of restricted collision stopping power,  $L_{\Delta}$ , to unrestricted collision stopping power,  $S_{\text{col}}$ , for 1 MeV and 10 MeV electrons in water. (From Nahum, A. E., *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Medical Physics Publishing, Madison, WI, 1985.)

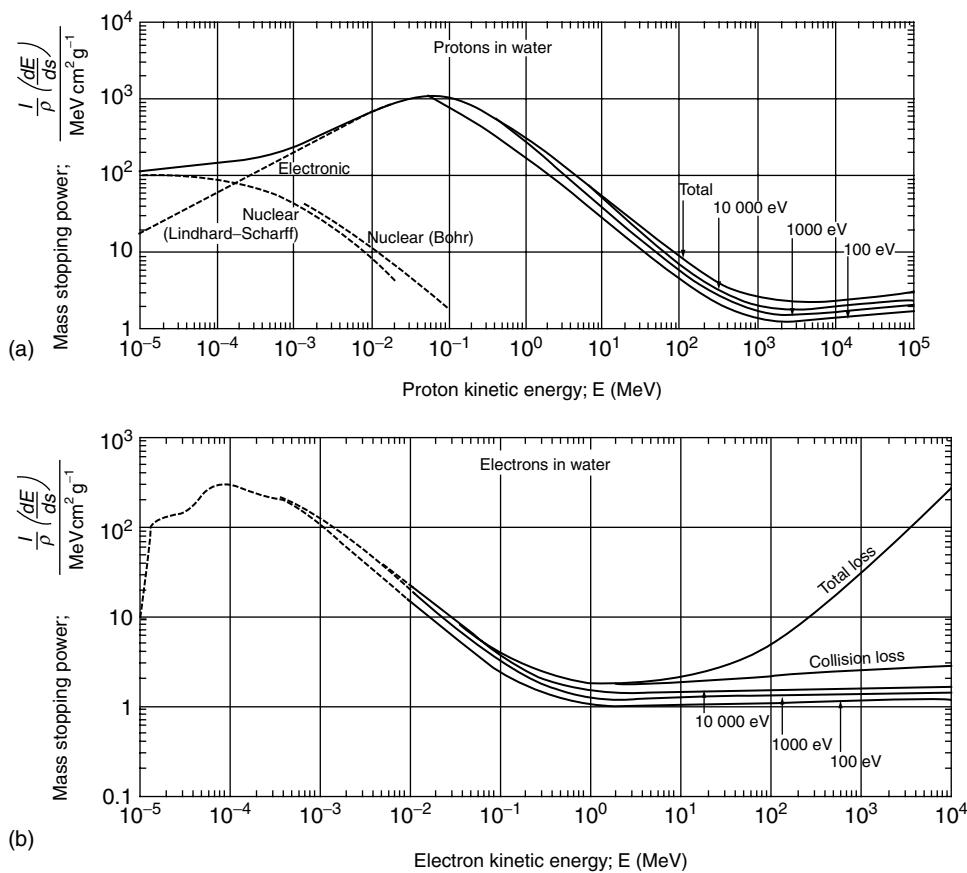

simplified to

$$\frac{1}{\rho} \left( \frac{dE}{ds} \right)_{\text{col}} = 0.1535 \frac{z^2}{\beta^2} \left\langle \frac{Z}{A} \right\rangle \left\{ 27.675 + 2 \ln \left( \frac{\beta^2}{1-\beta^2} \right) - 2\beta^2 - 2 \ln I - 2 \frac{C}{Z} - \delta \right\} \quad (3.12)$$

Compared to the corresponding formula for electron collision stopping power (Equation 3.6 and Equation 3.7), the above expression contains the so-called shell correction term  $C/Z$ . This is necessary as the Born approximation assumption (i.e.  $2Zz/137 \ll \beta$ ) is no longer satisfied when particle velocities approach those of the bound electrons in the stopping medium. K-shell electrons will be affected first as they have the highest (orbital) velocities, then the L-shell and so on. The shell correction approximately accounts for the resulting error in the stopping-power formula. As particle velocities approach those of the various shells,  $(dE/ds)$  decreases as those electrons can no longer take part in the energy transfer process. This term may be as large as 10% at low energies, but it is negligible for electrons  $> 0.1$  MeV in energy. The term  $C/Z$  is the same for all charged particles of the same velocity. Note that concerning the use of heavy particles in radiotherapy (see Chapter 46 and Chapter 49), the density-effect term  $\delta$  is almost always negligible as the beam energies necessary for adequate penetration generally fall far short of the relativistic region.

Figure 3.9 compares the collision stopping power in water for protons with that for electrons. It can be seen that the basic shapes are the same, but the proton curve is shifted in energy such that the particle velocities are roughly comparable. Therefore, the minimum for the proton case occurs at around 2000 MeV which is a factor 2000 greater than that for electrons and is basically the ratio of the rest masses.

Heavy charged particles with relatively high energies (100 MeV or greater) can also lose energy through interacting with the nucleus (see Chapter 46 and Chapter 49). This can give rise to neutrons and  $\gamma$ -rays. The magnitude is generally small. As an example, around 2.5% of the energy in a 100 MeV proton beam in a carbon absorber is lost because of nuclear interactions and therefore does not appear as excitations or ionisations (Attix 1986). The effect of nuclear interactions is conventionally not included in the stopping power (or the range) of heavy charged particles. However, in accurate computations of the dose deposited by proton beams, for example using Monte-Carlo simulation, nuclear interactions

**FIGURE 3.9**

Mass stopping power in water for protons (a) and electrons (b). Note the similarities in the shapes of the collision stopping power curves, with the minima close to the respected particles' rest mass energies. The curves labelled with energy numbers refer to mass restricted stopping power for different value of  $\Delta$ —see [Section 3.2.5](#). The curve for the total stopping power (see [Section 3.4.1](#)) is also shown. (From ICRU, *Linear Energy Transfer, Report 16*, ICRU, Bethesda, MD, 1970.)

must be taken account of by decreasing the number of particles in the beam as the depth increases; this corresponds to a decrease in the *planar* fluence of the beam with depth (see [Section 6.3.5](#)).

### 3.3 RADIATIVE LOSSES (BREMSSTRAHLUNG)

#### 3.3.1 THEORY

The acceleration of the (very light) electrons in the strong electric field of a nucleus leads to the production of *bremstrahlung*. The acceleration is proportional to the nuclear charge,  $Z$ , divided by the mass,  $m$ , of the moving particle (i.e.  $\propto Z/m$ ). The intensity of radiation produced is then proportional to  $(Z/m)^2$ . One sees immediately that this is a relatively unimportant energy loss mechanism below about 10 MeV in low- $Z$  materials, and it is completely negligible for heavy charged particles. The cross-section,  $\sigma_{\text{rad}}$ , for this totally *non-classical* process is extremely complicated. One significant feature is that,

very approximately:

$$\frac{d\sigma_{\text{rad}}}{dh\nu} \propto \frac{1}{h\nu} \quad (3.13)$$

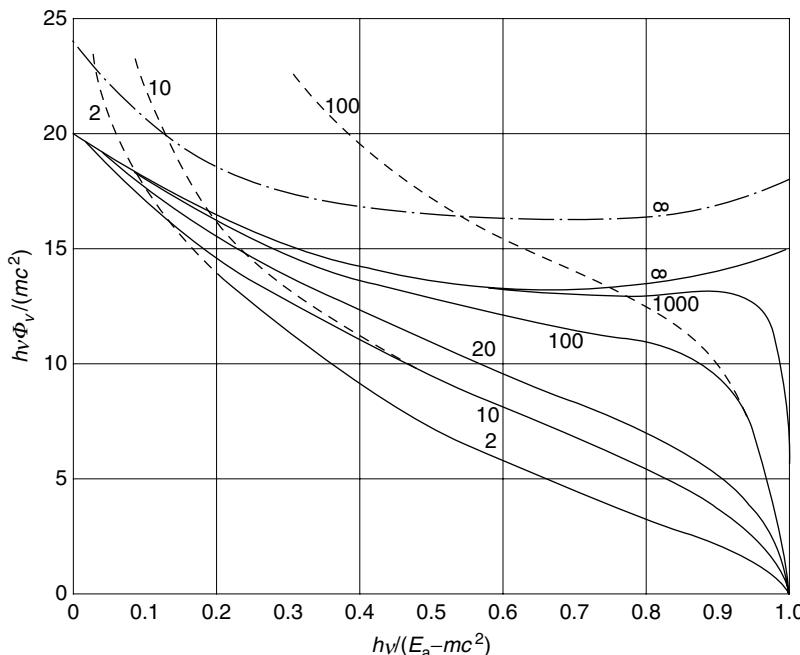

Therefore, on average, the losses will be appreciably larger than for collisions (cf. Equation 3.2). This means that one can expect considerable energy-loss straggling due to radiation losses (see [Section 3.4.2](#)). Figure 3.10 is a plot of the variation of the product of the differential cross-section (as in the expression above) and the photon energy (i.e. the intensity) with photon energy (expressed as a fraction of the electron kinetic energy) for the case of lead. These curves correspond to the x-ray spectrum that would be produced by monoenergetic electrons beam hitting a thin target, integrated over all directions of the emitted photons.

### 3.3.2 RADIATION STOPPING POWER

In an exactly analogous fashion to that for collision losses in the previous section, one can define a radiative stopping power,  $(dE/ds)_{\text{rad}}$  or  $S_{\text{rad}}$ , and also a mass radiation stopping power ( $S_{\text{rad}}/\rho$ ). The general form of the mass radiative stopping power for high energies (complete screening:  $\tau \gg 1/\alpha Z^{1/3}$ ) is given by:

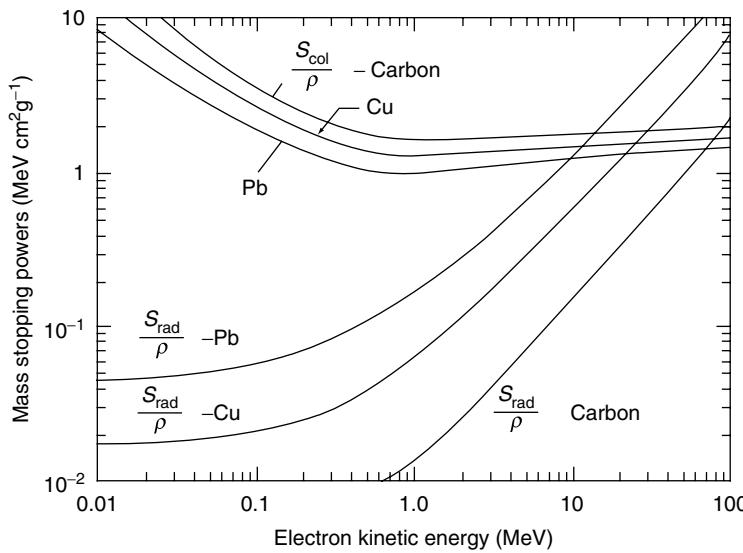

$$(S/\rho)_{\text{rad}} = \frac{4r_e^2 \alpha}{\beta^2} N_A \frac{Z(Z+1)}{M_A} (\tau + 1) m_e c^2 \ln(183Z^{-1/3} + 1/18) \quad (3.14)$$

where  $\alpha$  is the fine structure constant ( $\alpha \approx 1/137$ ). From an inspection of Equation 3.14, it can be seen that the radiative stopping power increases almost linearly with kinetic energy

**FIGURE 3.10**

Energy distribution of the radiation emitted by monoenergetic electrons hitting a thin target. Ordinate—intensity of radiation per unit frequency interval; abscissa—energy of emitted quantum as a fraction of the kinetic energy of the emitting electron. The numbers on the curves indicate the energy of the electron in units of  $mc^2$ . Solid curves are for lead, including the effect of screening. Dotted curves are without screening, valid for all  $Z$ . (From Evans, R. D., *The Atomic Nucleus*, McGraw Hill, New York, 1955.)

**FIGURE 3.11**

A comparison of the mass radiative and mass collision stopping powers,  $S_{\text{rad}}/\rho$  and  $S_{\text{col}}/\rho$  respectively, for carbon, copper, and lead as a function of the electron kinetic energy. (From Attix, F. H., *Introduction to Radiological Physics and Radiation Dosimetry*, Wiley, New York, 1986.)

in the MeV region, in contrast to the weak logarithmic energy dependence of the collision stopping power (see [Section 3.2](#)). Approximately, one can write:

$$\frac{S_{\text{rad}}}{\rho} \propto \frac{Z^2}{A} EB \quad (3.15)$$

where  $B$  is a very slowly varying function of  $E$  and  $Z$ . The factor  $Z^2/A$  causes an increase in  $S_{\text{rad}}/\rho$  for higher  $Z$  (cf.  $S_{\text{col}}/\rho$  that decreases slowly with increasing  $Z$ ). The combined effect of these influences is also evident in Figure 3.11.

From a comparison of Equation 3.9 and Equation 3.14, and also by examining the plots of  $S_{\text{col}}/\rho$  in [Figures 3.4](#) and [3.9](#) which show that  $S_{\text{col}}/\rho$  is approximately constant at the energies where  $S_{\text{rad}}/\rho$  is non-negligible, it is apparent that  $S_{\text{rad}}/S_{\text{col}} \propto ZE$ . A useful quantitative approximation is:

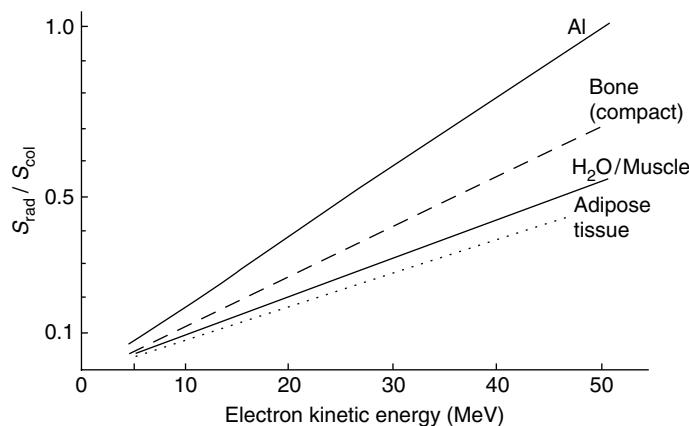

$$\frac{(S_{\text{rad}}/\rho)}{(S_{\text{col}}/\rho)} = \frac{ZE}{1600m_e c^2} \quad (3.16)$$

[Figure 3.12](#) illustrates the variation of  $S_{\text{rad}}/S_{\text{col}}$  with electron kinetic energy  $E$  for various media of interest in medical dosimetry as well as for aluminium. As the mean atomic number increases, from adipose tissue to bone,  $S_{\text{rad}}/S_{\text{col}}$  increases. It is less than 0.1 below 5 MeV, even for aluminium.

The bremsstrahlung process should be clearly distinguished from the much more frequent *elastic* scattering of charged particles in the Coulomb field of the nucleus that is responsible for almost all the changes in direction of electrons and is dealt with in [Section 3.5](#).

### 3.3.3 RADIATION YIELD

A useful quantity is the fraction of the initial electron energy,  $E_0$ , that is lost to bremsstrahlung in slowing down to rest. This fraction is known as the *Radiation Yield*,  $\Upsilon(E_0)$ , and is given by:

**FIGURE 3.12**

The energy and material dependence of the ratio of the radiative to the collision stopping power for electrons above 5 MeV. (From Nahum, A. E., *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Medical Physics Publishing, Madison, WI, 1985.)

$$\Upsilon(E_0) = \frac{1}{E_0} \int_0^{E_0} \frac{S_{\text{rad}}(E)}{S_{\text{col}}(E) + S_{\text{rad}}(E)} dE \quad (3.17)$$

The dependence of  $\Upsilon(E_0)$  on  $E_0$  and on  $Z$  is approximately linear, which closely corresponds to the relation between  $S_{\text{rad}}/\rho$ ,  $E$ , and  $Z$  discussed above.

The radiation yield is involved in calculating the dosimetric quantity,  $\mathcal{g}$ , which is the fraction of energy transferred (by photons) to a medium in the form of electron kinetic energy that is subsequently re-radiated as bremsstrahlung (see [Section 6.3.2](#)).

### 3.3.4 ANGULAR DISTRIBUTION OF BREMSSTRAHLUNG PHOTONS

The angular distribution of the emitted photons is very strongly forward-peaked at relativistic electron energies with a mean value  $\theta \approx mc^2/E$  where  $E$  is the total energy of the electrons. This forward-peaking is the reason for the flattening filter in a linear accelerator treatment head. It can be noted that, at the much lower electron energies involved in largely diagnostic but also some therapeutic kilovoltage x-ray machines, the angular distribution is much closer to isotropic; hence, the steep angle of x-ray targets (see [Section 10.3.1.3](#)).

[Chapter 9](#) in Attix (1986) should be consulted for more details on all aspects of the bremsstrahlung process.

---

## 3.4 TOTAL ENERGY LOSSES

### 3.4.1 TOTAL STOPPING POWER

The potentially confusing convention in this field is to term the inelastic electron-electron Coulomb interactions *collisions*; whereas bremsstrahlung losses are always termed *radiative losses*. The collision and radiative stopping powers are frequently summed to give the total stopping power, written  $(dE/ds)_{\text{tot}}$  or  $S_{\text{tot}}$ :

$$\left( \frac{dE}{ds} \right)_{\text{tot}} = \left( \frac{dE}{ds} \right)_{\text{col}} + \left( \frac{dE}{ds} \right)_{\text{rad}} \quad (3.18)$$

or

$$S_{\text{tot}} = S_{\text{col}} + S_{\text{rad}}$$

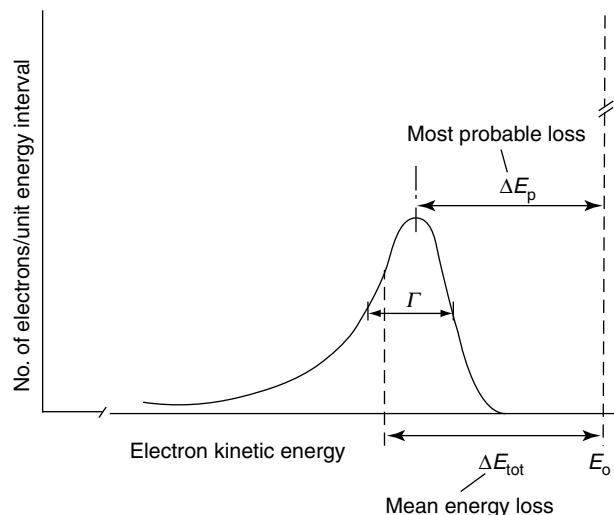

Figure 3.9b shows the total mass stopping power (labelled “Total Loss”), mass collision stopping power, and several restricted mass collision stopping powers ( $\Delta = 10 \text{ keV}$ ,  $1 \text{ keV}$  and  $100 \text{ eV}$ ) for water against electron kinetic energy  $E$  for values between  $10^{-5} \text{ MeV}$  and  $10^4 \text{ MeV}$ . It can be seen that  $(S/\rho)_{\text{tot}}$  varies slowly with  $E$  over the energy range of primary interest in radiotherapy (from  $1.937 \text{ MeV cm}^2 \text{ g}^{-1}$  at  $4 \text{ MeV}$  to only  $2.459 \text{ MeV cm}^2 \text{ g}^{-1}$  at  $25 \text{ MeV}$ ).

Several features should be noted:

- Radiation losses only become important above around  $10 \text{ MeV}$  in water
- The relativistic rise in the collision losses is small because of the density effect
- Collision losses restricted to  $\Delta < 10 \text{ keV}$  only result in a modest reduction in stopping power compared to the unrestricted  $S_{\text{col}}$  which emphasizes the predominance of very small losses
- The approximate value for the electronic stopping power in water in the MeV region is around  $2 \text{ MeV cm}^{-1}$ ; the value in tissue is very similar.

### 3.4.2 ENERGY-LOSS STRAGGLING

It is important to realize that stopping power is an average value for the energy loss per unit distance. Fluctuations will occur about this mean value in any real situation. This gives rise to what is known as *energy-loss straggling*. Figure 3.13 illustrates the idea;  $E_0$  is the electron energy incident on a thin absorber and the distribution of electron energies emerging from the foil are shown where  $\Delta E_{\text{tot}}$  would be predicted by the product of the thickness of the absorber and the (total) stopping power,  $S_{\text{tot}}$ . The width  $\Gamma$  is related to the distribution of the individual energy losses. If all energy loss is much smaller than the electron kinetic energy, then  $\Gamma$  will be narrow. This implies that most of the straggling results from the rare, large-energy losses (see Berger and Wang 1988 for a more in-depth treatment).

**FIGURE 3.13**

Energy broadening because of energy-loss straggling after the passage of a monoenergetic electron beam (energy  $E_0$ ) through a thin absorber. (From Nahum, A. E., *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Medical Physics Publishing, Madison, WI, 1985.)

### 3.4.3 CONTINUOUS-SLOWING-DOWN-APPROXIMATION (CSDA) RANGE

Charged particles lose energy in a quasi-continuous fashion along their tracks in matter, eventually coming to rest. This means that, unlike photons with their exponential attenuation (see Chapter 4), charged particles do have a finite, reasonably well-defined range. Mathematically it has been found convenient to define the so-called continuous-slowing-down-approximation (csda) range,  $r_0$  in the following fashion:

$$r_0 = \int_0^{E_0} \frac{1}{S_{\text{tot}}(E)} dE \quad (3.19)$$

This represents the average pathlength travelled in coming to rest by a charged particle having kinetic energy,  $E_0$ . Note that for electrons, as opposed to heavy charged particles, this will always be considerably greater than the average penetration depth because of the marked angular deflections that electrons suffer in slowing down (see Section 3.5). The csda range  $r_0$  is approximately proportional to  $E_0$  in the therapeutic energy range because of the relatively slow variation of  $S_{\text{tot}}$  in this energy range (see Figure 3.9b). The quantity  $r_0\rho$  is analogous to the mass stopping power,  $(S/\rho)$ , and has the units of mass per unit area (e.g. g cm<sup>-2</sup>). Other definitions of electron range of particular use in radiotherapy with electron beams, such as the practical range,  $R_p$ , and  $R_{50}$ , are discussed elsewhere in the book (see Section D.3.2 and Section 24.1).

### 3.4.4 TABULATED STOPPING-POWER DATA

ICRU (1984a) provides total mass stopping powers, mass collision stopping powers, mass radiative stopping powers, csda ranges, radiation yields, and density-effect corrections for electrons for a very wide range of materials, including many of interest in radiotherapy dosimetry. A selection of stopping-power and range data can be found in Tables M.2, at the end of this book.

## 3.5 ELASTIC NUCLEAR SCATTERING

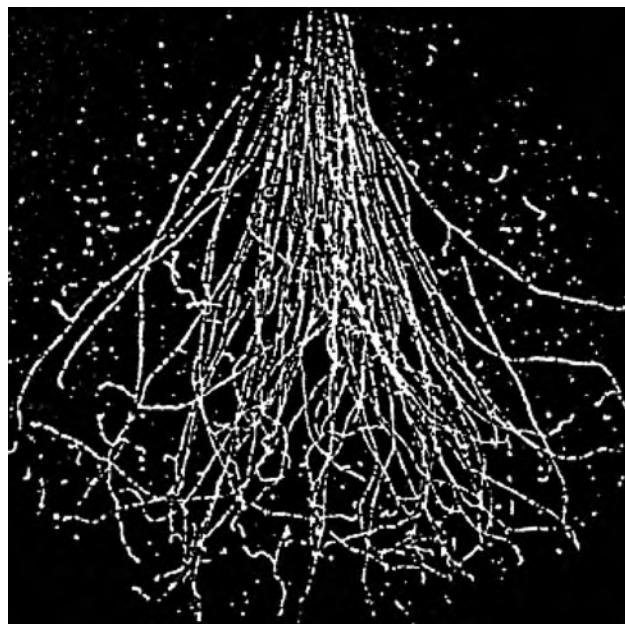

When a charged particle passes close to the atomic nucleus, at a distance much smaller than the atomic radius, the Coulomb interaction will now be between the fast particle and the nuclear charge rather than with one of the bound electrons (see Section 3.2). In the case of electrons, this causes appreciable changes of direction, but almost never (with the exception of the bremsstrahlung process—see Section 3.3) any change in energy. The scattering is basically *elastic*, the energy lost being the negligible amount required to satisfy momentum conservation between the very light electron and the positively charged nucleus (at least two thousand times heavier). Figure 3.14 gives an indication of the importance of this process which accounts for almost all the changes in electron direction.

This interaction process is essentially Rutherford scattering with differential cross-section:

$$\frac{d\sigma}{d\theta} = \frac{\pi e^4 Z^2 (1 - \beta^2)}{2m^2 v^4} \frac{\sin \theta}{\sin^4(\theta/2)} \quad (3.20)$$

A correction for screening is essential to prevent the cross-section from becoming infinite when integrated over all angles. A more accurate cross-section that accounted for electron spin was later derived by Mott (see Berger and Wang 1988).

In order to be able to treat the very large number of (single) scatterings occurring in even thin absorbers, analytical theories for multiple scattering (i.e. the combined effect of many

**FIGURE 3.14**

Bubble chamber picture of a narrow 9.3 MeV electron beam in propane. The increasing multiple scatter toward the end of the electron range is clearly seen. (From Harder, D., Harigel, G., and Schultz, K., *Strahlentherapie*, 115,1, 1961.)

individual single-scattering events) were developed (Rossi 1952; Andreo 1985; Berger and Wang 1988; Fernández-Varea et al. 1993). The simplest multiple scattering theory, though of limited accuracy, is the Gaussian small-angle one (Rossi 1952) that can be expressed as

$$P(\theta)d\theta = \frac{2}{\theta^2} \theta \exp\left(-\frac{\theta^2}{\theta^2}\right) d\theta \quad (3.21)$$

which is the probability of finding an electron with a direction between  $\theta$  and  $\theta + d\theta$  after traversal through an absorber. The mean square scattering angle,  $\overline{\theta^2}$ , is given by the product of the absorber thickness,  $s$ , and the scattering power, defined as  $(d\overline{\theta^2}/ds)$  and usually (and somewhat confusingly cf. kinetic energy) denoted by  $T$ :

$$\overline{\theta^2} = s \left( \frac{d\overline{\theta^2}}{ds} \right) = sT \quad (3.22)$$

The quantity scattering power is analogous to stopping power. The mass scattering power is similarly written  $T/\rho$ . It increases with decreasing electron energy and increasing atomic number. Scattering power is dealt with in detail in Kase and Nelson (1978) and in ICRU (1984a) which gives tables of  $T/\rho$  for materials and energies of relevance in dosimetry. Li and Rogers (1994) should be consulted for an excellent discussion of the validity and application of the concept of electron mass scattering power.

Following Rossi (1952) and Kase and Nelson (1978), through the superposition of small and independent events, the mass scattering power (expressed for instance in  $\text{radians}^2 \text{ cm}^{-1}$ ) is given by

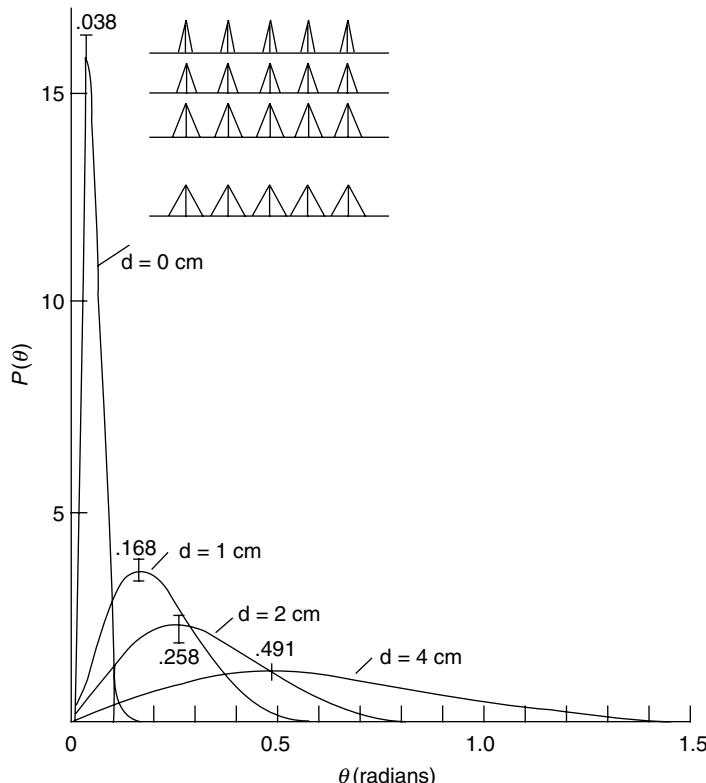

$$\frac{1}{\rho} \frac{d\overline{\theta^2}}{ds} \equiv T = \frac{N_0}{A} \int_{\theta_1}^{\theta_2} \theta^2 \frac{d\sigma}{d\omega} d\omega \quad (3.23)$$

which becomes

$$\frac{T}{\rho} = 16\pi N_0 \frac{Z^2}{A} r_0^2 \left( \frac{mc^2}{p\beta c} \right)^2 \ln[196(Z/A)^{1/6} Z^{-1/3}] \quad (3.24)$$

where the Rutherford single-scattering cross-section has been used (Equation 3.20),  $p$  is the electron momentum, the screening angle  $\theta_1$  is given by  $\alpha Z^{1/3}(m/p)$ , the large-angle limit  $\theta_2$  by  $280 A^{-1/3} (m/p)$ , and the small-angle assumption  $\sin \theta \approx \theta$  has been made. Equation 3.24 illustrates the dependence of  $T/\rho$  on the electron kinetic energy and on  $Z$ .

An idea of the magnitude of electron scattering in low-atomic number materials is given in Figure 3.15, where the Gaussian multiple-scattering distribution (Equation 3.21) has been evaluated in the framework of small-angle Fermi-Eyges transport theory (Chapter 27) for 11.8 MeV electrons in water.

**FIGURE 3.15**

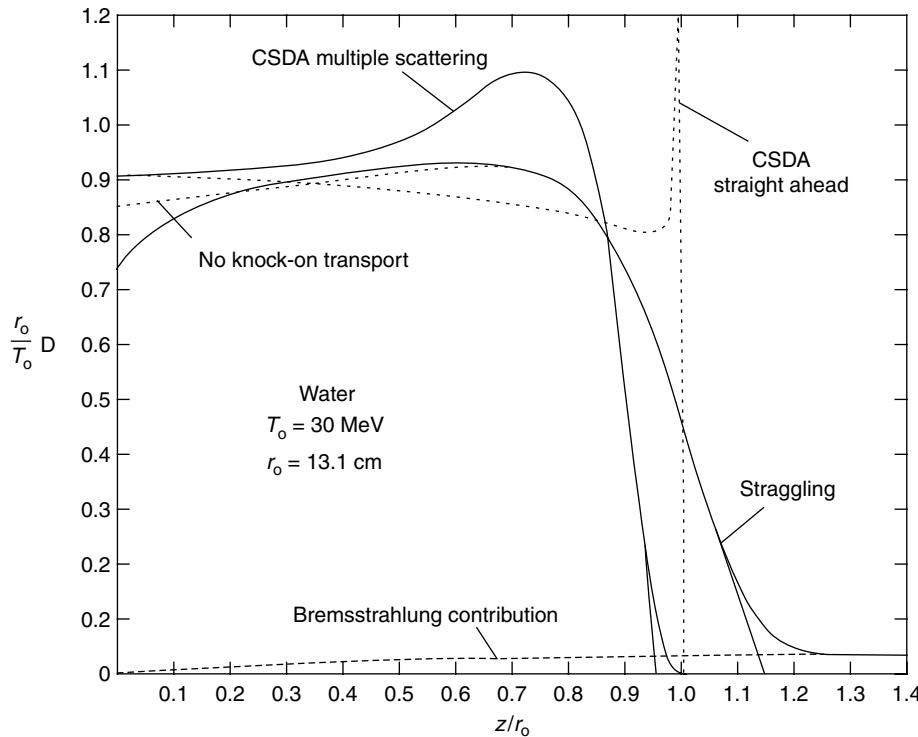

The angular distribution of electrons ( $E_0 = 11.8$  MeV) vs. depth,  $d$ , in water based on Fermi-Eyges transport theory which uses simple Gaussian multiple scattering; note that a small angular spread was assumed at the surface. (From Hogstrom, K. R. and Almond, P. R., *The Effect of Electron Multiple Scattering on Dose Measured in Non-Water Phantoms*, AAPM Annual Meeting, 1982.)

## 3.6 APPLICATION TO AN ELECTRON DEPTH–DOSE CURVE

Figure 3.16 illustrates the physics of electron interactions as they apply to electron beams used in radiotherapy (see also Nahum and Brahme 1985); it shows three different depth–dose curves obtained through Monte-Carlo simulation (see Chapter 5), corresponding to different approximations about electron transport physics for a 30 MeV broad, monoenergetic, and parallel electron beam in water (see also Section 24.2 for a detailed description of electron depth–dose curves).

The curve labelled “CSDA straight ahead” corresponds to straight tracks and shows the Bragg Peak, normally associated with heavy charged particles (see Chapter 46); this extremely simple approximation illustrates very clearly the behaviour of the total stopping power  $S_{\text{tot}}$  as the electron energy gradually decreases with depth (see Section 6.6 for the relation between absorbed dose, electron fluence, and mass stopping power). The gradual decrease in dose with depth mirrors the decrease in total stopping power with falling electron energy. At an energy close to that of the electron rest mass (0.511 MeV), however, the collision stopping power goes through a minimum and then rises rapidly (principally because of the  $1/\beta^2$  term in Equation 3.5).

The “CSDA multiple scattering” curve involves directional changes through multiple scattering (Equation 3.20 through Equation 3.23), but does not involve any secondary particle transport or any simulation of energy-loss straggling (see Section 3.4.2). The increase in dose away from the surface is entirely due to the increasing average obliquity of the electron tracks with depth and the fact that the beam is *broad* (i.e. there is lateral scattering equilibrium); this is

**FIGURE 3.16**

The effect of various approximations on the electron depth-dose curve for a broad, 30 MeV electron beam in water ( $r_0 = 13.1 \text{ cm}$ ), illustrating the physics of electron interactions covered in this chapter. (From Seltzer, S. M., Hubbel, J. H., and Berger, M. J., *National and International Standardization of Radiation Dosimetry*, Vol. 2, IAEA, Vienna, 1978.)

sometimes known as *scatter buildup*). At around  $z/r_0=0.7$ , the planar fluence (see [Section 6.3.5](#)) starts to decrease as electron tracks begin to reach their end. The maximum occurs as a result of a competition between the scatter build-up and the decrease in the planar fluence because of electrons reaching the end of their range.

The “No knock-on transport” curve does not include the generation and transport of knock-on electrons or delta rays, but it does include radiative losses (i.e. bremsstrahlung [see [Section 3.3](#)]) and one sees the so-called *bremsstrahlung tail* beyond the practical range. Also, now the slope of the dose falloff is much reduced; this is primarily due to the incorporation of energy-loss straggling (see [Section 3.4.2](#)). Finally, the unlabelled full curve corresponds to a simulation including the full electron transport physics (of most relevance in this energy region). The effect of simulating  $\delta$ -ray transport is clearly seen in the build-up close to the surface; this is analogous to the much more pronounced one in megavoltage photon beams where the ranges of the mainly Compton electrons are significantly greater than those of the predominantly low-energy  $\delta$ -rays.

In the case of heavy charged particles, the depth-dose curve (for a broad, approximately parallel beam) has a totally different appearance. The well-known Bragg Peak is the most prominent feature; in fact, this is the reason why proton beams are so well-suited to radiotherapy (see [Chapter 46](#)). In marked contrast to electron beams, the angular deflections in this case are much less pronounced due to these particles being at least 2000 times more massive than electrons. Consequently, all heavy-particle tracks are approximately straight except at the very end of their range; therefore, the appearance of depth-dose (and the fluence) curves most resembles that labelled “CSDA straight ahead” in [Figure 3.16](#). Furthermore, there is negligible bremsstrahlung, and consequently much less energy-loss straggling, and also a gradual *increase* in the stopping power and hence the dose with decreasing (sub-relativistic) particle kinetic energy (i.e. increasing depth).

## 4.1 INTRODUCTION

Electromagnetic radiation consists of electromagnetic waves that propagate with their electric and magnetic field vectors perpendicular to each other and to the direction of propagation. An electromagnetic wave is characterized by its wavelength,  $\lambda$ , and moves in a vacuum at the speed of light,  $c$ . Therefore, the number of oscillations per unit time, the frequency  $\nu$ , is given by  $\nu = c/\lambda$ . Electromagnetic radiation is classified as ionising when it is capable of ionising atoms and molecules. In this case, the interactions with matter are most suitably described by considering the electromagnetic wave as a stream of particles, the photons. Each photon carries energy  $h\nu$  where  $h$  is Planck's constant.

Photon interactions are stochastic (i.e. random) by nature. Unlike electrons, they may undergo a few, one, or no interactions as they pass through matter. In this chapter, the basic interaction processes and the probability of each interaction occurring when a beam of photons enters a medium are described. In each interaction, secondary ionising particles are created. These may be charged particles (usually electrons) or uncharged particles (usually photons). The charged particles deposit their energies close to the interaction site and contribute to the local energy deposition, whereas, secondary photons may be transported some distance before interacting. The transfer of energy to charged particles has particular significance in dosimetry, and interaction coefficients quantifying this energy transfer will also be introduced.

Secondary photons are important because they contribute to the photon fluence inside and around an irradiated body and to dose when they interact and produce secondary electrons. The relative importance of secondary photons depends on the energies of the primary photons. In external beam therapy using megavoltage beams, the dominant contribution to the absorbed doses within the patient is due to primary photons. This is also the case with low energy photons (<40 keV) such as those emitted from radioactive nuclides, e.g.  $^{125}\text{I}$ , used in brachytherapy where photoelectric absorption is the dominant interaction process. In the intermediate range of photon energies, 50 keV to 200 keV, a considerable fraction of the absorbed dose may, depending on the depth in the body, be due to scattered photons. This is particularly so at photon energies in the interval 60 keV to 100 keV where multiple scattering becomes important within tissue depths relevant to radiotherapy.

This chapter gives an outline treatment of photon interactions. For more detailed information, the reader is referred to Evans (1955), Attix (1986) Hubbell (1999), and other references cited\*.

## 4.2 PHOTON INTERACTION CROSS-SECTIONS

### 4.2.1 INTERACTION CROSS-SECTIONS

Photons interact with various target entities such as atomic electrons, nuclei, atoms or molecules. The probability of interaction with a target entity is usually expressed in terms of the cross-section  $\sigma$ . This may be interpreted as the cross-sectional area that the target presents in the plane normal to the incident photon direction and can be used to estimate the probability of interaction in the following way. Consider a beam with one photon randomly incident on an absorber containing one target entity per unit area measured in a plane normal to the photon direction. Further, assume that the photon will interact provided it passes through the cross-sectional area of the target. The probability,  $p$ , of interaction is then given by the fraction of the unit area that is occupied by the target area. This is numerically equal to  $\sigma$ .

---

\* See also [Section 5.3](#) for some historical references related to the fundamental photon interaction process.

Photon interactions can be characterized as absorption or scattering processes. In a full absorption process, the incoming photon loses all its energy and the energy is transferred to the target entity. Secondary particles are emitted during or subsequently to the interaction. In a full scattering process, an incoming photon interacts with a target entity and its direction of motion, energy and momentum may be changed because of this interaction. The photon, however, is not absorbed, and changes of energy and momentum are governed by the laws of relativistic kinematics. The main absorption processes are photoelectric (pe) absorption, pair (pair), and triplet (trip) production. The main scattering processes are coherent (coh) and incoherent (incoh) scattering. Nuclear photo-effect (phn) is an absorption process that is mostly neglected but needs to be considered in some cases. The total interaction cross-section, independent of which process occurs, is the sum of the cross-sections for the individual processes:

$$\sigma = \sigma_{\text{pe}} + \sigma_{\text{coh}} + \sigma_{\text{incoh}} + \sigma_{\text{pair}} + \sigma_{\text{trip}} + \sigma_{\text{phn}} \quad (4.1)$$

As noted above, the target entity may be an atomic electron, a nucleus, an atom or a molecule. Care must be taken to distinguish between these targets. In the following, the type of target for the interaction is marked, when necessary, by adding an index to  $\sigma$ . Therefore,  $_{e}\sigma$  and  $_{a}\sigma$  designate the cross-section per electron and per atom, respectively. The relation between them is given by  $_{a}\sigma = Z \times _{e}\sigma$  where  $Z$  is the atomic number of the atom.

The unit of cross-section is  $m^2$ . Although it does not belong to the International System of Units, the barn is still frequently used (including in this chapter):

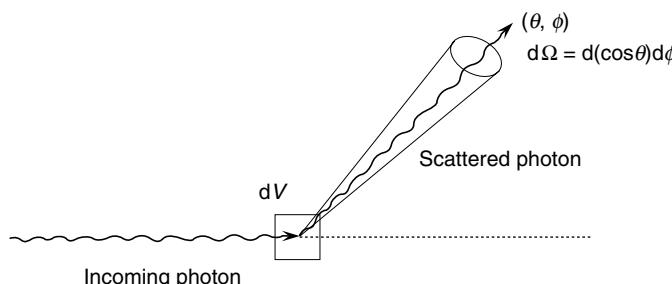

$$1 \text{ barn} = 10^{-24} \text{ cm}^2 = 10^{-28} \text{ m}^2$$

#### 4.2.2 DIFFERENTIAL SCATTERING CROSS-SECTIONS

In a scattering process, the distribution of scattered photons may not be isotropic, but may instead be anisotropic in some fashion related to the direction of the incoming photon and its polarisation. In order to quantify such effects, the cross-section is regarded as a function of the solid angle  $\Omega$  in the direction of the scattered photon and the concept of the differential cross-section  $d\sigma/d\Omega$  is introduced. The differential cross-section is defined in a way analogous to the total cross-section with  $(d\sigma/d\Omega)d\Omega$  related to the probability that the photon scatters into solid angle  $d\Omega$  (Figure 4.1). It follows that:

$$\sigma = \int_{4\pi} \frac{d\sigma(\theta, \phi)}{d\Omega} d\Omega \quad (4.2)$$

where  $\theta$  is the scattering (polar) angle, and  $\phi$  is an azimuthal angle. In many situations, the scattering will, on average, have no azimuthal dependence, and the equation can then be

**FIGURE 4.1**

Scattering angles and solid angle. A photon incident on a small volume element  $dV$  with one target entity per unit area normal to its direction of motion has probability  $(d\sigma/d\Omega)d\Omega$  to scatter into the solid angle element  $d\Omega$  (spherical polar angles  $\theta$  and  $\phi$ .)

written

$$\sigma = \int_0^\pi \frac{d\sigma(\theta)}{d\Omega} 2\pi \sin \theta d\theta \quad (4.3)$$

For isotropic scattering  $d\sigma/d\Omega = \sigma/4\pi$ .

Equation 4.3 may also be written

$$\sigma = \int_0^\pi \frac{d\sigma(\theta)}{d\theta} d\theta \quad (4.4)$$

where

$$\frac{d\sigma(\theta)}{d\theta} = 2\pi \sin \theta \frac{d\sigma(\theta)}{d\Omega} \quad (4.5)$$

The quantity  $d\sigma/d\theta$  is also referred to as a differential cross-section. Indeed, this concept can be further generalised. For example, cross-sections differential in the energy of the scattered photon,  $d\sigma/d(h\nu')$ , can also be of utility.

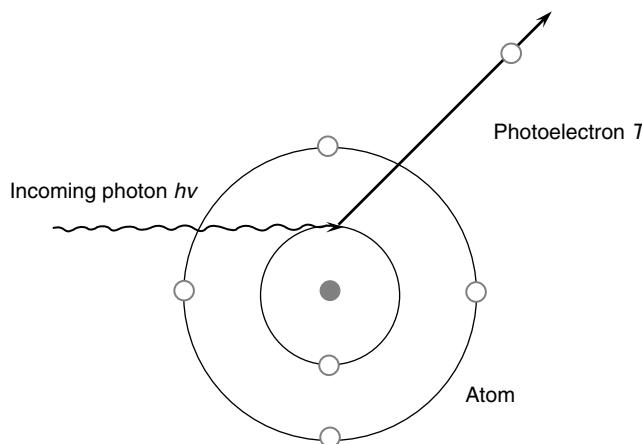

## 4.3 PHOTON INTERACTION PROCESSES

### 4.3.1 PHOTOELECTRIC ABSORPTION

Photoelectric absorption is illustrated in Figure 4.2. In this process, an incoming photon interacts with an atom and is absorbed. An atomic electron is ejected with kinetic energy  $T$  from one of the atomic shells. Its kinetic energy is given by:

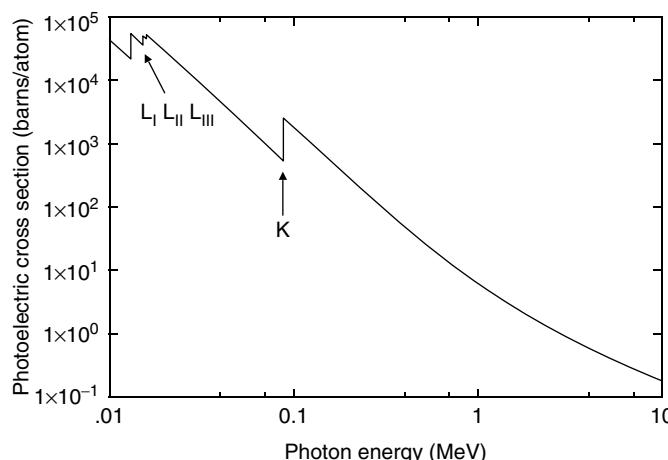

$$T = h\nu - E_B \quad (4.6)$$

Here,  $h\nu$  is the energy of the interacting photon, and  $E_B$  is the binding energy of the atomic electron. The process cannot occur with a free electron. The atom is needed in order to conserve momentum. Because of the heavy mass of the nucleus, the energy transferred to the atom is negligible.

**FIGURE 4.2**

Photoelectric absorption. An incoming photon with energy  $h\nu$  interacts with the atom and ejects a photoelectron with kinetic energy  $T$ .

**FIGURE 4.3**

The total photoelectric absorption cross-section for lead as a function of photon energy. The positions of the  $L_I$ ,  $L_{II}$ ,  $L_{III}$ , and K absorption edges are indicated. (Data taken from Berger, M. J. and Hubbell, J. H., *XCOM: Photon Cross Sections on a Personal Computer*, 87-3597, NBS, Washington, DC, 1987.)

In general, the cross-section  $\sigma_{pe}$  for photoelectric absorption increases strongly with decreasing photon energy. Figure 4.3 shows this cross-section for lead over the photon energy range 10 keV to 10 MeV. The cross-section displays a series of discontinuities at energies corresponding to the binding energies of the electrons in the atomic shells. These discontinuities are known as absorption edges. Below the absorption edge, the photon does not have sufficient energy to liberate an electron from the shell. At energies just above the edge, the photon has sufficient energy to liberate the electron. Therefore, the cross-section abruptly increases because the number of electrons that can take part in the absorption process increases. The larger the binding energy, the larger the increase of the cross-section at the absorption edge. The absorption edge is most pronounced at the K shell in a high atomic number material. The L-shell has three sub-shells and, correspondingly, three absorption edges are seen in Figure 4.3 at the energies 13.04 keV, 15.20 keV, and 15.86 keV of the L sub-shells in lead. At energies above the K absorption edge, about 80% of the interactions take place in the K shell (see also [Section 1.3.2.2](#)).

The cross-section for photoelectric absorption depends strongly on atomic number. Above the K absorption edge, the cross-section per atom as a function of photon energy and atomic number is approximately given by

$$_a\sigma_{ph} \cong kZ^4/(h\nu)^3 \quad (4.7)$$

The cross-section increases as the fourth power of the atomic number and is inversely proportional to the third power of photon energy. This points to the strong impact of this process at low photon energies, particularly, at high atomic numbers. It also explains why bones offer high beam attenuation in soft tissue radiography.

The angular distribution of the photoelectrons is peaked at angles of  $\pi/2$  to the forward direction at low photon energies, but it becomes increasingly forward directed as the photon energy increases.

After photoelectric absorption, a vacancy is left in the atomic shell. This vacancy is subsequently filled with an electron from an outer shell. The energy released is equal to the difference in the binding energies of an electron in the two shells (e.g.  $E_K - E_L$  in a transition from the L to the K shell). The energy released is carried away either by the emission of a

photon or an electron. The photon is known as a characteristic x-ray because of its fixed energy determined by the atomic number of the atom and the shells involved. Characteristic x-rays are isotropically emitted. At energies immediately above an absorption edge, they may carry a substantial fraction of the incident photon energy. They will have a lower photoelectric cross-section than the primary photon as their energy will be below that of the absorption edge. Electrons emitted after electronic rearrangement are known as Auger electrons (see [Section 1.4.4](#)). They are also isotropically emitted. The kinetic energy of an Auger electron is equal to the energy released in the transition minus its binding energy (e.g. an Auger electron emitted from the L shell after filling a K shell vacancy with an electron from the L shell receives kinetic energy  $E_K - 2E_L$ ).

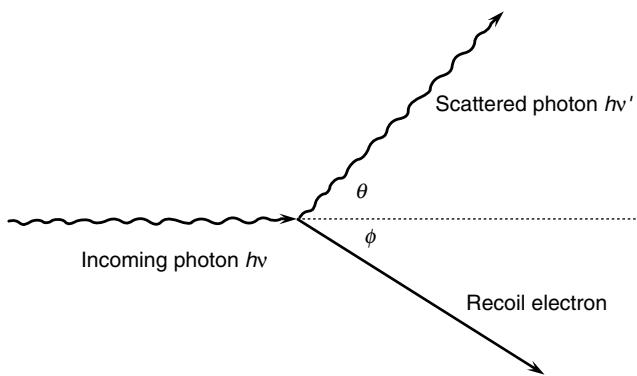

The probability of emission of a characteristic x-ray is called the fluorescence yield,  $\omega$ , leaving probability  $1 - \omega$  for emission of an Auger electron. Values of the K-fluorescence yield  $\omega_K$  and energies of characteristic x-rays are given for some elements in Table 4.1.

The fluorescence yield is large when filling a vacancy in the K-shell of a high atomic number material and strongly decreases as the binding energy of the electrons in the shell containing the vacancy decreases. Therefore, the K-fluorescence yield strongly decreases with decreasing atomic number, and the fluorescence yields of the L- and higher shells are considerably lower than those of the K shell. As a vacancy has been filled, one or two new vacancies are created in outer shells. A cascade of events follow that may finally leave the atom in a highly ionized condition, particularly after the ejection of a K shell electron in a high atomic number atom (see also [Section 1.4](#)).

### 4.3.2 COMPTON INTERACTION AND SCATTERING PROCESSES

In a scattering process, the photon changes its direction of motion. If its energy is reduced, the scattering is called incoherent. The scattering may also occur without energy loss and is then referred to as coherent scattering. The terms *elastic* and *Rayleigh scattering* have also been used for this process.

For photon energies that considerably exceed the binding energies of the atomic electrons, the kinematics of the scattering process is usually described by considering the target electron to be free and at rest at the moment of collision. In this case, the scattering is incoherent because the photon will lose energy upon being scattered. At lower photon energies, the binding energies of the atomic electrons cannot be neglected. The photon can then scatter from individual bound electrons (incoherent scattering) or from all the bound electrons together, scattering in phase (coherent scattering). In the latter case, the whole atom takes part in the scattering process to conserve momentum.

**FIGURE 4.4**

Scattering angles and energies for Compton scatter. An incoming photon of energy  $h\nu$  scatters to produce a scattered photon of energy  $h\nu'$  and a recoil electron.

#### 4.3.2.1 Incoherent Scattering

*Compton Scattering by Free Electrons:* In incoherent scattering, the photon transfers part of its energy to an atomic electron that is ejected from the atomic shell. The process was first described by Compton who assumed the electron to be free and at rest at the moment of collision. In this approximation, the process is also known as Compton scattering. The kinematics of Compton scattering is illustrated in Figure 4.4.

The incoming photon with energy  $h\nu$  is scattered through the angle  $\theta$  (the scattering angle). The energy  $h\nu'$  of the scattered photon is given by the Compton equation

$$h\nu' = \frac{h\nu}{1 + \alpha(1 - \cos \theta)} \quad (4.8)$$

where  $\alpha = h\nu/(m_0c^2)$  and  $m_0$  is the rest mass of the electron.

The equation shows that the photon loses no energy when scattered in the forward direction ( $\theta = 0$ ). For  $180^\circ$  scattering (backward scattering), the photon loses the largest fraction of its energy. This fraction increases with increasing photon energy, and the energies of back-scattered photons approach the limiting value of  $m_0c^2/2$  (256 keV) at high photon energies. For  $90^\circ$  scattering, the corresponding limiting value is  $m_0c^2$  (511 keV).

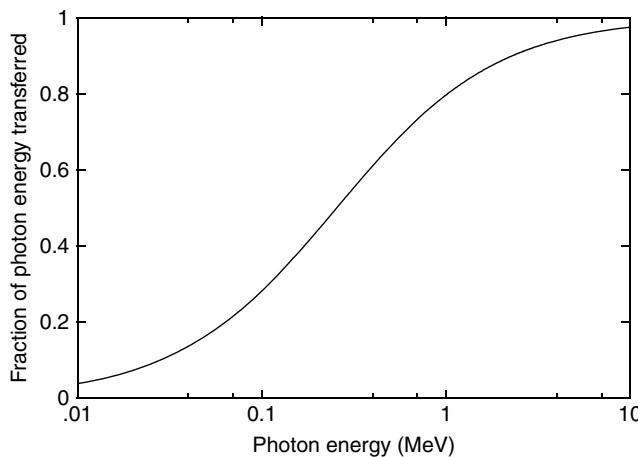

Kinetic energy  $T_e = h\nu - h\nu'$  is transferred to the electron. This energy is zero when the photon scatters in the forward direction and takes its largest value,  $T_e = (h\nu 2\alpha)/(1 + 2\alpha)$ , when the photon is backscattered. Figure 4.5 shows the maximum kinetic energy of the electron expressed as a fraction of the incident photon energy. The figure shows that at low photon energies, the energy transferred is small, but at high energies, the energy transfer is almost complete.

The angle  $\phi$  between the directions of the incoming photon and the electron (Figure 4.4) is given by

$$\cot \phi = (1 + \alpha)\tan \frac{\theta}{2} \quad (4.9)$$

This equation shows that  $\phi \leq \pi/2$ , and the recoil electron is never emitted in the backward direction.

The cross-section for Compton scattering is named after Klein and Nishina who first derived an expression for its value. The differential Klein–Nishina cross-section per electron

**FIGURE 4.5**

Fraction of the incident photon energy that is transferred to the recoil electron for Compton collisions where the photon is backscattered at 180°.

is given by

$$\frac{d_e \sigma_{KN}(\theta)}{d\Omega} = \frac{r_e^2}{2} \left( \frac{h\nu'}{h\nu} \right)^2 \left[ \frac{h\nu'}{h\nu} + \frac{h\nu}{h\nu'} - \sin^2 \theta \right] \quad (4.10)$$

At low energies ( $h\nu \rightarrow 0$ ), this reduces to

$$\frac{d_e \sigma_{Th}(\theta)}{d\Omega} = \frac{r_e^2}{2} (1 + \cos^2 \theta) \quad (4.11)$$

This cross-section is known as the classical Thomson differential cross-section. In Equation 4.11,  $r_e$  is the classical electron radius given by  $r_e = e^2/m_0 c^2 = 2.8179 \times 10^{-15}$  m.

The total Klein–Nishina cross-section per electron may be obtained by integrating Equation 4.10, substituting for  $h\nu'$  using Equation 4.8. The result is:

$$e \sigma_{KN} = 2\pi r_e^2 \left( \frac{1+\alpha}{\alpha^2} \left[ \frac{2(1+\alpha)}{1+2\alpha} - \frac{\ln(1+2\alpha)}{\alpha} \right] + \frac{\ln(1+2\alpha)}{2\alpha} - \frac{1+3\alpha}{(1+2\alpha)^2} \right) \quad (4.12)$$

The total cross-section per atom is  ${}_a \sigma_{KN} = Z_e \sigma_{KN}$ .

Similarly, the total Thomson scattering cross-section is

$$e \sigma_{Th} = \int_0^\pi \frac{r_e^2}{2} (1 + \cos^2 \theta) 2\pi \sin \theta d\theta = \frac{8}{3} \pi r_e^2 = 0.665 \text{ barns} \quad (4.13)$$

The energy transferred to the Compton electron will be subsequently deposited close to the point of interaction (within the electron range), whereas, the secondary photon may travel much farther. It is interesting to partition the total cross-section into absorption,  $\sigma_a$ , and scatter,  $\sigma_s$ , components

$$\sigma = \sigma_a + \sigma_s \quad (4.14)$$

where

$$\sigma_a = \frac{\langle T \rangle}{h\nu} \sigma$$

and

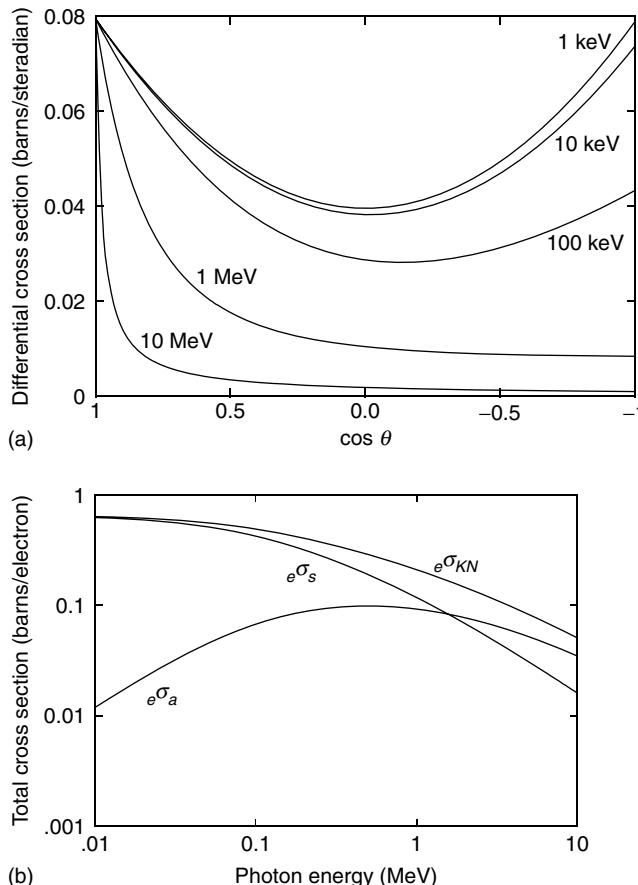

$$\sigma_s = \frac{\langle h\nu' \rangle}{h\nu} \sigma$$

Here,  $\langle T \rangle$  and  $\langle h\nu' \rangle$  are the expectation values of the energies of the Compton electron and the scattered photon, respectively. Equation 4.8 and Equation 4.10 may be combined to yield the following expression for  ${}_e\sigma_s$ :

$${}_e\sigma_s = \pi r_e^2 \left[ \frac{\ln(1+2\alpha)}{\alpha^3} + \frac{2(2\alpha^3 - 3\alpha - 1)}{\alpha^2(1+2\alpha)^2} + \frac{8\alpha^2}{3(1+2\alpha)^3} \right] \quad (4.15)$$

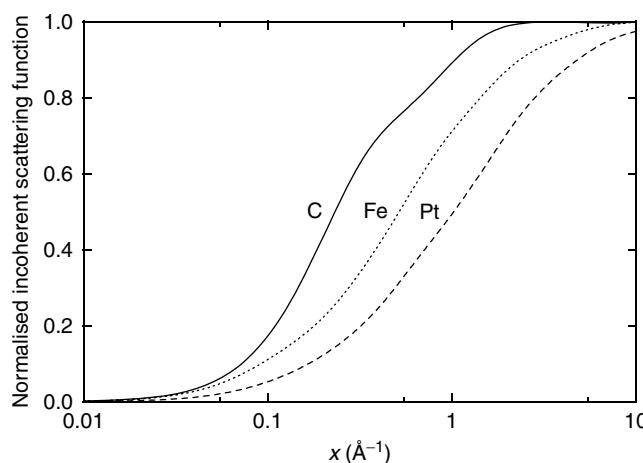

The differential Klein–Nishina cross-section is shown in Figure 4.6a; the total cross-section and the partial cross-sections  ${}_e\sigma_a$  and  ${}_e\sigma_s$  in Figure 4.6b.

At low photon energies, the Compton scattering angular distribution is almost symmetrical about  $\cos \theta = 0$  (Figure 4.6a). With increasing energy, the photons are increasingly scattered into the forward direction, and an increasing fraction of the energy is transferred to the Compton electron (Figure 4.6b). At 0.01 MeV, only 1.87% of the photon energy is converted to electron kinetic energy. This fraction increases to 50% at 1.7 MeV and reaches 79.4% at 100 MeV. These fractions are, of course, limited by those shown in Figure 4.5.

**FIGURE 4.6**

Cross-sections for Compton scattering from free electrons: (a) Variation of differential cross-section with  $\cos \theta$  and the energy of the incident photon, (b) Variation of the total cross-section, KN (Klein Nishina) and the partial cross-sections for scattered energy,  $s$ , and energy absorption,  $a$ , with the energy of the incident photon.

**FIGURE 4.7**

Variation of the incoherent scattering function with the momentum transfer parameter  $x^*$ . Results are shown for carbon (C), iron (Fe), and platinum (Pt). In each case, the incoherent scattering function has been normalised to the atomic number. (Data taken from Hubbell, J. H., et al., *J. Phys. Chem. Ref. Data*, 23(2), 339–364, 1994.)

**Scattering from Bound Electrons:** The influence of electron binding on the incoherent scattering cross-section is usually quantified by the incoherent scattering function  $S(x, Z)$ . The differential scattering cross-section for incoherent scattering per atom is then given by

$$\frac{d_a \sigma_{incoh}(\theta)}{d\Omega} = \frac{d_e \sigma_{KN}(\theta)}{d\Omega} S(x, Z) \quad (4.16)$$

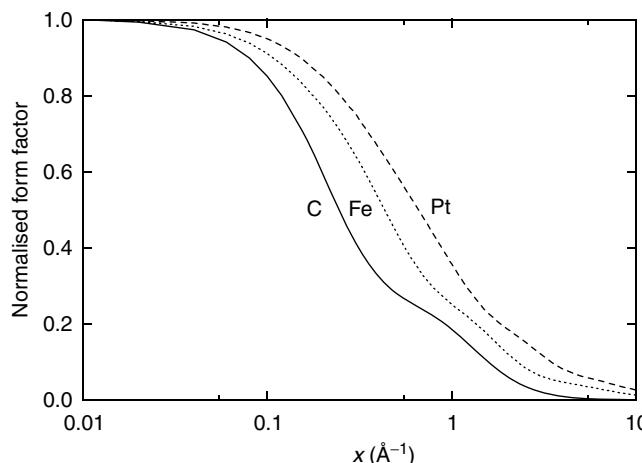

The incoherent scattering function is generally assumed to be a function of the momentum transfer and the atomic number,  $Z$ . It is tabulated in terms of the momentum transfer related quantity  $x$  given by

$$x = \frac{\sin(\theta/2)}{\lambda} \quad (4.17)$$

where  $\lambda$  is the wavelength of the primary photon.

The incoherent scattering function is related to the probability that the electron will be ejected from the atomic shell as a result of the momentum transfer  $x$  to the atom. It takes its lowest value at  $\theta=0$  where  $S(x, Z)=0$ . It monotonically increases with increasing  $x$  (increasing photon energy and/or scattering angle) and approaches  $Z$ , the number of electrons in the atom, as  $x$  approaches infinity. The cross-section then reduces to the free electron cross-section. At high photon energies, the cross-section for Compton scattering is approached at all scattering angles. The incoherent scattering function is shown in Figure 4.7 for the elements carbon, iron, and platinum. To facilitate comparison, the function has been normalized to the atomic number. It can be seen that the momentum transfer required for the incoherent scattering function to approach its maximum value increases with increasing atomic number.

\* The momentum transfer is expressed in units of inverse ångström ( $\text{\AA}^{-1}$ ) to match the units used in the standard reference cited (1 ångström =  $10^{-10}\text{m}$ ).

**FIGURE 4.8**

Variation of the form factor for coherent scattering with the momentum transfer parameter  $x^*$ . Results are shown for carbon (C), iron (Fe), and platinum (Pt). In each case, the form factor has been normalized to the atomic number. (Data taken from Hubbell, J. H. and Øverbø, I., *J. Phys. Chem. Ref. Data*, 9, 69, 1979.)

#### 4.3.2.2 Coherent Scattering

In coherent scattering, the photon is collectively scattered by the atomic electrons. Essentially, no energy is lost by the photon as it transfers momentum  $x$  to the atom while being scattered through the angle  $\theta$ . The scattering from the different electrons is in phase, and the resultant angular deflection is determined by an interference pattern characteristic of the atomic number of the atom. The differential cross-section for coherent scattering is obtained as the product of the differential Thomson scattering cross-section and the atomic form factor  $F$  squared

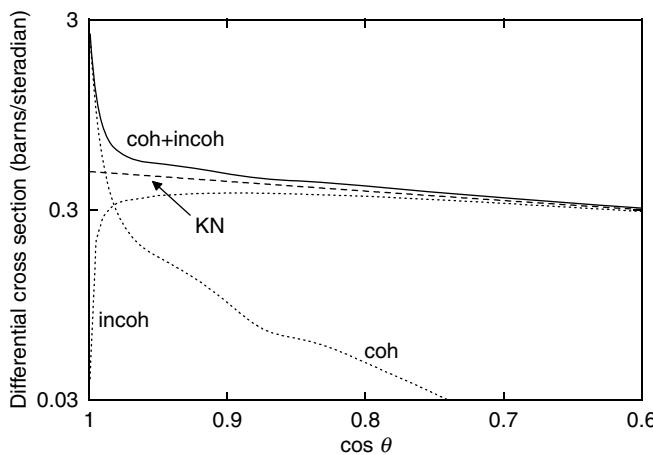

$$\frac{d_e \sigma_{coh}(\theta)}{d\Omega} = \frac{d_e \sigma_{Th}(\theta)}{d\Omega} F^2(x, Z) \quad (4.18)$$

The atomic form factor is, like the incoherent scattering function, a universal function of  $x$ . Figure 4.8 shows this form factor for the elements carbon, iron, and platinum. To facilitate comparison, the form factor is normalised to the atomic number.

The form factor takes its maximum value in the forward direction ( $\theta=0$ ) where  $F(0, Z)=Z$ . It decreases to zero as  $x$  increases; with increasing momentum transfer  $x$ , it gets increasingly difficult for all electrons to scatter in phase without absorbing energy. However, for a given momentum transfer, the normalised form factor  $F/Z$  increases with increasing atomic number.

As noted above, the form factor  $F$  increases with decreasing  $x$  (Figure 4.8). Corresponding to this increase, the incoherent scattering function  $S$  decreases (Figure 4.7) and, to some extent, compensates for the increase in  $F$ . In hydrogen with only one atomic electron, the compensation is exact, and  $S(x, 1)+F^2(x, 1)=1$  at all values of  $x$ . In higher atomic number media, for small values of  $x$ , coherent scattering more than compensates for the reduced incoherent scattering. This is illustrated in Figure 4.9 where differential cross-sections for coherent scattering, incoherent scattering, and the sum of coherent and incoherent scattering are compared to the free electron differential scattering cross-section for carbon at a photon energy of 50 keV. The data in the figure is plotted just for the range  $\cos \theta=1.0-0.6$  in order to show the peaking of the coherent and total differential scattering cross-section in the forward direction.

\* The momentum transfer is expressed in units of inverse ångström ( $\text{\AA}^{-1}$ ) to match the units used in the standard reference cited (1 ångström =  $10^{-10}\text{m}$ ).

**FIGURE 4.9**

The differential cross-sections for coherent scattering (coh), incoherent scattering (incoh), total scattering (coh+incoh), and free electron scattering (KN) from carbon for the  $\cos \theta$  range 1.0–0.6. (Data taken from Hubbell, J. H. and Øverbø, I., *J. Phys. Chem. Ref. Data*, 9, 69, 1979; Hubbell, J. H., et al., *J. Phys. Chem. Ref. Data*, 23(2), 339–364, 1994.)

At low photon energies,  $x$  is close to zero at all scattering angles, and the total cross-section for coherent scattering is then

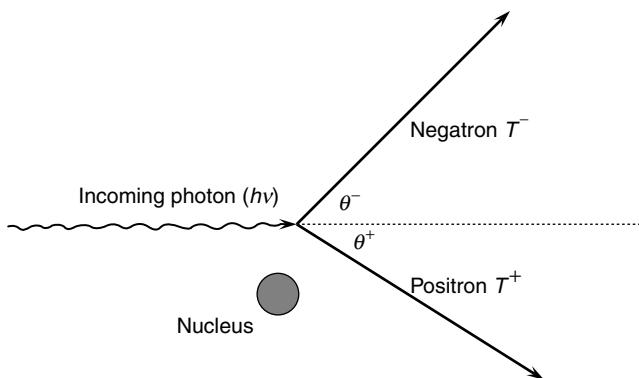

$$_a\sigma_{coh} \approx e\sigma_{Th}Z^2 \quad (4.19)$$

At higher energies,  $x$  becomes larger, and  $F$  is small for much of the energy range. The cross-section then decreases with increasing energy, approximately as

$$\sigma_{coh} \propto (hv)^{-2} \quad (4.20)$$

### 4.3.3 PAIR AND TRIPLET PRODUCTION

Pair production is illustrated in Figure 4.10. In pair production, the photon is absorbed in the electric field of the nucleus. An electron (negatron)-positron pair is created and emitted with the sum of their kinetic energies,  $T^- + T^+$ , being determined by the requirement for

**FIGURE 4.10**

Pair production. An incoming photon with energy  $hv$  is absorbed in the electric field of a nucleus. An electron (negatron)—positron pair is created with kinetic energies  $T^-$  and  $T^+$ , respectively.

conservation of energy

$$T^- + T^+ = h\nu - 2m_0c^2 \quad (4.21)$$

Here,  $m_0c^2$  is the energy equivalent of the electron rest mass  $m_0$ .

As in photoelectric absorption, the nucleus is needed to conserve momentum. Also in this case, the energy associated with the recoil of the atom is negligible. From the above equation, it is clear that the process has a threshold value of  $2m_0c^2$  (1.02 MeV), the minimum energy required to create two electrons. On average, the electron–positron pair about equally shares the kinetic energy available. The probability for either particle to absorb most of the energy is small.

The two electrons tend to be ejected in the forward direction. At energies well above the threshold energy, the average angle of *departure* from the photon direction,  $\bar{\theta}$ , is

$$\bar{\theta} \approx \frac{m_0c^2}{\bar{T}}; \quad \bar{T} = \frac{1}{2}(h\nu - 1.02 \text{ MeV}) \quad (4.22)$$

The process of pair production may also occur in the electric field of an atomic electron. The atomic electron will recoil with sufficient energy to be ejected from the atomic shell. Three electrons appear as a result of the interaction and, accordingly, the process is called *triplet production*. Triplet production has an energy threshold at  $4m_0c^2$  (2.04 MeV).

The cross-section for pair production in the nuclear field is zero below threshold. It then rapidly increases with increasing energy and, well above threshold, varies approximately as the square of the nuclear charge  $Z$ , i.e.

$${}_{\alpha}\sigma_{Pair} \propto Z^2 \quad (4.23)$$

The cross-section for triplet production, at energies above threshold, approximately varies as  $Z$

$${}_{\alpha}\sigma_{Pair} \propto Z \quad (4.24)$$

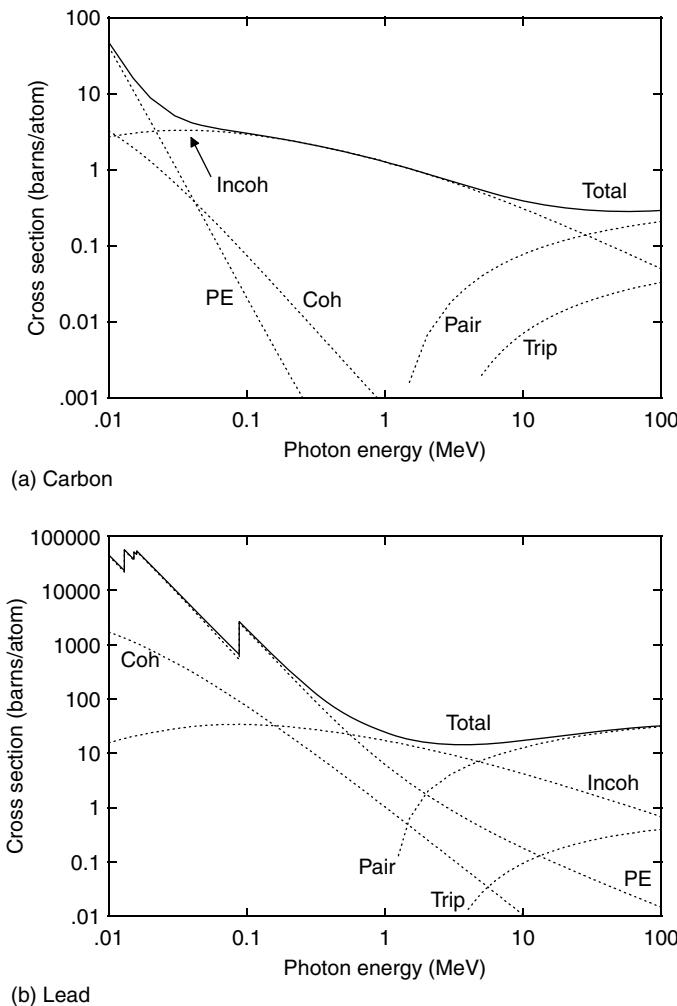

Triplet production is as important as pair production in hydrogen ( $Z=1$ ), but it gets increasingly less important, compared to pair production, with increasing atomic number. In high atomic number media,  $Z$  dependence of these processes becomes weaker because of screening of the electric fields of the target entities by the surrounding atomic electrons.

#### 4.3.4 NUCLEAR PHOTOEFFECT

When the photon energy exceeds that of the binding energy of a nucleon, it can be absorbed in a nuclear reaction (see [Section 2.1.1](#)). As a result of the reaction, one or more nucleons (neutrons and/or protons) are ejected. The cross-section for the nuclear photoeffect depends, in a complicated manner, on both the atomic number,  $Z$ , and the atomic mass,  $A$ , and thus on the isotopic abundance in a sample of a given element. Because of these irregularities, it is not readily given in tabulated form. The cross-section has an energy threshold, and it is shaped as a giant resonance peak. The peak occurs between 5 and 40 MeV, depending on the element, and it can contribute between 2% (high- $Z$  element) and 6% (low- $Z$  element) to the total cross-section.

#### 4.3.5 THE TOTAL ATOMIC CROSS-SECTION

The total atomic cross-section and its partial cross-sections are given in [Figure 4.11](#) for the elements carbon ( $Z=6$ ) and lead ( $Z=82$ ). In both elements, photoelectric absorption is the

**FIGURE 4.11**

The total and partial cross-sections for carbon (a) and lead (b) for photon energies from 10 keV to 100 MeV. (Data taken from Berger, M. J. and Hubbell, J. H., *XCOM: Photon Cross Sections on a Personal Computer*, 87-3597, NBS, Washington, DC, 1987.)

dominating interaction at low photon energies (<50 keV in carbon, <800 keV in lead). With increasing photon energy the next process to become dominant is incoherent scattering (although the absolute amount of incoherent scattering actually decreases as the energy increases - see Figure 4.11). In a low atomic number medium such as carbon, this process remains the most important over a wide range of energies, 100 keV to 20 MeV. In a high atomic number element, the predominance of incoherent scattering is limited to a much smaller energy interval, 800 keV to 5 MeV in lead. This is due to the onset of pair production at energies above 1.02 MeV and the strong dependence of this process on atomic number. The cross-section for pair production approaches a constant value at 100 MeV in both elements. The larger relative contribution of triplet production in the low atomic number element is clearly seen. Nuclear photoeffect significantly contributes to the total cross-section in a narrow energy interval around the giant resonance peak. The threshold for nuclear photoeffect is above 10 MeV in carbon, but it occurs at a lower photon energy in lead. Coherent scattering is never the dominating interaction. At low energies, it is more important than incoherent scattering; however, at these energies, photoelectric absorption is, by far, the most important process.

## 4.4 MACROSCOPIC BEHAVIOUR

### 4.4.1 BEAM ATTENUATION AND ATTENUATION COEFFICIENTS

Photons incident on an absorber will either interact in it (producing secondary electrons and/or scattered photons) or else pass through it without interacting. The number of photons transmitted undisturbed through an absorber of thickness  $t$  of a given element and density can, for mono-energetic photons, be derived in the following way (see Figure 4.12). The number of primary photons,  $d\Phi$ , interacting in a thin layer  $dx$  at depth  $x$  is proportional to the thickness of the layer and the number of photons incident on the layer so that

$$d\Phi = -\mu dx \Phi(x) \quad (4.25)$$

The linear attenuation coefficient  $\mu$  is a property of the material and depends on photon energy. The minus sign indicates that photons are removed from the beam. Integrating the equation from  $x=0$  to  $x=t$  gives the number,  $\Phi(t)$ , of primary photons that are transmitted through the absorber. This number decreases exponentially with increasing thickness  $t$  according to

$$\Phi(t) = \Phi_0 e^{-\mu t} \quad (4.26)$$

with  $\Phi_0 = \Phi(0)$  the number of incident photons.

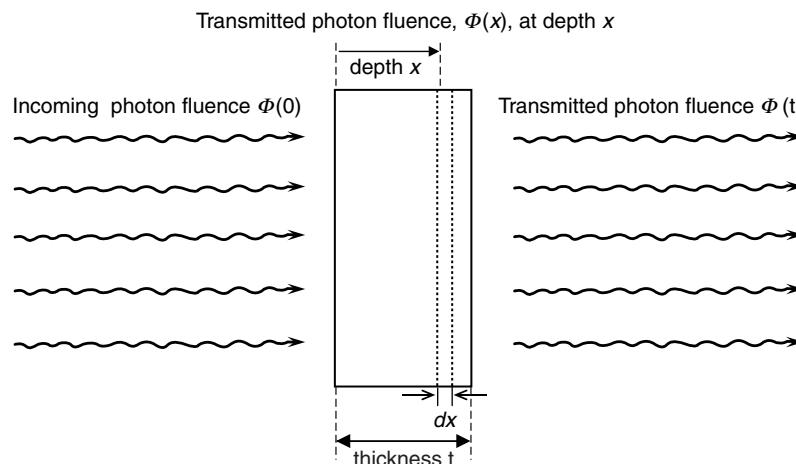

The linear attenuation coefficient is the probability per unit length for interaction and is related to the total atomic cross-section,  $\sigma_{\text{tot}}$ , through the relation

$$\mu = N \sigma_{\text{tot}} \quad (4.27)$$

where  $N$  is the number of target entities per unit volume. It is given by

$$N = \frac{N_A}{A} \rho \quad (4.28)$$

where  $N_A$  is the Avogadro's number ( $N_A = 6.022 \times 10^{23}$  atoms/mol),  $A$  is the relative atomic mass of the target element (normalized to the mass of an atom of the nuclide  $^{12}\text{C}$ ), and  $\rho$  its density.

**FIGURE 4.12**

Calculation of photon transmission through a slab of matter. The incident fluence of primary photons  $\Phi(0)$  is reduced to a fluence  $\Phi(x)$  of primary photons at depth  $x$  in the slab.

The mass attenuation coefficient,  $\mu/\rho$ , obtained by dividing  $\mu$  with  $\rho$ , is independent of the actual density of the absorber and makes this quantity attractive for use in compilations.

The penetration power of a photon beam is commonly expressed by means of the mean free path. This is defined as the average distance,  $\bar{x}$ , travelled by the photon before it interacts. For mono-energetic photons it is given by

$$\bar{x} = \int_0^\infty xe^{-\mu x} dx = \frac{1}{\mu} \quad (4.29)$$

The mean free path equals the thickness of an absorber that reduces the primary photons to a fraction  $1/e = 37\%$  of their initial number.

The mass attenuation coefficient for mixtures and compounds such as water can be calculated as the weighted sum of the mass attenuation coefficients of their components.

$$\frac{\mu}{\rho} = \sum w_i \left( \frac{\mu}{\rho} \right)_i \quad (4.30)$$

Here,  $w_i$  is the fraction by weight of the element  $i$  in the compound, e.g. for water

$$\left( \frac{\mu}{\rho} \right)_{H_2O} = \frac{2}{18} \left( \frac{\mu}{\rho} \right)_H + \frac{16}{18} \left( \frac{\mu}{\rho} \right)_O \quad (4.31)$$

#### 4.4.2 ENERGY TRANSFER AND ENERGY ABSORPTION COEFFICIENTS

The energy transferred to kinetic energy of secondary electrons in a photon interaction is of particular interest in dosimetry because the electrons will impart their energies close to the point where they were released (within their maximum range). The mass energy transfer coefficient  $\mu_{tr}/\rho$  has been defined to allow calculations of this energy and is defined as

$$\frac{\mu_{tr}}{\rho} = \frac{\mu}{\rho} \frac{\langle T \rangle}{h\nu} \quad (4.32)$$

where  $\langle T \rangle$  is the expectation value of the energy converted to kinetic energy of secondary electrons in an interaction. Considering each type of interaction  $i$  separately, the right side is obtained as the weighted sum

$$\frac{\mu_{tr}}{\rho} = \sum_i f_i \frac{\mu_i}{\rho} \quad (4.33)$$

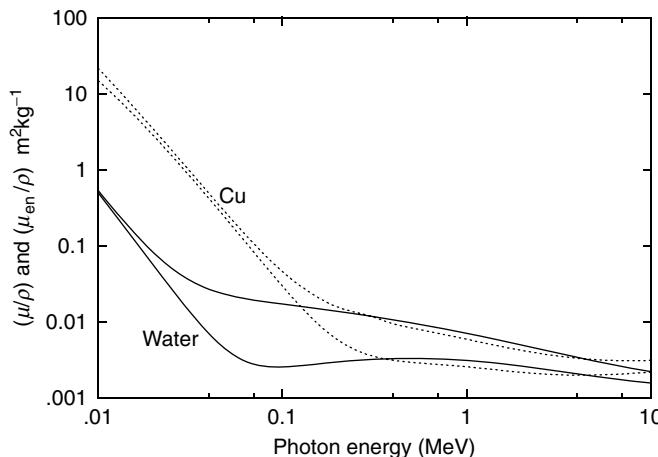

The weighting factors,  $f$ , for the different processes (photo electric, incoherent, coherent, pair production) are given respectively by

$$f_{pe} = 1 - \frac{\delta}{h\nu} \quad (4.34a)$$

$$f_{incoh} = 1 - \frac{\langle h\nu' \rangle + \delta}{h\nu} \quad (4.34b)$$

$$f_{coh} = 0 \quad (4.34c)$$

$$f_{pp} = 1 - \frac{2m_0e^2}{h\nu} \quad (4.34d)$$

**FIGURE 4.13**

Mass attenuation coefficient  $\mu/\rho$ , and mass energy absorption coefficients  $\mu_{\text{en}}/\rho$ , for water (solid curves) and copper (dotted curves). For each material the mass attenuation coefficient lies above the mass absorption coefficient. (Data taken from Hubbell and Seltzer 1995).

Here,  $\delta^*$  is the average energy of characteristic x-rays emitted subsequent to an ionization event (photoelectric absorption or incoherent scattering) because of rearrangements of vacancies in the atomic shells and  $\langle h\nu \rangle$  is the average energy of an incoherently scattered photon.

In slowing down, the electrons may lose energy to secondary photons (mainly bremsstrahlung, see [Section 3.3.3](#)). The mass energy absorption coefficient  $\mu_{\text{en}}/\rho$  allows for these losses

$$\frac{\mu_{\text{en}}}{\rho} = \sum_i (1 - g_i) f_i \frac{\mu_i}{\rho} = (1 - g) \frac{\mu_{\text{tr}}}{\rho} \quad (4.35)$$

Here,  $g$  is the fraction of the kinetic energy lost to photons during the complete slowing down of secondary electrons. It is usual to allow for bremsstrahlung when estimating  $g$  (e.g. ICRU 1980); however, account should also be taken of positron annihilation in flight and characteristic x-rays (Seltzer 1993).

In Figure 4.13, values of  $\mu/\rho$  and  $\mu_{\text{en}}/\rho$  are compared for water and copper. In a low atomic number medium such as water, the mass energy absorption coefficient comes close to the mass attenuation coefficient at low photon energies where photoelectric absorption prevails. Both fluorescence yields and energies of the characteristic x-rays are low so that  $\delta$  (the average energy emitted as fluorescence radiation) becomes a negligibly small fraction of the photon energy. In copper, however, for photon energies immediately above the K absorption edge, the high fluorescence yield and energies of characteristic x-rays produce a significant deviation between the mass energy absorption and the mass attenuation coefficients. At higher photon energies,  $\delta$  will be an increasingly smaller fraction of the photon energy and the deviation between the mass energy absorption and mass attenuation coefficients is mainly due to the fraction of energy carried away by incoherently scattered photons. At still higher energies, bremsstrahlung and annihilation in flight additionally contribute to the deviation between the two coefficients.

\* The symbol delta used here should not be confused with the symbol used for *delta-rays*(electrons) discussed in [Section 3.2.1](#)., nor with the *density effect correction factor* discussed in [Section 3.2.3](#).

As the photon energy increases, the energies and ranges of their secondary electrons also increase. In particular, the quotient,  $\mu R$ , between the maximum range of the secondary electrons,  $R$ , and the mean free path of the photons,  $1/\mu$ , increases, and the applicability of the mass energy absorption coefficient needs to be carefully considered.

---

## 4.5 SOURCES OF INTERACTION DATA

The overall fluence of photons inside and around a body consists of photons that have not interacted (primary photons) and secondary photons of various generations. With knowledge of the actual irradiation geometry including the energy spectrum of photons emitted from the source, the attenuation coefficients for relevant materials, and the differential cross-sections for scattering processes, the photon field may be calculated using analytical or Monte Carlo methods. For high atomic number media, the energies of absorption edges, characteristic x-rays and fluorescence yields also need to be known.

The cross-section data needed for such calculations are available in published tabulations and are known with a high degree of accuracy. In the photon energy range of most interest in medical applications, 5 keV–50 MeV, attenuation coefficients are known within 1–2% (one standard deviation; see review by Hubbell 1999). Mass attenuation coefficients can be obtained from the XCOM program first published by Berger and Hubbell (1987) and available on line at <http://physics.nist.gov/PhysRefData/Xcom/Text/XCOM.html>. They are tabulated in Part M for energies 0.001 MeV up to 50 MeV and for several materials of interest in radiotherapy physics (e.g. biological tissues, detectors components, radiation protection barriers). Information on mass attenuation and mass energy absorption coefficients is available from the NISTIR compilation (Hubbell and Seltzer 1995). The compilation by Hubbell et al. (1975) provides information on the incoherent scattering function,  $S(x,Z)$  that may be used to derive differential scattering cross-sections for incoherent scattering. Differential cross-sections for coherent scattering may be derived from the compilation of relativistic form factors,  $F(x,Z)$ , by Hubbell and Øverbø (1979), replacing the atomic form factors in Hubbell et al. (1975).

Data on absorption edges in different materials and energies of characteristic x-rays are available from Storm and Israel (1970). Fluorescence yields are tabulated in Hubbell et al. (1994).

## 5.1 INTRODUCTION

As applied to radiation transport applications in radiotherapy and dosimetry, the Monte Carlo method provides a numerical solution to the Boltzmann transport equation (e.g. Kase and Nelson 1978; Duderstadt and Martin 1979) that directly employs the fundamental microscopic physical laws of electron-atom and photon-atom interactions. Monte Carlo simulation

faithfully reproduces the individual particle tracks, in a statistical sense, within current knowledge of the physical laws: the scattering and absorption cross-sections. The radiation fields' macroscopic features (e.g. the average track-length per incident photon in a given volume of space) are computed as an average over many individual particle simulations or histories. If the true average  $\bar{x}$  exists and the distribution in  $x$  has a true finite variance,  $\sigma_x^2$ , the *Central Limit Theorem* (Lindeberg 1922; Feller 1967) for energies 0.001 MeV up to 50 MeV guarantees that the Monte Carlo estimator for  $\bar{x}$ , that is referred to here as  $\langle x \rangle$ , can be made arbitrarily close to  $\bar{x}$  by increasing the number,  $N$ , of particle histories simulated. Moreover, the *Central Limit Theorem* predicts that the distribution of  $\langle x \rangle$  is Gaussian, characterised by a variance  $\sigma_{\langle x \rangle}^2$  that may be simply estimated in the simulation. The *Central Limit Theorem* also predicts that in the limit  $N \rightarrow \infty$ ,  $\sigma_{\langle x \rangle}^2 \rightarrow 0$ . This limiting result is also proven by the *Strong Law of Large Numbers* (Feller 1967).

It is these facts that have been partly responsible for the rapid increase in the use of the Monte Carlo method in radiotherapy and dosimetry applications (Nahum 1988), a trend that has continued since Nahum's review article\*. If one knows the governing physical laws to sufficient accuracy and has access to sufficient computing resources, then the answer to any well-posed physical question may be computed. Fortunately, the physical laws required for most applications in radiotherapy and dosimetry are well known. They are the results of Quantum Electrodynamics (QED) (Bjorken and Drell 1965; Sakurai 1967), one of the most successful theories of theoretical physics. Additionally, the computer resources required for most of our applications are modest, and they may be executed to sufficient accuracy on affordable desktop computers and workstations. Today's powerful PCs, generally running under Linux, effectively function as Monte Carlo calculation engines. This confluence of theory and computational ability puts the Monte Carlo method into the standard toolbox of the medical physicists, especially if they are involved in research.

Of course, there are significant technical obstacles to be overcome, but these are surmountable. The point of this chapter is to demonstrate the power and utility of the Monte Carlo method without the detail that would be considered in a fuller discussion. Fortunately, there are some valuable detailed reviews on this topic (Raeside 1976; Mackie 1990; Rogers and Bielajew 1990; Andreo 1991; Zaidi and Sgouros 2003). The reader should realise that an application with tens of thousands of volume elements and many different materials to describe a simulation geometry is only slightly more complicated than a simple two-medium interface problem. More organisation and computer coding is required, but the technical ability to solve the simpler problem empowers one with the ability to solve the geometrically more complex problem.

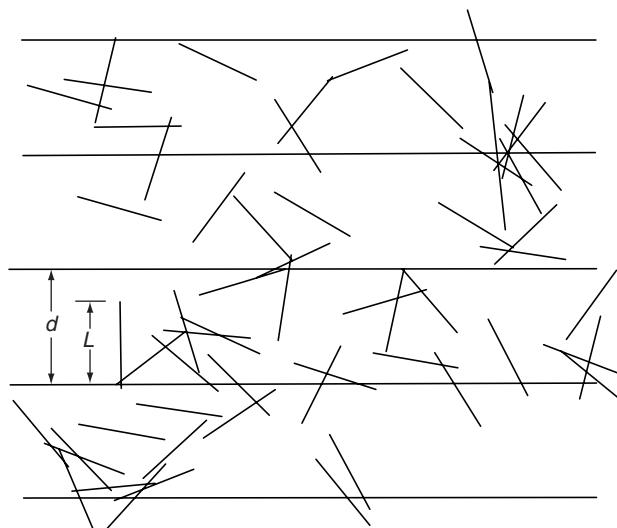

## 5.2 A BRIEF HISTORY OF MONTE CARLO

Usually, the first reference to the Monte Carlo method is that of the Comte de Buffon (Buffon 1777) who proposed a Monte Carlo-like method to evaluate the probability of tossing a needle onto a ruled sheet. This reference goes back to 1777, well before automatic calculating machines. Buffon calculated that a needle of length  $L$  randomly tossed on a plane ruled with parallel lines of distance  $d$  apart, where  $d > L$ , would have a probability:

$$p = \frac{2L}{\pi d} \quad (5.1)$$

---

\* A more recent paper by Carrier et al. (2004) clearly illustrates how widespread Monte Carlo simulation has become in Medical (radiation) Physics, and it also demonstrates the impressive choice of sophisticated public domain Monte Carlo codes today's hospital physicist may access.

**FIGURE 5.1**

A computer simulation of the Buffon needle problem. The distance  $d$  between lines is larger than the length  $L$  of each needle ( $L/d = 3/4$ ). 50 needles are randomly tossed. The probability that a needle will cross one line is  $(2/\pi) \times (3/4) \approx 1/2$  (i.e. 25 needles crossing a line).

A computer simulation of 50 needles (where  $L/d = \frac{3}{4}$ ) on a finite grid of 5 lines is shown in Figure 5.1.

Much later, Laplace (1886) suggested that this procedure could be employed to determine the value of  $\pi$ , albeit slowly. Several other historical uses of Monte Carlo predating computers are cited by Kalos and Whitlock (1986). The modern Monte Carlo age was ushered in by von Neumann and Ulam during the initial development of thermonuclear weapons\*. Ulam and von Neumann coined the phrase *Monte Carlo*, and they were pioneers in the development of the Monte Carlo technique and its realisations on digital computers†.

### 5.3 PHOTON INTERACTION PROCESSES

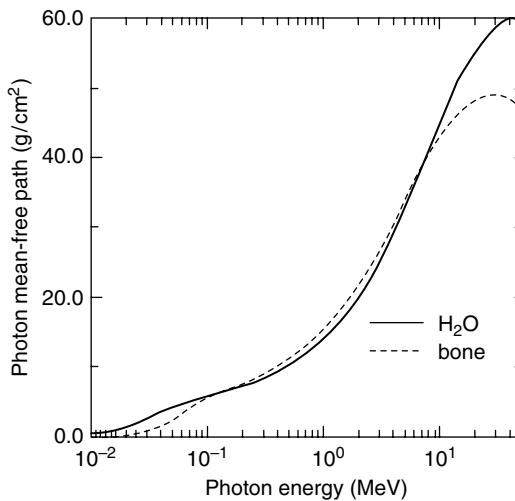

The photon interaction processes that should be modelled by a Monte Carlo code designed for applications in radiotherapy and dosimetry are:

- Pair production in the nuclear and atomic fields (Davies et al. 1954; Motz et al. 1969; Tsai 1974)
- Compton scattering from atomic electrons (incoherent scattering) (Klein and Nishina 1929; Compton and Allison 1935)
- Photoelectric absorption and photoelectron production (Sauter 1931)
- Rayleigh scattering from atomic and molecular fields (coherent scattering) (Rayleigh 1871)

These processes are reviewed in systematic detail in Chapter 4.

\* The two books by Richard Rhodes, *The Making of the Atomic Bomb* and *Dark Sun* are excellent historical sources for this period.

† Despite their history, thermonuclear weapons have never been deployed in conflict. Therefore, Monte Carlo calculations have not been employed for destructive purposes.

**FIGURE 5.2**

Mean-free path of photons in water and bone. (Data extracted from EGS4 code system: Nelson W. R. et al., *The EGS4 Code System Report SLAC-265*, Stanford Linear Accelerator Center, Stanford, California, 1985.)

The relative importance of the various processes involved for materials common to radiotherapy applications are now considered. For water and bone, the mean-free path, i.e. the average distance a photon travels before interacting via one of the interaction processes, is shown in Figure 5.2 as a function of energy. When presented in units of grams per square centimetre, the mean-free path in bone is almost the same as that in water between 100 keV and 10 MeV, but it is higher outside of this range. These differences may be quite easily modelled with Monte Carlo methods.

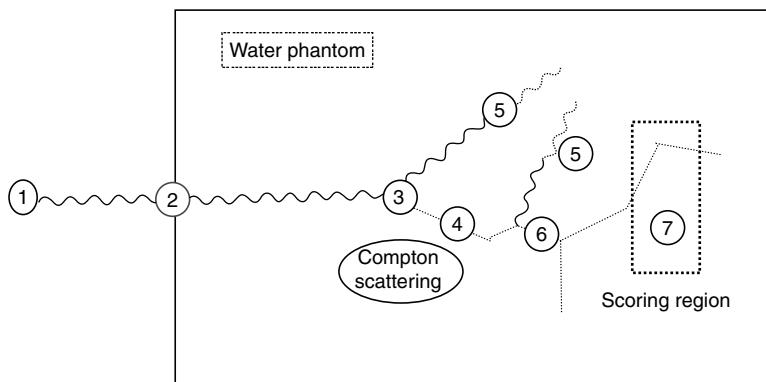

Figure 5.2 shows that photon's interaction distances in the energy range  $10 \text{ keV} \leq E_{\gamma} \leq 40 \text{ MeV}$  are of the order of 20 cm for common low-Z materials (i.e. the photons will interact only a few times in macroscopic objects such as a radiation measuring device, a tank of water, or a human being undergoing treatment with radiotherapy)\*. This means that if one considers the transport of photons alone, it is feasible, with modest computational resources, to simulate hundreds of millions of particle histories.

Figure 5.3 is a schematic illustration of an actual photon history that includes the tracks of the secondary particles. The history begins at position 1 in a vacuum; photons are indicated by sinusoidal tracks and the secondary electrons by straight lines.

The simulation consists of the following steps (here, steps 1 to 7 are explicitly labelled in the figure):

1. Choose photon energy, direction, and starting position based on sampling from distribution of incident photons, and transport photon to first boundary
2. Choose distance to first interaction (see [Section 5.6.2](#)) and transport photon to this interaction point
3. Choose the type of interaction (Compton scatter, photo-electric, pair-production, Rayleigh scatter)
4. Choose direction, energy, etc. of new particles (such as Compton electrons by sampling from the Klein–Nishina differential cross-section; characteristic photons; Auger electrons). Put them on the stack (i.e. a list of secondary particles to be followed later)

\* Monte Carlo based radiotherapy treatment planning requires of the order of  $10^8$  to  $10^9$  photon histories (see [Chapter 28](#)).

**FIGURE 5.3**

A schematic illustration of a Monte Carlo photon history (Reproduced courtesy of F. Verhaegen, private communication). Electron transport is dealt with in much greater detail in Section 5.4 and [Section 5.5](#).)

5. Transport scattered photon until it either leaves the geometry, or it reaches some pre-determined energy cut-off (e.g. PCUT in the EGS code system)
6. Transport secondary electron. Keep track of any  $\delta$  electrons and bremsstrahlung photons produced
7. Score deposited energy, fluence spectra, etc. in region of interest
8. Repeat steps 1–7 for many more particles until scored quantities reach a sufficiently low statistical uncertainty

[Figure 5.4](#) shows a flow diagram for a photon Monte Carlo simulation.

The techniques involved in sampling from distributions, including random number generation as well as the trigonometric relationships required in ray-tracing, are dealt with briefly in [Section 5.6](#).

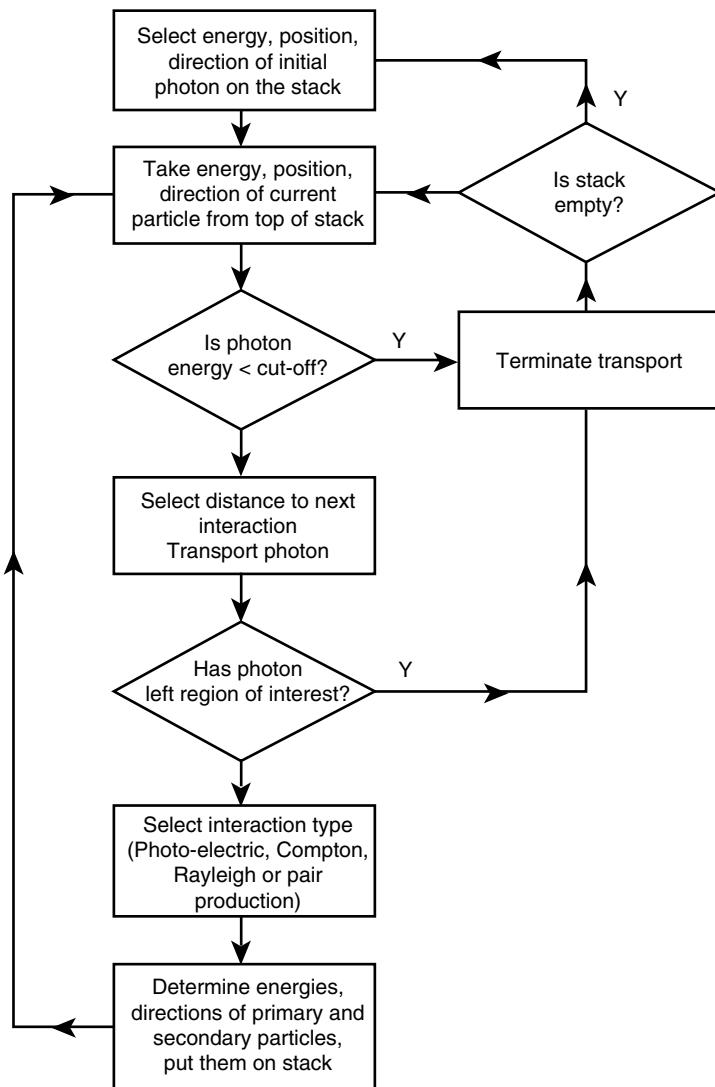

## 5.4 ELECTRON INTERACTION PROCESSES

The electron and positron interaction processes that should be modelled by a Monte Carlo code designed for applications in radiotherapy and dosimetry are

- Møller scattering of electrons from atomic electrons (Møller 1932)
- Bhabha scattering of positrons from atomic electrons (Bhabha 1936)
- Bremsstrahlung photon creation in the nuclear and atomic fields (Koch and Motz 1959; Tsai 1974)
- Positron annihilation with atomic electrons (Heitler 1954)
- Elastic scattering of electrons and positrons from nuclei (Mayol and Salvat 1997)
- Excitation of atoms and molecules by electrons and positrons

The most important of the above processes are dealt with in some detail in [Chapter 3](#).

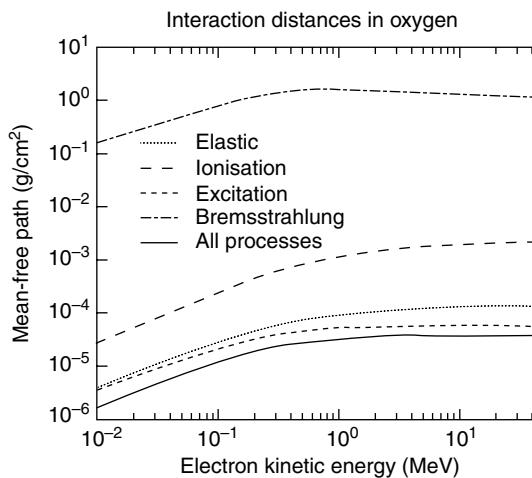

[Figure 5.5](#) presents the electron mean-free paths for the elastic, ionisation, excitation, and bremsstrahlung interactions in oxygen. The distance to an interaction in the relativistic region (greater than, say, 1 MeV) is noted as between  $10^{-5}$  and  $10^{-4}$  g/cm<sup>2</sup>. The range of a 10 MeV electron in oxygen is 5.6 g/cm<sup>2</sup>. This means, for example, that a relativistic electron must undergo  $10^5$  to  $10^6$  interactions before slowing down. A typical electron is completely

**FIGURE 5.4**

Flow chart showing the essential steps in the Monte-Carlo transport of photons; the transport of electrons is not dealt with here. (Reproduced courtesy of F. Verhaegen, Private communication).

slowed down in a typical simulation geometry. This means that each one of the  $10^5$  to  $10^6$  interactions would have to be simulated for each electron history. This form of calculation is called *analogue* simulation, and it is always done for photons (see [Section 5.3](#)). However, it requires Teraflop computational resources for most practical problems involving electron transport.

Fortunately, there is a practical solution to this problem that was pioneered by Berger (1963). Berger called his technique *Condensed History Electron Transport*. It is based on the realisation that, whereas electrons undergo many interactions, relatively few of these interactions cause a great deal of energy loss or directional change. Therefore, the effect of most of these interactions is small, involving little energy loss or small angular deflections. Therefore, one can combine the effect of these small-effect interactions into single virtual large-effect interactions. These large-effect interactions can be theoretically predicted through cumulative-event theories. For energy losses, there is the continuous slowing down approximation

**FIGURE 5.5**

Electron elastic, ionisation, excitation, and bremsstrahlung mean-free path in oxygen (Data derived from the Lawrence Livermore Evaluated Electron Data Library, Perkins, S. T., et al., *Lawrence Livermore National Laboratory Report UCRL-50400*, 31, 1991.)

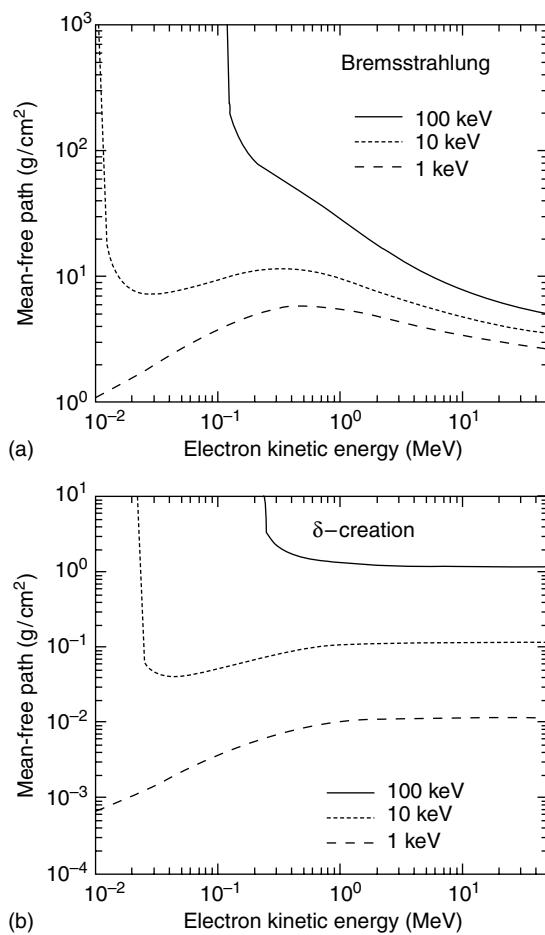

(CSDA) method with the energy loss being characterised by the stopping power\* (Bethe 1930, 1932; Bloch 1933; ICRU 1984a and 1984b) or by distributions that are a function of the length of the electron path (Landau 1944; Vavilov 1957). The effect of cumulative elastic scattering events is predicted by several *small-angle* theories (Molière 1947; Eges 1948; Molière 1948; Bethe 1953); although, these are being superseded by the *any-angle* theory of Goudsmit and Saunderson (1940a, 1940b). All of these theories require single-event elastic scattering models. The Goudsmit–Saunderson approach is favoured because it can be employed to use any cross-section. In particular, elastic cross-section calculations using partial-wave analysis are becoming quite sophisticated (Mayol and Salvat 1997) and are being adopted in advanced Monte Carlo algorithms. Fortunately, the elastic scattering that produces the angular deflections produces no energy loss. Additionally, the energy-loss process produces very little angular deflection. Therefore, these two processes nearly decouple, making the theoretical development somewhat simpler and the construction of algorithms somewhat easier<sup>†</sup>.

The *Condensed History Method* (CHM) has been put on a stronger theoretical footing by Larsen (1992) who showed that the CHM converges at the exact solution of the Boltzmann transport equation in the limit of small electron path-lengths. This is actually a warning that the CHM is an approximation, and its use can lead to calculation artefacts when applied outside of its range of validity (Bielajew et al. 1985; Bielajew and Rogers 1989; Seltzer 1991). This has led to the development of high-accuracy CHM (Bielajew and Rogers 1987; Seltzer 1991; Fernández-Varea et al. 1993; Kawrakow and Bielajew 1998a). Research in this area remains quite active. Nahum (1999) has provided a review of the breadth of applications of the CHM in medical physics.

The benefits of adopting the CHM are evident in the partial mean-free-paths depicted in Figure 5.6. In this figure, the mean-free-path to a bremsstrahlung interaction and a Möller interaction ( $\delta$ -creation event) are shown for secondary particle thresholds of 1, 10, and 100 keV. The analogue Monte Carlo method is employed for interactions that produce

\* See Chapter 3 for a detailed treatment of electron collision stopping power.

<sup>†</sup> High accuracy approaches have to consider this coupling and treat it carefully (Kawrakow and Bielajew 1998a, 1998b).

**FIGURE 5.6**

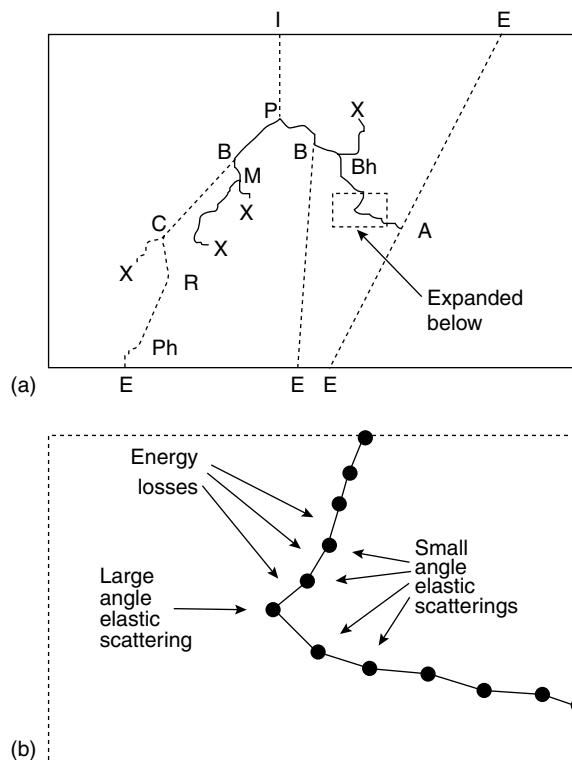

Mean-free-path to a bremsstrahlung interaction (a) or a Møller interaction (b) for different thresholds. (Data extracted from the EGS4 code system: Nelson W. R. et al., *The EGS4 Code System Report SLAC-265*, Stanford Linear Accelerator Center, Stanford, California, 1985.)

secondary particles above the thresholds. The *Continuous Slowing Down* (CSD) or other energy-loss methods are employed for the sub-threshold events. It should be noted that higher thresholds produce longer mean-free paths and more efficient calculation. This is traded for a loss of information on particle fluences below the thresholds. Selection of these thresholds (and other parameters like electron path-length) becomes one of the skills of the Monte Carlo user. Further information on these parameters is best obtained from the extensive literature describing the various general-purpose Monte Carlo codes available such as EGS4 (Nelson et al. 1985; Bielajew et al. 1994), ETRAN (Seltzer 1989, 1991), ITS (Halbleib and Mehlhorn 1984; Halbleib 1989; Halbleib et al. 1992), MCNP (Briesmeister 1986, 1993, 1997), and PENELOPE (Baró et al. 1995; Salvat et al. 1996; Sempau et al. 1997).

## 5.5 COUPLED ELECTRON-PHOTON TRANSPORT

The process by which coupled electron-photon transport is carried out is described in Figure 5.7.

In Figure 5.7a, the simulation geometry is depicted by the outer rectangular box. Photons are represented by straight dashed lines; electrons and positrons by solid curves. A photon

**FIGURE 5.7**

(a) Global picture of electron transport. Photons are represented by straight dashed lines; electrons and positrons by solid curves (I, insertion; E, escape; P, pair production; B, bremsstrahlung; M, Møller; X, end-of-range; C, Compton; R, Rayleigh; Ph, photoelectric; Bh, Bhabha; A, annihilation). (b) Expanded version of the dashed box in (a).

starts the simulation by insertion, I, into the simulation geometry. It undergoes a pair interaction, P, producing an  $e^-e^+$  pair. The electron track (on the left) undergoes a bremsstrahlung interaction at B. Following the photon, it can be seen that there is a Compton interaction at C. The resulting electron is then transported until it runs out of energy at X. The photon undergoes a Rayleigh interaction at R, and it is then absorbed in a photoelectric event at Ph. The photoelectron escapes the simulation geometry at E. Returning to the initial electron, it undergoes a Møller interaction at M. Both the electron and its knock-on are then transported until their end-of-range at the X's. The positron that was born in the pair interaction at P undergoes a bremsstrahlung interaction at B, followed by a Bhabha interaction at Bh. The electron from B reaches its end-of-range at X. The positron eventually annihilates, producing two back-to-back annihilation quanta that escape the simulation geometry at their respective Es. The details of the CHM depicted in Figure 5.7b are now the focus. At each one of the vertices, represented by a solid circle, the positron changes direction. (Electron and positron transport in the CHM are essentially the same.) The deposition of energy according to the CSD or other models can be considered to happen anywhere along the track segments.

## 5.6 MATHEMATICAL METHODS OF MONTE CARLO

Before concluding this chapter, some of the basic mathematics of the Monte Carlo method will be briefly covered. A complete treatment would involve a detailed discussion of random number generation, sampling theory, displacements and rotations, estimating means and variances, and geometry. References are provided to allow a more in-depth study.

### 5.6.1 RANDOM NUMBER GENERATION

It will be assumed that a good source of random numbers is being used. Much mathematical study has been devoted to random number generation (Ehrman 1981; Knuth 1981; James 1988). These latter three references are excellent reviews of random number generation theory and methods up to about 1987. The following references contain more modern material: Marsaglia et al. (1990); Marsaglia and Zaman (1991); James (1994); Lüscher (1994); and Knuth (1981). It should also be noted that random number generation continues to be an area of active research; therefore, information that was given last year may be proven to be misleading this year. The best way to stay in tune is to track the discussions concerning this topic on the web sites of organisations where random number generation is critical. A particularly good example is that of the European Laboratory for Particle Physics (CERN: [www.cern.ch](http://www.cern.ch)).

### 5.6.2 ELEMENTARY SAMPLING THEORY

There are a number of sampling techniques well-known to all constructors of Monte Carlo codes. Only the *Cumulative Probability Distribution Function Method* is dealt with here.

Assume that a probability function  $p(x)$  that is normalised over some range between  $a$  and  $b$  is used; that is:

$$\int_a^b dx' p(x') = 1 \quad (5.2)$$

Its cumulative probability distribution function is now constructed:

$$c(x) = \int_a^x dx' p(x') \quad (5.3)$$

that is monotonically increasing and bounded between 0 and 1. It can be shown that a variable  $x$  is distributed randomly according to  $p(x)$  if  $x$  values are selected by inverting  $c(x)$  according to:

$$x = c^{-1}(R) \quad (5.4)$$

where  $R$  is a uniformly distributed random number between 0 and 1.

For example, it can be shown that the distance to an interaction is given by:

$$x = -\frac{1}{\mu_{\text{tot}}} \log_e(1-R) \quad (5.5)$$

where  $\mu_{\text{tot}}$  is the attenuation coefficient (or macroscopic cross-section) for photons of that energy in the medium concerned\*. This follows directly from the probability distribution for interaction distances:

$$p(x) = \mu \exp(-\mu x) \quad 0 \leq x \leq \infty \quad (5.6)$$

It is important to note that the technique of inverting a function implicit in Equation 5.4 and Equation 5.5 may not always be analytically possible, but it is always numerically possible. A treatment of other sampling techniques can be found elsewhere (e.g. Raeside 1976; Nelson et al. 1985; Turner 1985; Bielajew 1993).

---

\* Written here as  $\mu_{\text{tot}}$  to emphasise that it is the sum of the interaction coefficients for the separate processes (i.e. pair + Compton + photoelectric + Rayleigh);  $1/\mu_{\text{tot}}$  is equal to the mean-free path between interactions. ( $\mu_{\text{tot}}$  is simply denoted  $\mu$  in [Section 4.4.1](#)).

### 5.6.3 DISPLACEMENTS AND ROTATIONS

Ray tracing (displacement and rotation) is carried out using very simple geometrical constructs. Given that a particle has a position  $\vec{x}_0$  and direction  $\vec{u}_0$  and distance to travel  $s$ , the new position,  $\vec{x}$ , is given by:

$$\vec{x} = \vec{x}_0 + \vec{u}_0 s \quad (5.7)$$

where  $\vec{u}_0 = (u_0, v_0, w_0) = (\sin \theta_0 \cos \phi_0, \sin \theta_0 \sin \phi_0, \cos \theta_0)$ ,  $\theta_0$  and  $\phi_0$  are the polar and azimuthal angles, respectively.

Rotation after a scattering by polar angle  $\Theta$  and azimuthal angle  $\Phi$  is carried out via the rotation

$$\begin{aligned} u &= \sin \theta \cos \phi = u_0 \cos \Theta + \sin \Theta (w_0 \cos \Phi \cos \phi_0 - \sin \Phi \sin \phi_0) \\ v &= \sin \theta \sin \phi = v_0 \cos \Theta + \sin \Theta (w_0 \cos \Phi \sin \phi_0 + \sin \Phi \cos \phi_0) \\ w &= \cos \theta = w_0 \cos \Theta - \sin \Theta \sin \phi_0 \cos \Phi \end{aligned} \quad (5.8)$$

that provides the new direction for the particle after a scattering.

### 5.6.4 ESTIMATING MEANS AND VARIANCES

The conventional approach to calculating the estimated error is as follows:

- Assume that the calculation calls for the simulation of  $N$  particle histories.
- Assign and accumulate the value  $x_i$  for the score associated with the  $i$ th history where  $1 \leq i \leq N$ . As well, assign the square of the score  $x_i^2$  for the  $i$ th history.
- Estimate the mean value of  $x$

$$\langle x \rangle = \frac{1}{N} \sum_{i=1}^N x_i \quad (5.9)$$

- Estimate the variance associated with the distribution of the  $x_i$

$$s_x^2 = \frac{1}{N-1} \sum_{i=1}^n (x_i - \langle x \rangle)^2 = \frac{1}{N-1} \sum_{i=1}^n (x_i^2 - \langle x \rangle^2) \quad (5.10)$$

- The estimated variance of  $\langle x \rangle$  is the standard variance of the mean

$$s_{\langle x \rangle}^2 = \frac{s_x^2}{N} \quad (5.11)$$

Note that it is the error in  $\langle x \rangle$  that is sought, not the spread of the distribution of the  $x_i$ .

- Report the final result as  $\langle x \rangle = \pm s_{\langle x \rangle}$ .

The *Central Limit Theorem* interpretation is that  $\langle x \rangle$  satisfies  $|\bar{x} - \langle x \rangle| < s_{\langle x \rangle}$  68% of the time.

### 5.6.5 GEOMETRY

Geometrical elements are made up of regions of space bounded by planes and quadric surfaces (spheres, cylinders, etc.). The essential problem is to determine the smallest intercept

distance along the forward flight direction to one of the bounding surfaces. A well-defined prescription for doing this (Nelson and Jenkins 1987; Bielajew 1995) is summarised below.

Borrowing from the notation of Olmsted (1947), an arbitrary quadric surface in  $3(x,y,z)$ -space\* can be represented by

$$f(\vec{x}) = \sum_{i,j=0}^3 a_{ij}x_i x_j = 0 \quad (5.12)$$

The  $a_{ij}$  symbols are arbitrary constants, and the 4-vector  $x_i$  has components  $(1, x, y, z)$ . The 0<sup>th</sup> component is unity by definition, allowing a very compact representation and  $a_{ij}$  is symmetric with respect to the interchange of  $i$  and  $j$ , that is  $a_{ij}=a_{ji}$ . Equation 5.12 is very general and encompasses a wide variety of possibilities, including solitary planes (e.g. only  $a_{0i}$  non-zero), intersecting planes (e.g. only  $a_{11}$  and  $a_{22}$  non-zero), cylinders (circular, elliptical, parabolic, and hyperbolic), spheres, spheroids and ellipsoids, cones (circular and elliptical), hyperboloids of one and two sheets, and elliptic and hyperbolic paraboloids. These surfaces can be combined to make geometrical objects of great complexity and are extremely useful in Monte Carlo modelling of physical objects.

Despite having apparently ten independent constants, Equation 5.12 represents only ten independent real surfaces (including the simple plane), unique after a translation and rotation to standard position. The three cross terms ( $a_{ij}$  for  $i \neq j$  and  $i, j \geq 1$ ) can be eliminated by rotation. The resultant equation then only involves terms like  $x_i^2$  and  $x_i$ . In addition, providing that a given variable's quadratic constant is non-zero, the linear terms can be eliminated by a translation. The result is that there are only two generic forms:

$$f(\vec{x}) = \sum_{i=1}^3 a_i x_i^2 + c = 0 \quad (5.13)$$

and

$$f(\vec{x}) = \sum_{i=1}^2 a_i x_i^2 + b x_3 = 0 \quad (5.14)$$

Equation 5.13 and Equation 5.14 describe only ten distinct possibilities with real solutions

1. Ellipsoids:  $a_1^2 x_1^2 + a_2^2 x_2^2 + a_3^2 x_3^2 - c^2 = 0$
2. Cones:  $a_1^2 x_1^2 + a_2^2 x_2^2 - a_3^2 x_3^2 = 0$
3. Cylinders:  $a_1^2 x_1^2 + a_2^2 x_2^2 - c^2 = 0$
4. Hyperboloids of one sheet:  $a_1^2 x_1^2 + a_2^2 x_2^2 - a_3^2 x_3^2 - c^2 = 0$
5. Hyperboloids of two sheets:  $a_1^2 x_1^2 + a_2^2 x_2^2 - a_3^2 x_3^2 + c^2 = 0$
6. Elliptic paraboloids:  $a_1^2 x_1^2 + a_2^2 x_2^2 + a_3 x_3 = 0$
7. Hyperbolic paraboloids:  $a_1^2 x_1^2 - a_2^2 x_2^2 + a_3 x_3 = 0$
8. Hyperbolic cylinders:  $a_1^2 x_1^2 - a_2^2 x_2^2 + c^2 = 0$
9. Parabolic cylinders:  $a_1^2 x_1^2 + a_3 x_3 = 0$
10. Simple planes:  $a_3 x_3 + c = 0$

There are other possible imaginary surfaces such as imaginary ellipsoids ( $a_1^2 x_1^2 + a_2^2 x_2^2 + a_3^2 x_3^2 + c^2 = 0$ ) or quadrics that can be made up of two independent planes in various

---

\* The only variance with Olmsted's notation is that the 4th component is labelled as the 0th component in this text.

orientations (e.g. intersection planes  $\alpha_1^2x_1^2 - \alpha_2^2x_2^2 = 0$ , parallel planes  $\alpha_1^2x_1^2 - c^2 = 0$ , and coincident planes  $\alpha_1^2x_1^2 = 0$ ).

For more information on the reduction to canonical form, the reader is encouraged to read Olmsted's book (1947). Olmsted also gives the classification of the surfaces and lists the entire set of 17 canonical quadric forms.

To calculate the intercept distance to an arbitrary quadric surface, consider that the particle's trajectory is given by:

$$\vec{x} = \vec{p} + \vec{\mu}s \quad (5.15)$$

where the starting position of the particle is  $\vec{p} = (p_x, p_y, p_z)$ . A positive value of  $s$  expresses a distance along the direction that the particle is going (forward trajectory), and a negative value is associated with a distance along the direction that the particle came from (backward trajectory). Therefore, negative solutions that are found for  $s$  below will be rejected.

In Monte Carlo particle transport calculations as well as ray-tracing algorithms, a common problem is to find the distance a particle has to travel in order to intersect a surface. This is done by substituting for  $\vec{x}$  from Equation 5.15 in Equation 5.12 to give:

$$s^2 \left( \sum_{i,j=0}^3 \alpha_{ij} \mu_i \mu_j \right) + 2s \left( \sum_{i,j=0}^3 \alpha_{ij} p_i \mu_j \right) + \left( \sum_{i,j=0}^3 \alpha_{ij} p_i p_j \right) = 0 \quad (5.16)$$

where the convention that  $\mu_0 = 0$  and  $p_0 = 1$  has been adopted. This is a quadratic equation in  $s$  of the form  $A(\vec{\mu})s^2 + 2B(\vec{\mu}, \vec{p})s + C(\vec{p}) = 0$  where  $A(\vec{\mu}) = \sum_{i,j=0}^3 \alpha_{ij} \mu_i \mu_j$ ,  $B(\vec{\mu}, \vec{p}) = \sum_{i,j=0}^3 \alpha_{ij} p_i \mu_j$  and  $C(\vec{p}) = \sum_{i,j=0}^3 \alpha_{ij} p_i p_j$ .

The intercept distance is given by the smallest positive solution of the above quadratic equation.

## 5.7 CONCLUSION

This chapter merely skims the surface of the Monte Carlo method as applied to radiotherapy and dosimetry. However, the simplicity of the approach or the power of the method cannot be overstated. With sufficient computational resources, any well-posed question can be answered as accurately as the knowledge of the basic cross-sections allows. Other approaches suffer from systematic uncertainties whose magnitude may be impossible to estimate\*. However, these methods may be useful if the computational time for a Monte Carlo approach is prohibitive. If a computation is feasible by Monte Carlo methods, one is not required to estimate systematic errors, and one may proceed with some confidence to tackle other problems. If one factors in the human effort, ultimately, the Monte Carlo approach may prove to be the most productive.

\* A relevant example is the variety of analytical (i.e. non-Monte Carlo approaches) to computing the dose distributions from megavoltage photon or electron beams required in radiotherapy treatment planning (see Part G) in extremely heterogeneous regions of patient anatomy such as the thorax and the head and neck; this is dealt with in Part F where the limitations of the various methods (pencil-beam, 3D superposition-convolution, etc.) are discussed, and it is then shown (in Chapter 28) how Monte Carlo simulation can overcome these more or less serious approximations involved though generally at the cost of a substantial increase in computation time.

## 6.1 INTRODUCTION

The accurate determination of absorbed dose is crucial to the success of radiotherapy because of the relatively steep sigmoidal dose–response curves for both tumour control and normal-tissue damage. A difference of only a few percent in the dose (to the tumour) may separate uncomplicated tumour eradication from either failure to control the tumour through underdosage or serious normal tissue damage through overdosage (see [Section 37.4.2](#)). There are many different steps involved in the determination of the absorbed dose distribution in the patient. One of the most important of these involves measurements with a detector (often termed a *dosimeter*) in a phantom (often water, sometimes water-like plastic) placed in the radiation field. Such measurements include determining the absolute dose at a reference depth in a reference-size field ([Chapter 18](#)), relative doses at many positions in the phantom in order to map out a complete dose distribution ([Chapter 19](#)), and so-called in-vivo doses on the patient’s skin during treatment ([Section 40.2](#)). In all cases the detector will, via a calibration factor, yield the dose  $D_{\text{det}}$  to its own sensitive material from a quantity of charge, light, film blackening, etc. Generally, the dose is required at a position  $r$  in the medium in the absence of the detector,  $D_{\text{med}}(r)$ . The conversion of  $D_{\text{det}}$  to  $D_{\text{med}}$  is, therefore, a fundamental step and requires a knowledge of the theoretical aspects of radiation dosimetry. The same is true of the calculation of the dose distribution inside the complicated inhomogeneous geometry of the patient (see [Part F](#)).

This chapter covers the fundamental ideas and principles involved in radiation dosimetry, independent of the particular detector being used. The characteristics of the different detectors or dosimeters used in radiotherapy, as well as the numerical values of the relevant quantities, are covered principally in [Part D](#). Comprehensive treatments of the theoretical aspects of radiation dosimetry are given in Greening (1981) and Attix (1986). Kase and Nelson (1978), Johns and Cunningham (1983), Rajan (1992) and Metcalfe et al. (1997) are also very useful references.

It may be thought from the formal definitions of the quantities such as *absorbed dose* and *kerma*, given below, that radiation dosimetry is an old, well-established discipline. In fact, it has a rather tortuous history. Following Röntgen’s discovery of x-rays in 1895, the first radiation unit proposed was based on its ionising power. Christen (1914) was ahead of his time in advocating the quantity *dose* defined as “radian energy per unit volume”. In 1928, the International x-ray Unit Committee defined the *Röntgen* as, “the quantity of x-radiation which, when secondary electrons are fully utilised and the wall effect of the chamber is avoided, produces in one cubic centimetre of atmospheric air at 0°C and 76 cm mercury pressure such a degree of conductivity that one electrostatic unit of charge is measured at saturation current”. This quantity later became known as *exposure* (see [Section 6.3.2](#)).

It was not until 1950 that the International Commission on Radiation Units and Measurements formalised the definition of *dose*, “in terms of the quantity of energy absorbed per unit mass (ergs per gram) of irradiated material at the point of interest” (ICRU 1951). In 1954 the ICRU finally approved the term *absorbed dose*, with the unit being the *rad* which is defined as “100 ergs per gram”. The modern unit, the *gray*, is equal to 100 rad. The meaning and formal definition of absorbed dose was further refined and its modern form (see [Section 6.3.1](#)) was given in ICRU (1980) and carried through to ICRU (1998).

**FIGURE 6.1**

Energy deposited per unit mass, plotted against the mass,  $m$ , of the scoring volume, as this volume is gradually changed in size for a given incident radiation fluence. The shaded portion represents the range where statistical fluctuations become important as the volume (i.e.  $m$ ) is getting smaller. (From Rossi, H. H., *Radiation Dosimetry*, Vol. 1, Academic Press, New York, 1968.)

## 6.2 THE STOCHASTIC NATURE OF ENERGY DEPOSITION

The absorbed dose arises from the deposition of energy in matter by radiation tracks. This is an inherently random process, as [Chapter 3](#) and [Chapter 4](#) make clear. Consider a situation where the energy,  $E$ , deposited in ever decreasing volumes centred on the same point in a uniform medium is determined for a series of irradiations of identical duration. A plot is then made of  $E$ , divided by the mass  $m$  of these volumes for each separate irradiation. Figure 6.1 reflects the anticipated result.

For large volumes (i.e. large  $\log m$ )  $E/m$  has the same value each time\*. Below a certain value of  $m$ , fluctuations start to appear which increase as  $m$  decreases. These are due to the fact that energy is deposited through interactions along particle tracks; some volumes, if small enough, will contain few or no tracks while others may contain many. Therefore, for a given particle fluence (see [Section 6.3.3](#)), at some size of the elementary volume in which we determine the dose in this experiment, the randomness of energy deposition will become apparent.

The absorbed dose discussed in what follows is *non-stochastic*, i.e. it is assumed to be determined in a mass element sufficiently large for the fluctuations to be negligible. The subject of fluctuations in the dose is generally dealt with under the heading of *microdosimetry* (ICRU 1983; Goodhead 1987) and falls outside the scope of this chapter.

## 6.3 DEFINITIONS OF DOSIMETRIC QUANTITIES

### 6.3.1 ABSORBED DOSE

ICRU (1980, 1998) defines *absorbed dose* as the quotient of  $d\bar{\epsilon}$  by  $dm$ , where  $d\bar{\epsilon}$  is the mean energy imparted by ionising radiation to matter of mass  $dm$ :

$$D = \frac{d\bar{\epsilon}}{dm} \quad (6.1)$$

\* The fall off at large values of  $m$  or  $\log m$  corresponds to attenuation of the radiation when the path length across the volume becomes comparable with the mean free path for radiation interactions and is not relevant in this discussion.

The unit of absorbed dose is the *gray* which is 1 Joule per kilogram ( $\text{J kg}^{-1}$ ); the old unit is the *rad* which is  $10^{-2}$  gray (sometimes referred as a centigray).

The *energy imparted*,  $\varepsilon$ , by ionising radiation to the matter in a volume is defined by ICRU (1980, 1998) as:

$$\varepsilon = R_{\text{in}} - R_{\text{out}} + \sum Q \quad (6.2)$$

where

$R_{\text{in}}$  is the sum of the *energies* (excluding rest mass energies) of all those charged and uncharged ionising particles that enter the volume (known as the *radiant energy*)

$R_{\text{out}}$  is the sum of the *energies* (excluding rest mass energies) of all those charged and uncharged ionising particles that leave the volume, and

$\sum Q$  is the sum of all *changes* (decreases: positive sign, increases: negative sign) of the rest mass energy of nuclei and elementary particles in any nuclear transformations that occur in the volume.

Figure 6.2 illustrates the concept of energy imparted. In the left part of the figure which represents a Compton interaction within the volume  $V$ , the energy imparted is given by

$$\varepsilon = h\nu_1 - (h\nu_2 + h\nu_3 + T') \quad (6.3)$$

where  $T'$  is the kinetic energy of the charged particle—of initial kinetic energy  $T$ —upon leaving the volume  $V$ . Note that the photon  $h\nu_4$  does not appear as this is not emitted within the volume  $V$ . The  $\sum Q$  term is not involved here.

The volume on the right in the figure involves  $\gamma$ -ray emission ( $h\nu_1$ ) from a radioactive atom, pair production (kinetic energies  $T_1$  and  $T_2$ ), and annihilation radiation as the positron comes to rest. The energy imparted in this case is given by

$$\varepsilon = 0 - 1.022 \text{ MeV} + \sum Q \quad (6.4)$$

where

$$\sum Q = h\nu_1 - 2m_0c^2 + 2m_0c^2 = h\nu_1 \quad (6.5)$$

In Equation 6.4, the zero is the  $R_{\text{in}}$  term; ‘1.022 MeV’ is the  $R_{\text{out}}$  term comprising the two annihilation  $\gamma$ -rays. The  $\gamma$ -ray energy  $h\nu_1$  arises from a *decrease* in the rest mass of the nucleus; the  $-2m_0c^2$  term is due to the creation of an electron–positron pair, i.e. an *increase* in rest mass

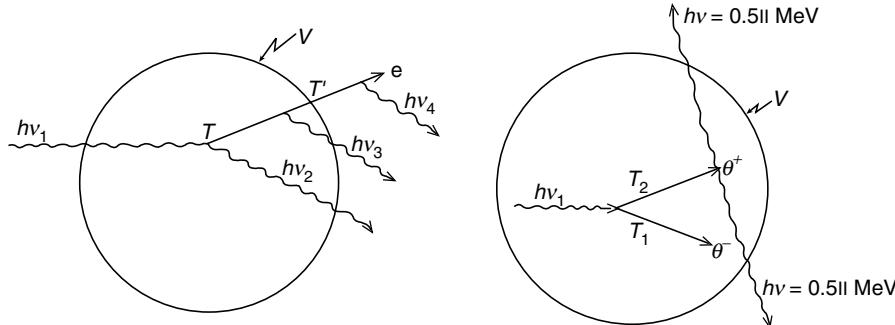

FIGURE 6.2

An illustration of the concept of the energy imparted to an elementary volume by radiation. (From Attix, F. H., *Introduction to Radiological Physics and Radiation Dosimetry*, Wiley, New York, 1986. With permission.)

energy. Finally the  $+2m_0c^2$  term is due to the annihilation of an electron and a positron. Careful thought is required in this example.

Note that the quantity,  $\varepsilon$ , is stochastic, although we require its mean value, which is nonstochastic, in the definition of absorbed dose.

### 6.3.2 KERMA (AND EXPOSURE)

The quantity *kerma*, can be thought of as a step towards absorbed dose. It is conceptually very close to *exposure*, the first radiation quantity to be formally defined (see [Section 6.1](#) and Greening 1981). All practising hospital physicists will come across kerma (in air in a cobalt-60  $\gamma$ -ray beam) in the context of calibrating ionisation chambers at a National Standards Laboratory (see [Section 18.2](#)). The formal definition (ICRU 1980, 1998) follows:

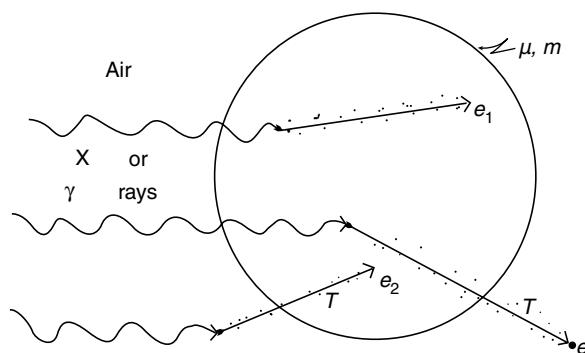

The *kerma*,  $K$ , is the quotient  $dE_{\text{tr}}$  by  $dm$ , where  $dE_{\text{tr}}$  is the sum of the initial kinetic energies of all the charged ionising particles liberated by uncharged ionising particles in a material of mass  $dm$ :

$$K = \frac{dE_{\text{tr}}}{dm} \quad (6.6)$$

The units of kerma are the same as for absorbed dose, i.e.  $\text{J kg}^{-1}$  or gray (Gy). Kerma applies only to indirectly ionising particles which, for our purposes, almost always mean photons, although neutrons also fall into this category.

Exposure is conceptually closely related to *air kerma*. Exposure, usually denoted by  $X$ , is the quotient of  $dQ$  by  $dm$  where  $dQ$  is the absolute value of the total charge of the ions of one sign produced in air when all the electrons (negatrons and positrons) liberated by photons in air of mass  $dm$  are completely stopped in air. Until the late 1970s, all ionisation chambers were calibrated in terms of exposure; subsequently this was replaced by air kerma.

Figure 6.3 illustrates the concept of kerma (and exposure). It is the initial kinetic energies that are involved; the eventual fate of the charged particles (i.e. if they do or do not leave the elementary volume), does not affect kerma. In the volume in the figure, the initial kinetic energies of the two electrons labelled  $e_1$  contribute to the kerma, as both were generated in the volume. The fact that one of these electrons leaves the volume with a residual kinetic energy  $T$  is irrelevant. None of the kinetic energy of the electron *entering* the volume with kinetic energy  $T$  contributes to kerma as this electron was generated *outside* the volume.

**FIGURE 6.3**

Illustration of the concepts of kerma and exposure. (Taken from Attix, F. H., *Introduction to Radiological Physics and Radiation Dosimetry*, Wiley, New York, 1986. With permission.)

It is important to realise that kerma includes the energy that the charged particles will eventually re-radiate in the form of bremsstrahlung photons. Kerma can be partitioned as follows (Attix 1979):

$$K = K_c + K_r \quad (6.7)$$

where c refers to collision losses and r to radiation losses. The collision kerma  $K_c$  is related to the (total) kerma by

$$K_c = K(1 - \mathcal{J}) \quad (6.8)$$

The quantity  $\mathcal{J}$  is the fraction of the initial kinetic energy of the electrons that is re-radiated as bremsstrahlung (in the particular medium of interest)\*.

Exposure and air kerma can be related to each other as follows. Multiplying the charge  $dQ$  (refer to the definition of exposure given above) by the mean energy required to produce one ion pair, divided by the electron charge, i.e.  $W/e$  (see [Section 15.1](#)), yields the collision part of the energy transferred, i.e.  $dE_{tr}(1 - \mathcal{J})$  and therefore

$$X(W/e) = K_{air}(1 - \mathcal{J}) \quad (6.9)$$

or

$$X(W/e) = K_{air,c} \quad (6.10)$$

### 6.3.3 PARTICLE FLUENCE

To calculate absorbed dose we require quantities that describe the radiation field; these are known as ‘field quantities’ (Greening 1981). Particle fluence is a very important basic quantity, involving the number of particles per unit area. The concept is illustrated in [Figure 6.4](#).

Let  $N$  be the expectation value of the number of particles striking a finite sphere surrounding point P (during a finite time interval). If the sphere is reduced to an infinitesimal one at P with a cross sectional area of  $dA$ , then the fluence  $\Phi$  is given by

$$\Phi = \frac{dN}{dA} \quad (6.11)$$

which is usually expressed in units of  $\text{m}^{-2}$  or  $\text{cm}^{-2}$  (ICRU 1980, 1998). Fluence is a *scalar* quantity—the direction of the radiation is not taken into account.

We will be meeting fluence, differential in energy, often written as  $\Phi_E$ :

$$\Phi_E = \frac{d\Phi}{dE} \quad (6.12)$$

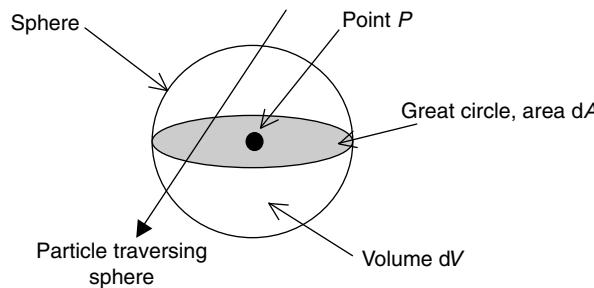

in which case the (total) fluence is given by:

$$\Phi = \int_0^{E_{max}} \Phi_E dE \quad (6.13)$$

It should be noted that fluence can also be expressed as the quotient of the sum of the track

---

\*  $\mathcal{J} \approx 0.003$  in the case of cobalt-60  $\gamma$ -rays in air (IAEA 1997).

**FIGURE 6.4**

Characterization of the radiation field at a point P in terms of the radiation traversing a sphere centred at P. (From Attix, F. H., *Introduction to Radiological Physics and Radiation Dosimetry*, Wiley, New York, 1986.)

lengths  $\Delta s$  of the particles crossing the elementary sphere and the volume of the sphere\* (Chilton 1978):

$$\Phi = \frac{\sum \Delta s}{dV} \quad (6.14)$$

This form is extremely useful when considering so-called *cavity integrals* (see [Section 6.7](#)) which involve evaluating the fluence averaged over a volume.

### 6.3.4 ENERGY FLUENCE

Energy fluence is simply the product of fluence and particle energy. Let  $R$  be the expectation value of the total energy (excluding rest mass energy) carried by all the  $N$  particles in Figure 6.4. Then the *energy fluence*  $\Psi$  is given by (ICRU 1980, 1998)

$$\Psi = \frac{dR}{dA} \quad (6.15)$$

If only a single energy  $E$  of particles is present, then  $R = EN$  and  $\Psi = E\Phi$ .

In a similar fashion, one can define the above quantities per unit of time, i.e. fluence rate and energy fluence rate.

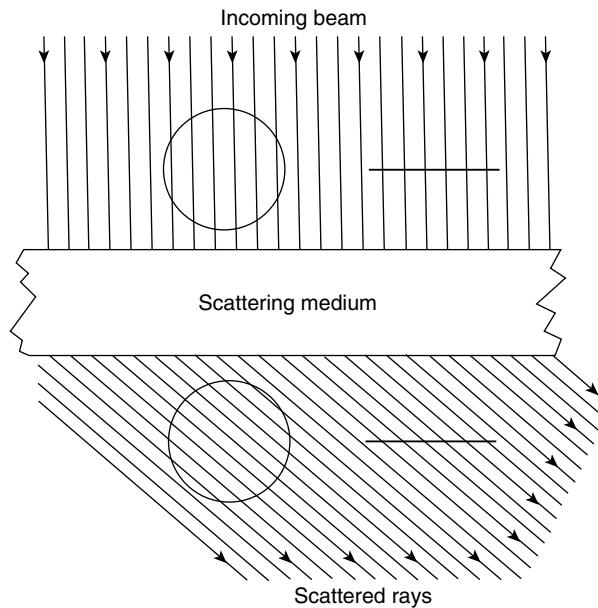

### 6.3.5 PLANAR FLUENCE

*Planar fluence* is the number of particles crossing a fixed plane in either direction (i.e., summed by scalar addition) per unit area of the plane. One can also define a vector quantity corresponding to *net flow* but this is of little use in dosimetry because it requires scalar, not vector, addition of the effects of individual particles.

Planar fluence is a particularly useful concept when dealing with beams of charged particles. In certain situations, e.g. at small depths in a parallel electron beam, one can say that the planar fluence remains constant as the depth increases; whereas, fluence generally increases due to the change in direction of the electron tracks (see [Section 3.6](#)). The difference between the two quantities is illustrated in [Figure 6.5](#).

---

\* This can be proved by noting that, for a sphere of volume  $V$  and external surface  $S$ , the mean chord length is  $4V/S$ .

**FIGURE 6.5**

Schematic 2D illustration of the concept of planar fluence. The number of particles crossing the two horizontal lines (of equal length) is the same. This shows that the planar fluence in the original beam direction remains constant, whereas the fluence, illustrated by the total track length in the two circles, is much greater on the downstream side of the scattering medium.

## 6.4 RELATIONS BETWEEN FLUENCE AND DOSIMETRIC QUANTITIES FOR PHOTONS

This section will relate quantities concerning energy *transferred to* (i.e. kerma) or *deposited in* (i.e. absorbed dose) a medium to the *fluence*, which is a basic description of the radiation field. This will first be done for indirectly ionising particles (i.e. photons) starting with the relation between fluence and kerma (Section 6.4.1), then moving on to fluence and absorbed dose (Section 6.4.2) via the important concept of *charged particle equilibrium* (Section 6.5). Subsequently, the corresponding fluence dose relation for electrons will be derived (Section 6.6). From these fluence absorbed dose relationships we will then be in a position to derive important expressions for detector or dosimeter response, often known as *cavity theory*.

### 6.4.1 RELATION BETWEEN FLUENCE AND KERMA

Consider the schematic Figure 6.6 showing  $N$  photons, each of energy  $E$ , crossing perpendicularly a thin layer (of material  $med$ ) of thickness  $dl$  and area  $dA$ . To extract energy from particle tracks and transfer it to the medium, we require an interaction coefficient. We can use the ICRU (1980, 1998) definition of the mass energy-transfer coefficient  $\mu_{tr}/\rho$  (see Section 4.4.2):

$$\frac{\mu_{tr}}{\rho} = \frac{1}{\rho dl} \frac{dR_{tr}}{R} \quad (6.16)$$

Identifying the fraction of incident radiant energy  $dR_{tr}/R$  as  $dE_{tr}/(N \times E)$ , and making a simple rearrangement, we have

$$dE_{tr} = \mu_{tr} dl / NE \quad (6.17)$$

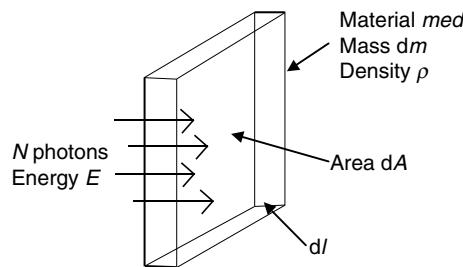

**FIGURE 6.6**

Illustration of  $N$  radiation tracks (photons) of energy  $E$  crossing a thin layer of material *med*, thickness  $dl$ , area  $dA$ , mass  $dm$ , density  $\rho$ .

Then, dividing both sides by the mass of the layer  $dm$  and rearranging again:

$$\frac{dE_{tr}}{dm} = \mu_{tr} E \left[ \frac{Nd l}{dm} \right] \quad (6.18)$$

Replacing  $dm$  by  $\rho \times dV$  we can write:

$$\frac{dE_{tr}}{dm} = \frac{\mu_{tr}}{\rho} E \left[ \frac{Nd l}{dV} \right] \quad (6.19)$$

where we recognise the left hand side as kerma (in medium *med*) and the expression in the square brackets as the sum of the track lengths divided by the volume [i.e. fluence (see [Section 6.3.3](#))], resulting in

$$K_{med} = \left( \frac{\mu_{tr}}{\rho} \right)_{med} E \Phi \quad (6.20)$$

or in terms of energy fluence  $\Psi$ :

$$K_{med} = \left( \frac{\mu_{tr}}{\rho} \right)_{med} \Psi \quad (6.21)$$

Note that the perpendicular incidence in Figure 6.6 was assumed for simplicity; Equation 6.20 and Equation 6.21 are valid for arbitrary angles of incidence\*.

Up to this point, we have confined ourselves to particles crossing the thin layer with a *single* energy. In the more practical case of a spectrum of energies, described by the fluence differential in energy,  $\Phi_E$ , we evaluate the  $K_{med}$  from:

$$K_{med} = \int_0^{E_{max}} E \Phi_E \left( \frac{\mu_{tr}(E)}{\rho} \right)_{med} dE \quad (6.22)$$

where the energy dependence of  $(\mu_{tr}/\rho)_{med}$  has been shown explicitly. Therefore, we have now arrived at a relationship connecting kerma and fluence for photons.

It will also be necessary to calculate the collision kerma,  $K_c$  from photon fluence (see [Section 6.3.2](#)). To do this, one replaces the mass energy *transfer* coefficient  $\mu_{tr}/\rho$  by the mass energy *absorption* coefficient  $\mu_{en}/\rho$ , where *energy absorbed* is defined to exclude that part of the initial kinetic energy of charged particles converted to bremsstrahlung photons (see also

\* This can most easily be seen by considering that fluence is the sum of the track lengths per unit volume, irrespective of their directions (see [Section 6.3.3](#)).

Section 4.4.2). The two coefficients are related by:

$$\mu_{\text{en}} = \mu_{\text{tr}}(1 - \mathcal{J}) \quad (6.23)$$

which is naturally the same factor that relates  $K_c$  and  $K$  (see Section 6.3.2). It therefore follows that:

$$(K_c)_{\text{med}} = \left( \frac{\mu_{\text{en}}}{\rho} \right)_{\text{med}} E \Phi \quad (6.24)$$

and, similarly, for the integral over  $\Phi_E$  in the case of a spectrum of incident photons:

$$(K_c)_{\text{med}} = \int_0^{E_{\text{max}}} E \Phi_E \left( \frac{\mu_{\text{en}}(E)}{\rho} \right)_{\text{med}} dE \quad (6.25)$$

## 6.4.2 RELATION BETWEEN KERMA AND ABSORBED DOSE

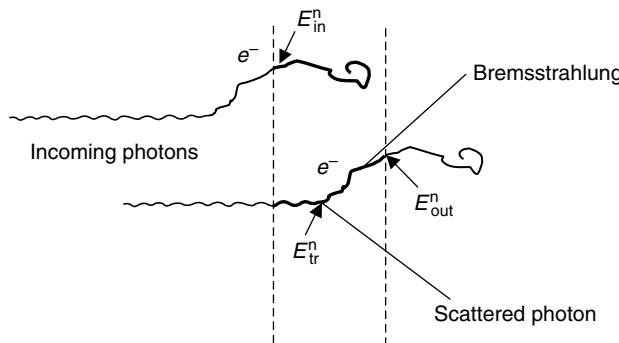

Having established a relationship between kerma and fluence in the previous section, if absorbed dose can be related to kerma then a relationship will finally be established between absorbed dose and fluence for photons. However, the absorbed dose  $D_{\text{med}}$  in medium *med* concerns the (mean) value of energy *imparted* to an elementary volume, whereas kerma concerns energy *transferred* as the charged particles can leave the elementary volume (or thin layer), taking a fraction of the initial kinetic energy with them. This is illustrated in Figure 6.7. Note that the quantity denoted in the figure by  $E_{\text{tr}}^n$  is the *net* energy transferred and excludes that part of the initial kinetic energy converted into bremsstrahlung photons. It is equal to  $E_{\text{tr}}(1 - \mathcal{J})$  as we have seen above.

In Figure 6.7, let the energy *imparted* to the layer be denoted by  $\varepsilon$ , the (net) kinetic energy leaving the layer be denoted by  $E_{\text{out}}^n$  and the (net) kinetic energy entering the layer on charged particles be denoted by  $E_{\text{in}}^n$ . Then, from Equation 6.2, we have:

$$\varepsilon = E_{\text{tr}}^n - E_{\text{out}}^n + E_{\text{in}}^n \quad (6.26)$$

If now the electron track that leaves the layer is replaced by an identical track that enters the layer we can write:

$$E_{\text{in}}^n = E_{\text{out}}^n$$

**FIGURE 6.7**

Schematic illustration of how secondary electrons created by photons can transfer (kinetic) energy  $E_{\text{tr}}^n$  to a thin layer, leave that layer, and also enter the layer from outside. If the energy leaving the layer ( $E_{\text{out}}^n$ ) is exactly replaced by energy entering ( $E_{\text{in}}^n$ ), then *charged particle equilibrium* is said to exist and absorbed dose can be equated to collision kerma. This is schematically represented on the figure, where the full length of the track of a secondary electron is exactly equal to the partial tracks of electrons (in bold) within the layer limits.

It then follows that:

$$\varepsilon = E_{\text{tr}}^n \quad (6.27)$$

The equality between energy leaving and energy entering on charged particles is known as *charged particle equilibrium* (CPE). This can be realised under certain circumstances as is explained in Section 6.5.

Dividing both sides of Equation 6.27 by the mass of the layer or volume element, and changing from stochastic to average quantities, we can write:

$$D_{\text{med}} \stackrel{\text{CPE}}{=} (K_c)_{\text{med}} \quad (6.28)$$

which is a very important result: under the special condition of charged particle equilibrium, the absorbed dose is equal to the *collision kerma*.

Consequently, replacing kerma by absorbed dose in Equation 6.24 and Equation 6.25, for monoenergetic photons it follows that

$$D_{\text{med}} \stackrel{\text{CPE}}{=} \left( \frac{\mu_{\text{en}}}{\rho} \right)_{\text{med}} E \Phi \quad (6.29)$$

and, similarly, for the integral over  $\Phi_E$  in the case of a spectrum of incident photons:

$$D_{\text{med}} \stackrel{\text{CPE}}{=} \int_0^{E_{\text{max}}} E \Phi_E \left( \frac{\mu_{\text{en}}(E)}{\rho} \right)_{\text{med}} dE \quad (6.30)$$

Equation 6.29 and Equation 6.30 are very important relationships in radiation dosimetry; they will be exploited in [Section 6.7.2](#).

## 6.5 CHARGED PARTICLE EQUILIBRIUM

Charged particle equilibrium (CPE), also known as *electronic equilibrium*<sup>\*</sup>, is said to exist in a volume  $V$  in an irradiated medium if each charged particle of a given type and energy leaving  $V$  is replaced by an identical particle of the same energy entering  $V$ .

There are, however, many situations where there is a lack of CPE. Strictly speaking, it is impossible to divide the lack of CPE into separate components (i.e. *longitudinal* or *lateral* disequilibrium). However, this distinction may be useful for a better understanding, especially for high energy photons where the secondary electrons are primarily peaked forward.

[Figure 6.8](#) illustrates schematically how charged particle equilibrium can actually be achieved in a photon beam. Naturally, the figure is a huge oversimplification as in practice there will be a whole spectrum of secondary electron energies and directions. However, the arguments are not essentially altered by showing only one electron starting in each voxel, (labelled A to G in the figure) and travelling in a straight line.

In each voxel, one electron is generated and therefore, the kerma will be constant as it is assumed here that there is no or negligible photon attenuation. Only a fraction of the electron track deposits energy in voxel A; therefore, the dose is low and there is clearly no replacement for the part of the track that leaves the volume. In voxel B a *new* electron starts but here there is also part of the electron track which started *upstream* in voxel A. Hence the dose is higher than in voxel A; in voxel C the dose is higher still. However, in voxel D, where the electron which

\* Other charged particles are involved but, in radiotherapy photon beams, the role of secondary electrons predominates.

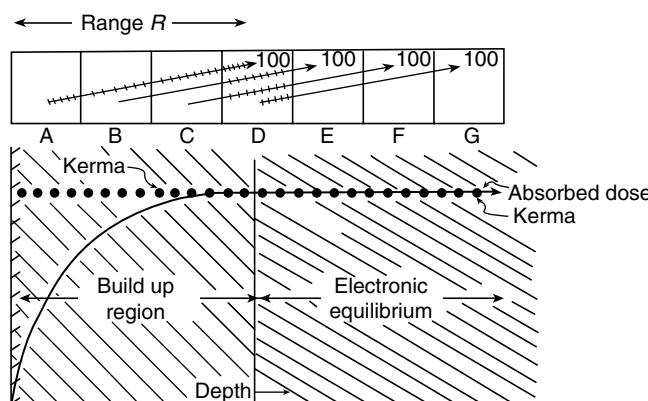

**FIGURE 6.8**

Diagram showing the build up to charged particle equilibrium for the idealised case of no attenuation of the photon beam and one straight electron track generated in each slab labelled A to G. (Taken from Johns, H. E. and Cunningham, J. R., *The Physics of Radiology*, 4th Ed., Charles, C., Ed., Thomas Publisher, Springfield, IL, 1983. With permission.)

started in voxel A comes to rest, all the sections of an electron track are present. This means that the sum of the kinetic energies leaving this volume must be exactly balanced by the sum of the kinetic energies entering and remaining in the volume, i.e. CPE is first attained in D. Subsequent voxels (E, F, G, etc.) will contain patterns of electron tracks identical to those in D and, therefore, CPE must also apply in these volumes. At the depth of voxel D, the absorbed dose is now equal to kerma (strictly this ought to be *collision* kerma) and this will also be the case in the subsequent voxels E, F, G, etc., in the absence of photon attenuation.

In the situation of a photon beam true CPE is strictly impossible to achieve in practice. Attenuation means that the photon fluence does not remain constant and, therefore, the number of secondary particles (electrons) starting at different depths also cannot be constant. Table 6.1 illustrates the degree of photon attenuation in water thicknesses ensuring *transient* electronic equilibrium for photon beams of different energies. The degree of CPE failure increases as the photon energy increases. Consequently, experimental determination of

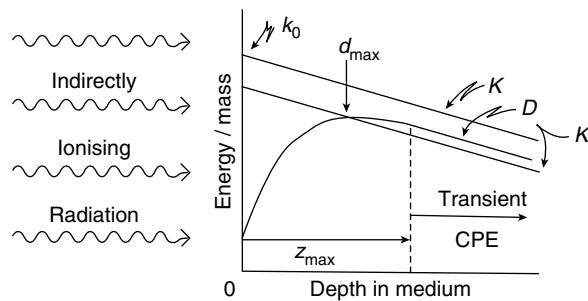

**TABLE 6.1**

Approximate Thickness of Water Required to Establish Transient Charged Particle Equilibrium.

Maximum Energy of Photons (MeV)	Approximate Thickness of Water for Equilibrium (mm)	Approximate Photon Attenuation (%)

**FIGURE 6.9**

Variation of kerma,  $K$ , collision kerma,  $K_c$ , and dose,  $D$ , with depth in a beam of indirectly ionising radiation such as a photon beam. (Taken from Attix, F. H., *Introduction to Radiological Physics and Radiation Dosimetry*, Wiley, New York, 1986. With permission.)

exposure (now air kerma) is not attempted at maximum photon energies above approximately 3 MeV (see [Section 15.3](#)). Even below this energy, small corrections have to be made for the effect of photon attenuation.

Even though strict CPE may not exist, in many situations it is very well approximated, such as at depths beyond the dose maximum in media irradiated by photons below around 1 MeV in energy. At higher energies, the equals sign in [Equation 6.28](#) can be replaced by a proportionality sign. This is then termed *transient charged particle equilibrium* (TCPE):

$$D \stackrel{\text{TCPE}}{\propto} K_c$$

The quantities  $K$ ,  $K_c$  and dose  $D$  are plotted as a function of depth in [Figure 6.9](#). The build-up region and the region of TCPE, where the  $D$  and  $K_c$  curves become parallel to each other are illustrated.

If radiative interactions and scattered photons are ignored it can be shown (Greening 1981) that:

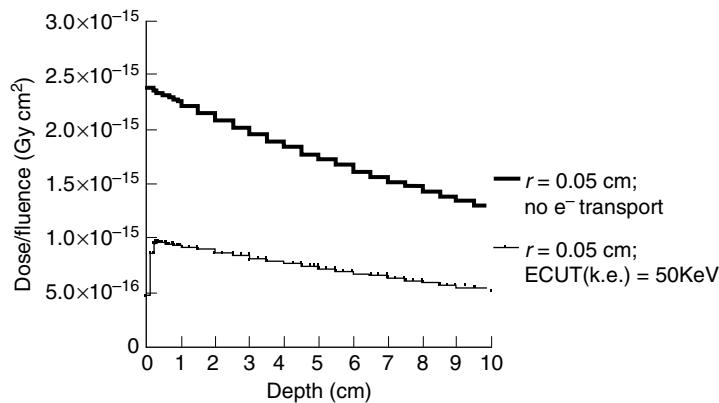

$$D \stackrel{\text{TCPE}}{\approx} K_c(1 + \mu\bar{x}) \quad (6.31)$$

where  $\mu$  is the common slope of the  $D$ ,  $K$  and  $K_c$  curves and  $\bar{x}$  is the mean distance the secondary charged particles carry their energy in the direction of the primary rays while depositing it as dose (Attix 1986). This constant of proportionality between dose and collision kerma is usually denoted by  $\beta$ , i.e.

$$D \stackrel{\text{TCPE}}{=} \beta K_c \quad (6.32)$$

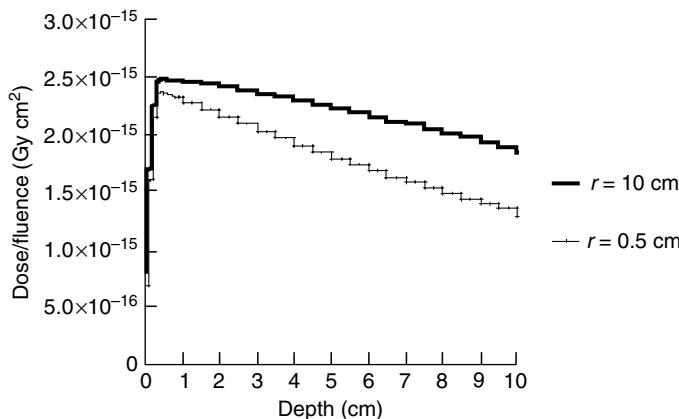

Another situation where the dose is different from the collision kerma because CPE is not achieved is for beams with very small cross sections. [Figure 6.10](#) and [Figure 6.11](#) show the results from a Monte-Carlo simulation (using the EGSnrc code—see [Section 28.2](#)) of depth-dose variation for a cylindrical cobalt-60  $\gamma$ -ray beam (energies 1.17 and 1.33 MeV, equally weighted) incident perpendicularly on the end of a cylinder of water with radius 20 cm and length 50 cm. The dose has been scored along the central axis in cylindrical columns of increasing radii,  $r$ , with 1 mm depth intervals for the first centimetre then 0.5 cm down to 10 cm depth (the results at greater depths are not shown)\*.

\* In [Figure 6.10](#) and [Figure 6.11](#), the doses, in units of gray per unit incident photon fluence ( $\text{Gy cm}^2$ ), have been renormalised so that they can be compared for each of the scoring radii,  $r$ , 0.05 cm, 0.5 cm, and 10.0 cm, by multiplying the doses for the latter two radii by  $\{r(\text{cm})/(0.05)\}^2$ . This converts all three dose distributions, via the so-called reciprocity theorem (e.g. see Nahum 1976; Bielajew 1993), into three mathematically equivalent geometries of beams equal to the actual respective scoring radii, with the dose scored in regions with a radius equal to the actual beam radius. Note however, that the numerical values of dose shown in [Figures 6.10](#) and [6.11](#) have only been rescaled in a relative and not an absolute sense to correspond to these equivalent geometries.

**FIGURE 6.10**

Cobalt-60  $\gamma$ -ray beam in water incident on a water cylinder (radius 20 cm, length 50 cm): depth–dose curves obtained from Monte-Carlo simulation ( $10^8$  photon histories for each case) when the *equivalent* beam radius,  $r$ , is 0.05 cm. A complete description of the geometry of the simulation geometry is given in the text and the normalisation is explained in the footnote. The upper curve, with no transport of secondary electrons, corresponds to the *kerma*. The lower curve includes full electron transport and shows clearly the lack of CPE. (Lasse Rye Aarup, private communication.)

In Figure 6.10 the radius of the scoring volume is very small, 0.05 cm. The upper curve corresponds to *no electron transport* (which is achieved by setting the electron transport cutoff to 0.5 MeV—see Section 5.4); thus the quantity scored corresponds exactly to (water) *kerma*. Upon switching electron transport back on (by simply reducing the electron transport cutoff to a suitably low value: 50 keV was chosen) the buildup of dose in the first 3 mm, due to electron transport, can now be observed. At the same time, however, the absolute value of the dose has fallen by more than a factor 2. Why should this be? The radius of only half a millimetre is in fact equal to only a fraction of the ranges of the highest energy secondary electrons created (virtually 100% of these will be due to Compton interaction—see Section 4.3.2) which is insufficient for the establishment of CPE or, put another way, the electrons will predominantly *leave* the scoring regions without being balanced by an equal number *entering* them, as the beam is so narrow. The absorbed dose is consequently much lower than the kerma in this very special geometry.

**FIGURE 6.11**

Depth-dose curves obtained for cobalt-60  $\gamma$ -ray beams from Monte-Carlo simulation ( $10^8$  photon histories) with equivalent radii,  $r$ , of 0.5 and 10.0 cm incident on a water cylinder (radius 20 cm, length 50 cm) with full electron transport (ECUT—KE=50 keV). The increased dose and reduced effective attenuation for the larger radius is due to photon (Compton) scatter. (Lasse Rye Aarup, private communication.)

In Figure 6.11, the equivalent beam radii,  $r$ , are 0.5 cm and 10.0 cm, respectively. The depth-dose curve for the larger radius lies considerably above that for the smaller one. The latter was chosen to be large enough for the establishment of (partial) CPE. The reduced effective attenuation at the larger beam radius is explained by an increasing build-up of Compton-scattered photons with depth. The dependence of depth-dose curves on field size is a well-known and important phenomenon in external-beam radiotherapy (see Chapter 22).

It must be stressed that for large collimated beams where CPE is achieved on the beam axis, it is still partially lost at the edge, which contributes to enlarging the penumbra region (see Section 22.3.3.2).

## 6.6 RELATION BETWEEN FLUENCE AND DOSE FOR ELECTRONS

### 6.6.1 STOPPING POWER AND CEMA

The previous two sections have concerned indirectly ionising particles, i.e. photons. In this section, equivalent relationships will be derived between charged particle fluence (i.e. electrons) and absorbed dose. Referring back to Figure 6.6, consider that we now have  $N$  electron tracks incident perpendicularly on the thin layer of medium *med* and thickness  $dl$ , etc. Instead of the mass energy-transfer coefficient for photons, for charged particles the quantity of relevance is *stopping power*, the energy lost per unit track length (see Chapter 3) and we denote this energy by  $dE_l$  to distinguish it from  $dE_{tr}$ , which is used for indirectly ionising radiation. We are interested in energy locally deposited in the thin layer so it is clearly appropriate to employ the collision stopping power,  $S_{col}$ , rather than the total stopping power as the latter would include the energy lost in the form of bremsstrahlung that would escape the thin layer (this is analogous to the difference between kerma and collision kerma). Thus we can write

$$dE_l = S_{col} dl/N \quad (6.33)$$

Note that, unlike the analogous Equation 6.17 for photons, we do not need the energy of the particles. Dividing both sides by the mass of the layer  $dm$  and expressing this as  $\rho \times dV$  on the right hand side, we obtain

$$\frac{dE_l}{dm} = \frac{S_{col} N dl}{\rho dV} \quad (6.34)$$

which can be rearranged to give:

$$\frac{dE_l}{dm} = \frac{S_{col}}{\rho} \left[ \frac{N dl}{dV} \right] \quad (6.35)$$

where, as in the case of indirectly ionising radiation, the quantity in the square brackets is the fluence  $\Phi$  and therefore:

$$\frac{dE_l}{dm} = \frac{S_{col}}{\rho} \Phi \quad (6.36)$$

Until recently, there was no equivalent of *kerma* for the case of charged particles. However, the quantity *cema*, converted energy per unit mass, was proposed by Kellerer et al. (1992). ICRU (1998) defines *cema* as the energy lost by charged particles, excluding secondary electrons, in electronic collisions in a mass  $dm$  of a material. ‘Secondary electrons’ refer to the delta rays generated by the incident primary electrons (see [Section 3.2](#)), and their kinetic energies have already been included in  $dE_l$ . Therefore, cema is equal to  $dE_l/dm$  and, consequently, to the product of electron fluence and mass collision stopping power.

*Cema* is not necessarily equal to *absorbed dose*, as some of the delta rays can leave the thin layer, just as secondary electrons can do in the case of the primary radiation being photons ([Figure 6.7](#)). To involve absorbed dose, it must follow that any charged particle kinetic energy *leaving* the thin layer or elementary volume is replaced by an exactly equal amount *entering* the layer and being deposited in it or imparted to it. Consequently, it must be assumed that there is *delta-ray equilibrium* in order to be able to equate cema with absorbed dose and therefore we can write, for a medium  $m$ :

$$D_m \stackrel{\delta\text{-eqm}}{=} \Phi \left( \frac{S_{\text{col}}}{\rho} \right)_m \quad (6.37)$$

or, in the case of polyenergetic electron radiation:

$$D_m \stackrel{\delta\text{-eqm}}{=} \int_0^{E_{\max}} \Phi_E \left( \frac{S_{\text{col}}(E)}{\rho} \right)_m dE \quad (6.38)$$

where  $\Phi_E$  is the fluence, differential in energy (see [Section 6.3.3](#)).

## 6.6.2 DELTA-RAY EQUILIBRIUM

Naturally, delta-ray equilibrium must always exist if charged particle equilibrium exists. However, where the primary radiation consists of charged particles CPE can never be achieved except in the rather special case of uniformly distributed  $\beta$  sources in a large medium. For the beams of high-energy electrons used in radiotherapy, the energy of the primary electrons decreases continuously with depth and hence there cannot be equilibrium. However, the ranges of the delta rays are predominantly extremely short (see [Section 3.2](#)) and almost all the energy transferred through collision losses, i.e. the cema, is deposited locally. One need only look at how close the ratio  $L_d/S_{\text{col}}$  is to unity for very small values of  $d$  to be convinced of the above ([Figure 3.8](#)), i.e. most of the collisions result in very small energy losses and electrons with these low energies have extremely short ranges. Thus, delta-ray equilibrium is generally fulfilled to a high degree in media irradiated by electron beams.

One situation where delta-ray equilibrium is definitely not a good approximation, however, is very close to the phantom surface in an electron beam. The appreciable range in the forward direction of the most energetic delta rays results in a small but discernible *delta-ray build up* (see [Figure 3.16](#))\*.

---

\* As illustrated in [Figure 3.16](#) and [Figure 6.5](#), the increase in primary electron fluence due to increasing obliquity of the tracks is the main reason for the dose increase with depth for an electron beam.

## 6.7 CAVITY THEORY

### 6.7.1 GENERAL

When a measurement is made with a detector, the detector material will, in general, differ from that of the medium into which it is introduced. As mentioned in [Section 6.1](#), the signal from a radiation detector will generally be proportional to the energy absorbed in its sensitive material and thus to the absorbed dose in this material,  $D_{\text{det}}$ . The step from the *raw* detector signal to  $D_{\text{det}}$  at some reference radiation quality, generally known as *calibration*, for the various detectors of interest, is dealt with in [Part D](#) and will not be covered further here.

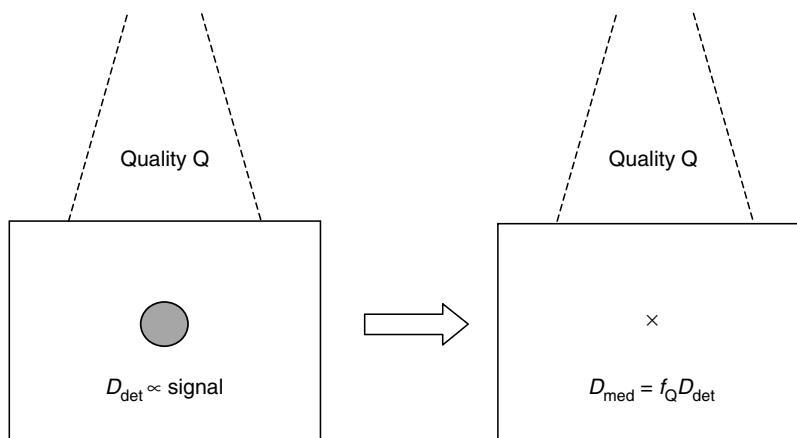

The detector can be thought of as a *cavity* introduced into the uniform medium of interest; this name stems from the fact that gas-filled ionisation chambers dominated the development of the subject (Greening 1981) and the associated theory, which relates  $D_{\text{det}}$  to  $D_{\text{med}}$ , is known as *cavity theory*. In its most general form, the aim of cavity theory is to determine the factor  $f_Q$  given by

$$f_Q = \left( \frac{D_{\text{med}}}{D_{\text{det}}} \right)_Q \quad (6.39)$$

for an arbitrary detector ‘det’, in an arbitrary medium ‘med’, and in an arbitrary radiation quality Q (here, photons or electrons). Figure 6.12 illustrates the situation schematically.

This section contains the key ideas and expressions as far as applying cavity theory to practical radiotherapy dosimetry is concerned. The treatment relies heavily on the results obtained in the previous sections, and is very much based on the concept of particle fluence. For a much more detailed treatment following more traditional lines, Burlin (1968) makes very interesting reading.

The two most important situations where it is possible to derive an exact expression for  $f_Q$  will now be considered. The first of these, presented below, is that of a so-called large detector in a photon-irradiated medium. The term large refers to its size in relation to the ranges of the secondary particles, i.e. electrons. The well-known Bragg–Gray cavity situation then follows in [Section 6.7.3](#).

**FIGURE 6.12**

The general situation of a detector introduced into a medium (left), yielding  $D_{\text{det}}$  for a given exposure to radiation of quality Q and then being converted into the dose  $D_{\text{med}}$  at X in the absence of the detector by multiplying by the cavity theory factor  $f_Q$ .

## 6.7.2 CAVITY THEORY FOR LARGE PHOTON DETECTORS

Let us imagine that the radiation beam in Figure 6.12 consisting for simplicity of mono-energetic photons is incident on a phantom of material, med, and has energy fluence  $\psi$  at the depth of interest  $z$ . Provided that this depth is sufficient for CPE to be established, then using Equation 6.29 the dose in the medium at depth  $z$  can be written as

$$D_{\text{med},z} \stackrel{\text{CPE}}{=} \Psi_{\text{med},z} \left( \frac{\mu_{\text{en}}}{\rho} \right)_{\text{med}} \quad (6.40)$$

Suppose now that a detector is placed with its centre at depth  $z$  and that the sensitive material of the detector, denoted by ‘det’, is large enough for there to be charged particle equilibrium in this material, i.e. that its extent is greater than the maximum range of the secondary electrons generated in this material. Figure 6.13 illustrates the situation schematically.

The photons interact with the detector material and produce secondary electrons tracks (changes in the photon direction/energy have been ignored for simplicity in the figure). Within a narrow rind region on either side of the detector wall (labelled ‘boundary’) there is no CPE, as electrons there are generated partly in the surrounding medium, partly in the material of the detector wall (which may or may not be present) and partly in the detector itself. In the detector material away from the *boundary* CPE will be re-established. The absorbed dose in the detector, with the bar indicating that this is an average over the detector volume, will be given by:

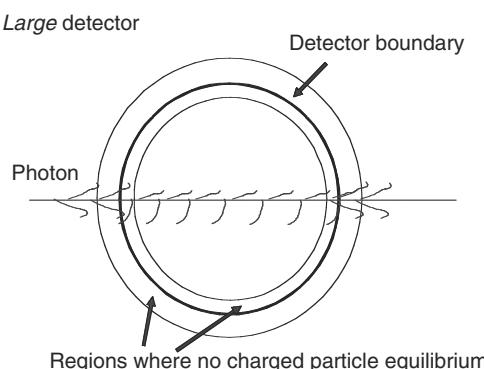

$$\bar{D}_{\text{det}} \stackrel{\text{CPE}}{=} \Psi_{\text{det},z} \left( \frac{\mu_{\text{en}}}{\rho} \right)_{\text{det}} \quad (6.41)$$

where the energy fluence is that in the detector material (strictly an average over the detector volume) and the mass-energy absorption coefficient applies to the detector material ‘det’. It is clear that the large detector condition is fulfilled when the volume of the no-CPE rind is only a small fraction of the total volume of the sensitive material of the detector.

Combining Equation 6.40 and Equation 6.41 we have

$$\frac{D_{\text{med}}}{\bar{D}_{\text{det}}} = \frac{\Psi_{\text{med},z} (\mu_{\text{en}}/\rho)_{\text{med}}}{\Psi_{\text{det},z} (\mu_{\text{en}}/\rho)_{\text{det}}} \quad (6.42)$$

Assuming further that the detector does not disturb the photon (energy) fluence existing in the medium, i.e.  $\Psi_{\text{det},z} = \Psi_{\text{med},z}$  then the ratio of the absorbed doses, or the cavity theory factor  $f_Q$ ,

**FIGURE 6.13**

The deposition of energy by photons (simplified to a single photon unusually represented by a straight line) in a *large* detector. The short tracks represent secondary electrons with ranges much less than any dimension of the detector.

is given by

$$f_Q = \frac{D_{\text{med},z}}{\bar{D}_{\text{det}}} = \frac{(\mu_{\text{en}}/\rho)_{\text{med}}}{(\mu_{\text{en}}/\rho)_{\text{det}}} \quad (6.43)$$

In all practical situations, there will be a spectrum of photon energies. This will be true even for a monoenergetic photon source as scattered photons of lower energy will be present at a depth in the medium. The dose ratio is then given by:

$$\frac{D_{\text{med},z}}{\bar{D}_{\text{det}}} = \frac{\int_0^{E_{\text{max}}} E \frac{d\Phi_{\text{med},z}}{dE} \left( \frac{\mu_{\text{en}}(E)}{\rho} \right)_{\text{med}} dE}{\int_0^{E_{\text{max}}} E \frac{d\Phi_{\text{med},z}}{dE} \left( \frac{\mu_{\text{en}}(E)}{\rho} \right)_{\text{det}} dE} \quad (6.44)$$

This ratio, often written in shorthand form as

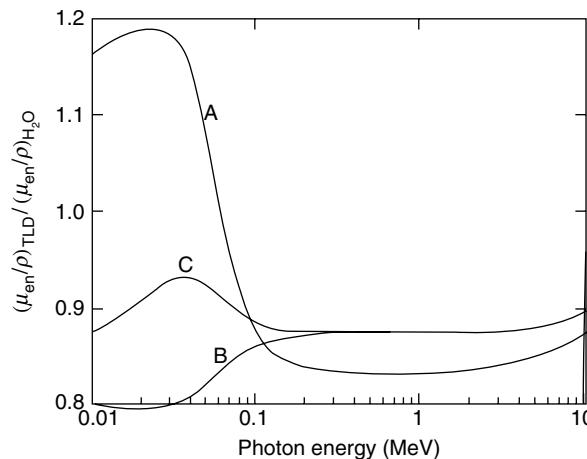

$$\frac{D_{\text{med}}}{\bar{D}_{\text{det}}} = (\bar{\mu}_{\text{en}}/\rho)_{\text{med,det}} \quad (6.45)$$

is the well-known mass–energy absorption coefficient ratio.

In general, the photon fluence spectrum at a depth in the medium can only be obtained by using Monte-Carlo simulation (see [Chapter 5](#) and [Chapter 28](#)).

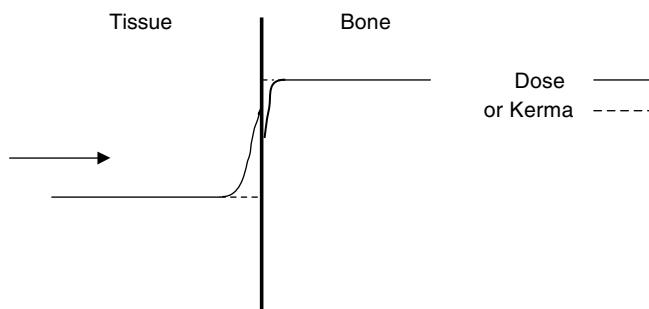

It should be noted that the detector should not be large with respect to the attenuation of photons within it; i.e. to the photon mean free path  $s=1/\mu$ , otherwise, it would be impossible to fulfil the requirement that the energy fluence in the detector is negligibly different from that in the medium. In such cases, it will be necessary to add a correction or perturbation factor for the differences in photon attenuation due to the detector thickness (i.e. its dimension in the beam direction) and an equal thickness of the medium. Mobit et al. (2000) have made a detailed Monte-Carlo based study of this problem.

An example of a large detector situation is the use of small thermoluminescent dosimeters (TLDs) (see [Section 16.2](#)) in kilovoltage photon fields; the maximum secondary electron range for kV x-rays in the common TLD material lithium fluoride is of the order of 0.5 mm (i.e. less than the dosimeter thickness). Figure 6.14 shows how the mass–energy absorption coefficient

**FIGURE 6.14**

Variation of the mass–energy absorption coefficient ratio relative to water for different TLD materials. (A) Lithium fluoride, (B) Lithium tetraborate  $\text{Li}_4\text{B}_4\text{O}_7$ , (C)  $\text{Li}_2\text{B}_4\text{O}_7 + 0.3\%$  Mn. (From Greening, J. R., *Fundamentals of Radiation Dosimetry*, Adam Hilger, Bristol, 1981. With permission.)

**FIGURE 6.15**

Variation of absorbed dose at an interface between soft tissue and bone, irradiated by kilovoltage photons but assuming negligible photon attenuation. There is charged particle equilibrium in both media except very close to the interface, where electron scattering effects will occur. The dashed lines indicate kerma where it differs from absorbed dose.

ratio (Equation 6.43) varies with photon energy for three different thermoluminescent materials. The rapid variation below around 100 keV is due to the marked dependence of the photoelectric effect on atomic number (see Section 4.3.1). The virtually flat portion of the curves corresponds to the energy region where the Compton effect dominates, i.e. the interaction coefficients only depend upon electron density (see Section 4.3.2).

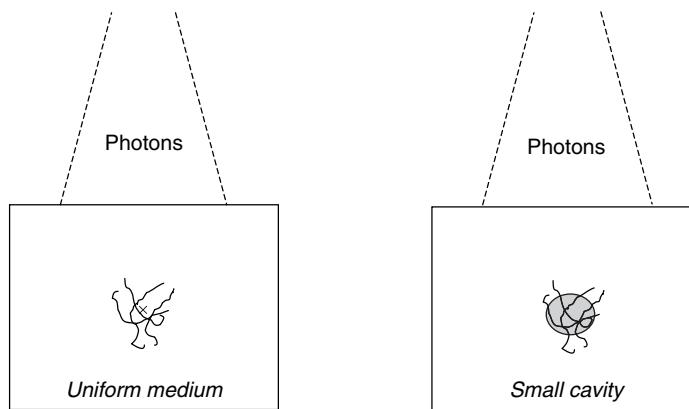

The large photon cavity result can be exploited to calculate the change in the absorbed dose close to an interface, e.g. going from tissue to bone in a patient irradiated by a low-energy x-ray beam. Figure 6.15 is only schematic; the effect of photon attenuation, which is appreciable at low energies, has not been shown. In Figure 6.15, the *equilibrium* dose levels in the tissue and the bone will be proportional to  $(\bar{\mu}_{en}/\rho)_{tissue}$  and  $(\bar{\mu}_{en}/\rho)_{bone}$ , respectively (evaluated over the photon spectrum). Extremely close to (i.e. within an electron range of) the interface there will not be CPE; the increased electron backscattering from the bone, due to its higher effective atomic number (see Section 3.5), produces the complicated behaviour indicated. Kerma, which is unaffected by electron transport, is also shown. The reader will understand after studying Section 6.7.3 that the ratio of the doses *exactly* on either side of the interface will be given by the (mass) stopping-power ratio as here it is the *electron* fluences which must be equal. Johns and Cunningham (1983) is recommended for more details on interface effects in photon beams.

In the megavoltage energy range, the appreciable ranges of the secondary electrons make it impossible for radiation detectors to fulfil the *large* photon detector condition without becoming impractically large. Nevertheless, the  $(\mu_{en}/\rho)$ -ratio will be encountered again in, Chapter 15 and Chapter 18 as a component in the correction factor for the wall materials of ionisation chambers.

### 6.7.3 BRAGG–GRAY CAVITY THEORY

We will now focus on a very different class of detector, one that is *small* compared to the ranges of the secondary electrons. Consider the situation shown in Figure 6.16. Photons irradiate the uniform medium on the left and the tracks of several secondary electrons are shown. On the right a detector has been introduced which is small enough so as not to disturb the electron tracks.

In this case, the extent of the detector in any direction represents only a tiny fraction of the buildup depth required for the establishment of charged particle equilibrium (cf. Figure 6.8). Therefore, we cannot derive the absorbed dose in this small detector from the product of photon energy fluence and  $(\mu_{en}/\rho)_{det}$ . Instead, it is much more logical to use the relationship between electron fluence and absorbed dose. In this small-detector case, it is precisely the *electron* fluence that connects the detector and undisturbed-medium situations.

**FIGURE 6.16**

An illustration of the behaviour of a small detector in a photon-irradiated medium. On the left, some of the secondary electron tracks close to the point of interest  $x$  are shown. The introduction of the small detector (on the right) does not disturb these tracks. Such detectors are known as *Bragg–Gray cavities*.

It therefore follows from Equation 6.37 that at the depth  $z$  in the medium:

$$\frac{D_{\text{med},z}}{\bar{D}_{\text{det}}} = \frac{\Phi_{\text{med},z} (S_{\text{col}}/\rho)_{\text{med}}}{\Phi_{\text{det}} (S_{\text{col}}/\rho)_{\text{det}}} \quad (6.46)$$

If we assume that the introduction of the detector does not disturb the electron fluence existing in the undisturbed medium, i.e.

$$\Phi_{\text{det}} = \Phi_{\text{med},z} \quad (6.47)$$

then the fluences in Equation 6.46 cancel out, yielding

$$\frac{D_{\text{med}}}{\bar{D}_{\text{det}}} = \frac{(S_{\text{col}}/\rho)_{\text{med}}}{(S_{\text{col}}/\rho)_{\text{det}}} \quad (6.48)$$

The above expression is known as the (mass) *stopping-power ratio*, often written simply as  $s_{\text{med},\text{det}}$ .

In all practical cases there will be a spectrum of electron energies and the stopping-power ratio must be evaluated from

$$\frac{D_{\text{med}}}{\bar{D}_{\text{det}}} = s_{\text{med},\text{det}}^{\text{BG}} = \frac{\int_0^{E_{\text{max}}} (\Phi_E)_{\text{med},z} (S_{\text{col}}(E)/\rho)_{\text{med}} dE}{\int_0^{E_{\text{max}}} (\Phi_E)_{\text{med},z} (S_{\text{col}}(E)/\rho)_{\text{det}} dE} \quad (6.49)$$

where the energy dependence of the collision stopping power has been made explicit and it is understood that  $(\Phi_E)_{\text{med},z}$  refers to the medium *in the absence of the detector* in both the numerator and the denominator. It must be stressed that this is the fluence of *primary* electrons only; no delta-rays are involved (see Section 6.7.4). For reasons that will become apparent in the next paragraph, it is convenient to denote the stopping-power ratio evaluated according to Equation 6.49 by  $s_{\text{med},\text{det}}^{\text{BG}}$  (Nahum 1978; ICRU 1984b).

Detectors that behave in the above fashion in photon-irradiated media, i.e. that respond to, but do not disturb, the electron fluence that exists in the absence of any detector, are known as *Bragg–Gray cavities* after the pioneering work of Bragg (1912) and Gray (1929, 1936). As we have seen in the introduction to this chapter, gas-filled detectors dominated all the early radiation measurement techniques. Bragg presented qualitative arguments and Gray reasoned in a more quantitative way that a small gas-filled cavity ought to negligibly modify the number, energy, and direction of electrons present in a photon-irradiated medium (there were no electron beams at the time). Gray showed that the ratio of energy *lost* per unit mass in the medium to that in the gas was equal to the ratio of mass stopping powers  $s_{\text{med,gas}}$  and then assumed further that ratio of energy *absorbed* in the respective media was also equal to  $s_{\text{med,gas}}$ . This is equivalent to assuming delta-ray equilibrium and is discussed further in [Section 6.7.4](#).

In radiotherapy we also deal with electron beams. In this case, the *primary* particles are electrons and there are no photon-generated secondary electrons (ignoring the small bremsstrahlung contribution). Thus the Bragg–Gray idea can easily be extended to detectors in electron beams—see below.

In order for a detector to be treated as a Bragg–Gray (B–G) cavity there is really only one condition which must be fulfilled:

*The cavity must not disturb the charged particle fluence (including its distribution in energy) existing in the absence of the cavity.*

In practice this means that the cavity must be small compared to the electron ranges, and in the case of photon beams, only *gas*-filled cavities, i.e. ionisation chambers fulfil this.

Generally a second condition is added:

*The absorbed dose in the cavity is deposited entirely by the charged particles crossing it.*

Now this means that any contribution to the dose due to photon interactions in the cavity must be negligible—clearly this only applies to photon beams. In many ways it is a corollary to the first condition. If the cavity is *small* enough to fulfil the first condition then the buildup of dose due to interactions in the cavity material itself has to be negligible; if this is not the case then the charged particle fluence will differ from that in the undisturbed medium for this very reason.

A third condition is sometimes added:

*Charged particle equilibrium must exist in the absence of the cavity.*

This condition is only of historical interest; Greening (1981) stated that Gray's original theory required this. In fact, provided that the stopping-power ratio is evaluated over the charged particle (i.e. electron) spectrum *at the position of the detector*, then CPE is *not* required. Nor in the electron beams used in radiotherapy is there ever CPE as has already mentioned. Gray and other early workers required this condition as they did not have the theoretical tools to evaluate  $\Phi_E$  in [Equation 6.49](#), except in the CPE situation, as Attix (1986) points out.

The air-filled ionisation chamber of the dimensions used in radiotherapy (see [Chapter 15](#)) irradiated by a *megavoltage* photon beam is a clear case of a Bragg–Gray cavity. The same is true for electron beams. But can we say the same for kilovoltage x-ray beams? (see [Section 18.6](#)) [Table 6.2](#) gives values of  $F_{\text{air}}^{\text{spec}}$ , the ratio of the dose to the air due to photon interactions (in the air cavity) to the equilibrium dose\* in the cavity for a plane-parallel ionisation chamber of typical dimensions, calculated by Monte-Carlo simulation (Ma and Nahum 1991). In a Bragg–Gray cavity,  $F_{\text{air}}^{\text{spec}}$  ought to be close to zero. It can be seen in the table that this is clearly true for the  $^{60}\text{Co}$   $\gamma$ -ray and 4 MV x-ray qualities but is definitely not the case for any of the kilovoltage x-ray

---

\* The dose corresponding to a *thick* wall, i.e. for which full buildup is achieved by the wall alone cf. ion chamber buildup caps (see [Section 15.3.2.2](#)).

**TABLE 6.2**

Calculated Dose Ratio  $F_{\text{air}}^{\text{spec}}$ , Direct Photon Interactions/Total Cavity Dose, for an Air Cavity Exposed to Different Photon Beam Qualities

Incident Beam		$F_{\text{air}}^{\text{spec}}$ (in vacuum)	$F_{\text{air}}^{\text{spec}}$ (5 cm depth in water)
Tube Potential	HVL (mm Al)		
50 kV	1.62	0.26	0.18
150 kV	5.01	0.27	0.29
240 kV	7.30	0.27	0.27
240 kV	17.4	0.18	0.23
$^{60}\text{Co}$		0.0037	0.0060
4 MV		0.0014	0.0098

The air cavity is a 6mm diameter and 6mm thick cylinder, located either in vacuum or at a depth of 5cm in water.  $F_{\text{air}}^{\text{spec}}$  is  $\ll$  in a Bragg–Gray Cavity.

Source: From Ma, C.-M. and Nahum, A. E., *Phys. Med. Biol.*, 36, 413–428, 1991. With permission.

qualities. Thus it is not possible to say that air-filled ion chambers behave as true *Bragg–Gray* cavities in any kilovoltage x-ray beam.

#### 6.7.4 THE SPENCER–ATTIX MODIFICATION OF BRAGG–GRAY THEORY

In Section 6.7.3, we neglected the question of delta-ray equilibrium, which is a pre-requisite for the strict validity of the stopping-power ratio as evaluated in Equation 6.49. The original Bragg–Gray theory effectively assumed that all collision losses resulted in energy deposition within the cavity; another way of expressing this is that the charged particles should lose energy by *continuous slowing down*, i.e. in a large number of extremely small energy-loss events. In fact, Greening (1981) made this one of the conditions for Gray’s cavity theory.

Experiments by Attix et al. (1958) amongst others with flat air-filled ion chambers with walls made of C, Al, Cu, Sn and Pb, ranging from low and air-like to high atomic numbers, showed clearly that the ionisation density (i.e. per unit mass of gas) depended on the wall separation (that was varied from tenths of a millimetre to 10 mm) in the 412 keV  $\gamma$ -rays from  $^{198}\text{Au}$ . Such a dependence should not exist in Bragg–Gray cavities. At the time it was suggested that the reason for this was delta ray production.

Spencer and Attix (1955) proposed an extension of the Bragg–Gray idea that took account of, in an approximate manner, the effect of the finite delta ray ranges. In their theory all the electrons above a cutoff energy  $\Delta$ , whether primary or delta rays, were considered to be part of the fluence spectrum incident on the cavity. All energy losses in the cavity below  $\Delta$  in energy were assumed to be *local* to the cavity and all losses above  $\Delta$  were assumed to escape entirely. The size of  $\Delta$  is related to the size of the cavity; Spencer and Attix suggested that  $\Delta$  be set equal to the energy of electrons with a range (in the cavity material, i.e. air) just sufficient to cross the cavity\*. The local energy loss was calculated by using the collision stopping power restricted to losses less than  $\Delta$ ,  $(dE/dS)_{\text{col},\Delta}$ , usually denoted by  $L_\Delta$  (see Section 3.2.5).

\* This is impossible to define uniquely even if the cavity is spherical, given the various directions that electrons will enter the gas volume. Generally, however,  $s_{\text{water},\text{air}}^{\text{SA}}$  only varies slowly with  $\Delta$ , which is conventionally set to 10 keV for the ionisation chambers used in radiotherapy. However, Buckley et al. (2003) found that  $\Delta=16$  keV corresponded to the mean chord length for a cylindrical ion chamber of Farmer dimensions (air cavity 6.3 mm in diameter and 2 cm in length) and that this value provided significantly better agreement between Spencer–Attix theory and Monte-Carlo simulation than assuming  $\Delta=10$  keV.

This approximate 2-component model leads to a stopping-power ratio given by (Nahum 1978, ICRU 1984b):

$$\frac{D_{\text{med}}}{\bar{D}_{\text{det}}} = \frac{\int_{\Delta}^{E_{\text{max}}} \Phi_E^{\text{tot}}(L_{\Delta}(E)/\rho)_{\text{med}} dE + [\Phi_E^{\text{tot}}(\Delta)(S_{\text{col}}(\Delta)/\rho)_{\text{med}}\Delta]}{\int_{\Delta}^{E_{\text{max}}} \Phi_E^{\text{tot}}(L_{\Delta}(E)/\rho)_{\text{det}} dE + [\Phi_E^{\text{tot}}(\Delta)(S_{\text{col}}(\Delta)/\rho)_{\text{det}}\Delta]} \quad (6.50)$$

The electron fluence has been denoted by  $\Phi^{\text{tot}}$  to emphasise that (all generations of) delta rays must be included. The term in square brackets accounts for the energy deposition by those electrons falling below  $\Delta$  in energy, the so-called *track-end term* (Nahum 1976, 1978; ICRU 1984b);  $\Phi_E^{\text{tot}}(\Delta)$  is the fluence, differential in energy, evaluated at energy  $\Delta^*$ . The shorthand form established in ICRU (1984b) for the Spencer–Attix stopping-power ratio is  $s_{\text{med,det}}^{\text{SA}}$ .

The use of  $s_{\text{med,det}}^{\text{SA}}$  instead of the conventional Bragg–Gray ratio based on the unrestricted stopping power,  $s_{\text{med,det}}^{\text{BG}}$ , was shown to result in improved agreement with experiment (Greening 1957; Attix et al. 1958; Burlin 1962). However, for cases where the atomic composition, and hence the mean atomic number,  $Z$ , of the cavity and the medium are quite similar (e.g. air and water), there is only a small difference between  $s_{\text{med,det}}^{\text{SA}}$  and the simpler  $s_{\text{med,det}}^{\text{BG}}$ . For example, for  $\Delta=10$  keV, Nahum (1978) showed that  $s_{\text{water,air}}^{\text{SA}}$  was generally about 1% higher than  $s_{\text{water,air}}^{\text{BG}}$  for megavoltage photon and electron beams.

The use of the Spencer–Attix expression implies that the electron fluence in the cavity and in the medium are identical only down to energy  $\Delta$ , but not necessarily below this. This is in principle an easier condition to fulfil than the original Bragg–Gray one where the fluences must be identical down to the lowest electron energies present in the fluence spectrum. In fact, at energies below  $\Delta$  the electron fluence in the cavity material will be largely determined by delta rays generated in the cavity material itself as their ranges will be smaller than the cavity dimensions.

Should we expect that  $s_{\text{med,det}}^{\text{SA}}$  tends towards  $s_{\text{med,det}}^{\text{BG}}$  for large cavities (i.e. large  $\Delta$ ) or for small cavities (i.e. small  $\Delta$ )? In fact, it is large cavities that most closely correspond to the simpler unrestricted BG ratio (Nahum 1976; Attix 1986). This is reasonable as it is largely primary electrons which deposit energy in *large* cavities, most delta rays having ranges which are small compared to the cavity size which corresponds better to the implicit BG assumption of negligible delta ray range. If the cavity is very small, however, then delta rays generated in the surrounding medium will be responsible for a much greater fraction of the cavity dose. However, in the case of photon radiation, the cavity size cannot be allowed to be so large that it violates the Bragg–Gray principle that a negligible fraction of the dose arises from photon interactions in the cavity. Nevertheless, Borg et al. (2000) concluded from their Monte-Carlo study that Spencer–Attix cavity theory with  $\Delta=10$  keV was applicable within 0.5% for photon energies at 300 keV or above. The behaviour of cavities which are too large for the Bragg–Gray assumptions to apply is discussed separately under *general cavity theory* in Section 6.7.6.

All modern dosimetry protocols for megavoltage photon and electron beams (see Chapter 18 and Appendix D) use values of  $s_{\text{water,air}}^{\text{SA}}$  evaluated according to Equation 6.50, as part of the conversion of the reading of an ion chamber to absorbed dose to water. Considerable detail can

\* It is instructive to read Spencer and Attix (1955) as the formalism they used is very different from that in Equation 6.50; they did not explicitly include a track-end term, but instead evaluated the stopping power in a different way in the energy interval between  $2\Delta$  and  $\Delta$ .

be found on the evaluation of  $s_{\text{water},\text{air}}^{\text{SA}}$  in [Appendix D](#), [Section D.1.2](#) (electron beams) and [Appendix D](#), [Section D.1.3](#) (photon beams).

### 6.7.5 DEPARTURES FROM PERFECT BRAGG–GRAY BEHAVIOUR IN SMALL CAVITIES

The expression relating the dose in the (undisturbed) medium to that in a detector behaving as a Bragg–Gray cavity can be written most simply as

$$D_{\text{med}} = D_{\text{det}} s_{\text{med,det}}$$

where it assumed that  $s_{\text{med,det}}$  has been evaluated using Spencer–Attix theory from the total electron fluence spectrum at the appropriate depth in the medium. In practice not even small gas-filled ionisation chambers in high-energy electron or photon beams truly fulfil the Bragg–Gray conditions. One clear reason for this is the effect of the chamber wall material in the photon-beam case. If the wall is not medium-equivalent in terms of radiation interactions, then some of the secondary electrons in the cavity will have originated from photon interactions in the wall material rather than in the surrounding medium, thereby violating the identical electron fluence condition. This will be the case, despite the fact that the air cavity itself is small enough to function as an *electron* detector.

In the case of electron beams, there are no photon-generated electrons to consider. The response of TLD chips and semiconductor diodes in megavoltage electron beams, for example, should be predicted by the stopping-power ratio. However, the assumption that the fluence must not be appreciably disturbed by the *cavity* limits the applicability of the above theory to detectors that are either small compared to the range of the primary electrons or to materials which scatter electrons in a similar way to the medium.

Departures from Bragg–Gray assumptions are generally treated as *perturbations* (see Nahum 1996) and a perturbation factor,  $p$ , (or the product of several factors) is generally added to the above expression, which becomes simply

$$D_{\text{med}} = D_{\text{det}} s_{\text{med,det}} p \quad (6.51)$$

The subject of perturbation factors is an extensive and important one in the use of ionisation chambers in radiotherapy due to the high demands placed on accuracy; [Section 18.5.3](#) and [Appendix D](#), [Section D.2](#) should be consulted for more details.

### 6.7.6 GENERAL CAVITY THEORY

We have so far looked at two extreme cases:

1. Detectors that are small compared to the electron ranges and that do not disturb the electron fluence (Bragg–Gray cavities)
2. Detectors that are large compared to the electron ranges, and in which, therefore, CPE is established (photon radiation only).

Many situations involve measuring the dose from photon (or neutron) radiation using detectors which fall into neither of the above categories. In such cases there is no exact theory. However, so-called *General Cavity Theory* has been developed as an approximation (Burlin 1966). Burlin was the first to formally tackle this problem and he proposed a factor, which is a weighted mean of the stopping-power ratio and the mass–energy absorption

coefficient ratio:

$$\frac{\overline{D_{\text{det}}}}{D_{\text{med}}} = d s_{\text{det,med}} + (1-d) \left( \frac{\mu_{\text{en}}}{\rho} \right)_{\text{det,med}} \quad (6.52)$$

where  $d$  is a weighting factor that varies between unity (or Bragg–Gray) cavities and zero for large cavities (or photon detectors). Burlin provided a very approximate theory to estimate  $d$  based on the exponential attenuation of the electron fluence entering the cavity through the wall, balanced by the exponential buildup of the cavity-generated electron fluence. Attix (1986) discusses in detail the Burlin theory and also subsequent attempts to develop a more sophisticated theory by Horowitz and Dubi (1982), Janssens (1983), Kearsley (1984), and others. Attix concluded that analytical theories were unlikely to be able to compete in accuracy with Monte-Carlo simulation in the future (Mobit et al. 1997).

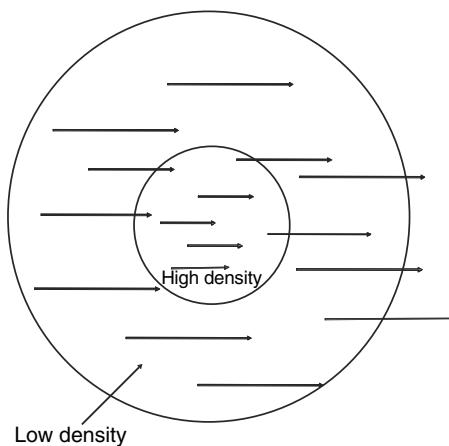

### 6.7.7 THE FANO THEOREM

Fano (see Greening 1981; Attix 1986) was able to prove in a formal mathematical way that:

*“In a medium of given composition exposed to a uniform fluence of primary radiation (such as x-rays or neutrons) the fluence of secondary radiation is also uniform and independent of the density of the medium as well as of the density variations from point to point”*

Figure 6.17 illustrates schematically the situation to which the Fano theorem applies. A medium large enough for CPE to be established is irradiated by indirectly ionising radiation which gives rise to electron tracks (shown as straight lines for simplicity). The central region has a higher density but exactly the same atomic composition as the region surrounding it. More electron tracks are started per unit volume in this central region but each track is correspondingly shorter due to the higher stopping power. Fano’s theorem then predicts that *the electron fluence (total track length per unit volume) in the central region will be exactly the same as that in the outer region*, irrespective of the size of the central region.

Electron tracks in medium with density variation

**FIGURE 6.17**

Illustration of the Fano theorem: the total track length of secondary electrons per unit volume, i.e. the electron fluence, remains the same although the density of the photon-irradiated medium may vary. The electron tracks are shown as straight lines for simplicity.

A practical example of the use of the Fano theorem is in the dosimetry of low-energy x-ray beams where it is not possible to make a gas cavity small enough to fulfil the Bragg–Gray condition (see [Section 6.7.3](#)). If the low-density cavity has the same elemental condition as the surrounding medium, then there is no limitation on the size of the cavity (e.g. air surrounded by air-equivalent walls).

The theorem assumes that the mass stopping power of a medium is independent of its density. At relativistic energies (i.e. above around 0.5 MeV for electrons) this is no longer the case as a result of the *density effect* (see [Section 3.2.3](#)). The consequences of this violation of the Fano theorem conditions may, however, have no practical importance.

## INTRODUCTION

Physical approaches to the optimisation of radiation therapy increasingly require attention to biological factors. The name of the game, as with any form of curative cancer treatment, is *selectivity*: how to maximise effects on tumours without incurring serious damage to normal tissues. This is largely achieved in the case of radiation therapy by careful attention to dose distributions, but biological effects depend not only on the *spatial* but also on the *temporal* distribution of dose, and selectivity depends on biological response processes. All these aspects will be covered in Part B.

It is fair to say that radiobiology is currently undergoing something of a renaissance with today's unprecedented ability to shape dose distributions through 3-D conformal and intensity-modulated therapy ([Chapter 43](#) and [Chapter 44](#)), stereotactic techniques ([Chapter 45](#)), and heavy charged-particle therapy ([Chapter 46](#) and [Chapter 49](#)) acting as the catalyst. With such dose-shaping tools available, one has many alternative treatment plans to choose from, and tools such as *dose-volume histograms* have become routine. The field is moving toward the use of so-called biological models of Tumour Control Probability (TCP) and Normal-Tissue Complication Probability (NTCP) (see [Chapter 36](#)). These models introduce the biological response on the top of the physical dose distribution; hence, radiobiological concepts are entering into the vocabulary of the radiotherapy physicist with renewed vigour (Glatstein 2002).

Many current issues in modern radiotherapy need radiobiological input in order to be used optimally. In recent years intriguing phenomena such as low-dose hypersensitivity (see [section 7.13.3](#)) and the possibility of low  $\alpha/\beta$  in prostate and breast (see [Section 9.3](#)) have been reported and their impact needs to be studied. Radiobiology is also needed to guide extra-cranial stereotaxy with large fraction sizes in lung and liver ([Chapter 45](#); Blomgren et al. 1995; Fowler et al. 2004; Grau et al. 2006; Lax et al. 2006; SBRT 2006). PET-guided dose painting to combat hypoxia (Chao et al. 2001; Chapman et al. 2003) and also to target regions of particularly high clonogen density, e.g. in the lung (van der Wiele et al. 2003; Paulino and Johnstone 2004) has become a possibility. In the prostate, Nutting et al. (2002) have proposed that images from magnetic resonance spectroscopy (MRS) could be used to target dose more precisely. All the above require radiobiological knowledge in addition to radiation physics. Physicists' involvement in radiotherapy even extends to radiobiologically based analyses of the clinical effects of waiting times for treatment (Wyatt et al. 2003) and on the effect of the time interval between surgery and postoperative radiotherapy (Al-Dewerri et al. 2004).

The field of radiation biology is now vast, comprising not only of applications to therapy but also to radiation protection (dealt with in [Part L](#); see also Sachs and Brenner 2005). Many areas covered in this Part are amplified in the book *Basic Clinical Radiobiology* (Steel 2002a) which also deals with topics not covered here, including the recent emphasis on molecular approaches. The review articles by Fowler (1984, 2006) and Peters et al. (1990) are also very useful.

This chapter begins with the basic concepts of cell killing by radiation. Although this is discussed in the context of killing tumour cells, most of these ideas equally apply to the normal tissues at risk in radiotherapy.

## 7.1 CONCEPT OF CLONOGENIC CELLS

The maintenance of tissue size, and therefore of tissue function, in the normal renewal tissues of the body depends on the existence of a small number of primitive *stem cells*. These are cells with unlimited proliferative capacity which are at the base of the hierarchy of cells that make up the normal epithelial and haemopoietic tissues of the body. Carcinomas are derived from such hierarchical tissues, and the ability to recognise this in histological sections derives from the fact that the tumours often maintain many of the features of differentiation of the tissue within which they arose. Well-differentiated tumours do this to a greater extent than do anaplastic tumours. It follows that not all the cells in a tumour are *neoplastic stem cells*; some have embarked on an irreversible process of differentiation. In addition, carcinomas contain many normal host cells that make up the stroma (fibroblasts, endothelial cells, macrophages, etc.). To some readers it may come as a surprise that most of the cells that make up the volume of many tumour types are not malignant. If these non-malignant cells were the only cells left intact at the end of therapy, then the tumour would not regrow. Tumour growth is driven by the neoplastic stem cells, and it is these that must be eradicated.

When a tumour regrows after non-curative treatment, it does so because some stem cells were not killed. Radiobiologists have recognised that the key to understanding tumour response is to determine how many tumour stem cells are left. It is almost impossible to recognise tumour stem cells *in situ*, and assays have been developed which allow these cells to be detected after removal from the tumour. These assays generally detect stem cells by their ability to form a colony within some growth environment. These cells are called *clonogenic* or *colony-forming* cells.

After exposure to a therapeutic dose of radiation, damaged cells do not immediately die, and they may produce a modest family of descendants. This is illustrated in Figure 7.1. The growth of single mouse L-cells was observed under the microscope, and one selected colony was irradiated with 200 *roentgens* (about 2 Gy) of x-rays at the 4-cell stage. Subsequent

**FIGURE 7.1**

Pedigree of a clone of mouse L-cells irradiated with an exposure of 200 roentgens at the 4-cell stage, illustrating the concept of surviving and non-surviving clonogenic cells. (From Trott, K. R., *Curr. Top. Radiat. Res.*, 7, 336–337, 1972. With permission.)

growth was carefully recorded, and in the figure each vertical line indicates the time from birth at mitosis to subsequent division of a daughter cell. The two irradiated cells on the left and the right of this figure produced continuously expanding colonies, although, some daughter cells had a long intermitotic time. The other two irradiated cells fared badly; they underwent a number of irregular divisions including a tripolar mitosis. But note that at the end of the experiment cells are present from each of the original four cells: the difference is that two produced expanding colonies while the other two did not. The two irradiated cells on the left and right of this diagram were *surviving clonogenic cells*, and the other two are usually described as having been *killed* by radiation. More precisely, they should be described as having *lost their colony-forming ability*; this is what irradiation of tumour cells seeks to achieve.

These examples of the kinetics of cell death after irradiation indicate the process of *proliferative cell death*. Another mechanism of cell death that is more prompt is *apoptosis*, or *programmed cell death*, which will be described later in this chapter.

## 7.2 CLONOGENIC ASSAYS

Clonogenic assays have formed the basis of cellular response studies in tumours as well as in some normal tissues. The basic idea is to remove cells from the tumour, place them in a defined growth environment, and test for their ability to produce a defined colony of descendants. Many types of assay have been described; here, the principle is illustrated by a simple assay in tissue-culture that is analogous to a microbiological assay.

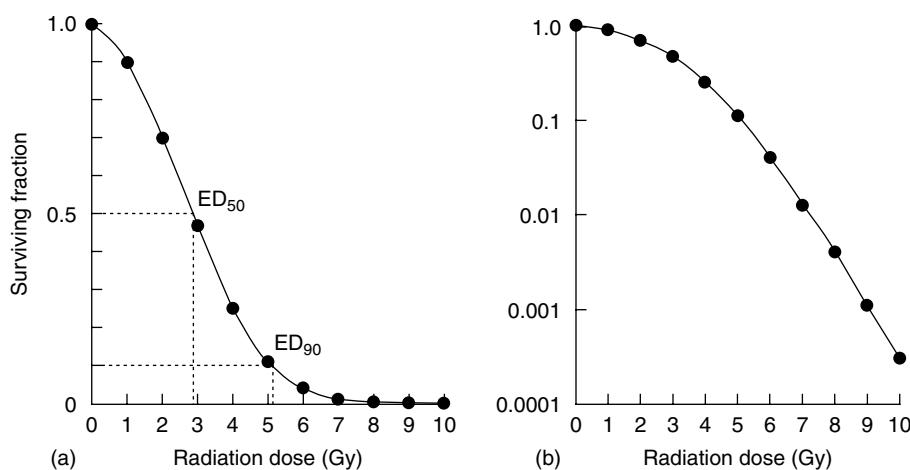

A single-cell suspension of tumour cells is prepared and divided into two parts. One is irradiated, the other kept as an unirradiated control. The two suspensions are then plated out in separate tissue culture dishes under identical conditions, but since it is expected that irradiation has killed some cells, a larger number of the irradiated cells will have to be plated. Plating 100 control cells and 400 irradiated cells is typical. After allowing growth over a suitable period of incubation, the colonies are *scored*. To do this, it must first be decided what number of cells should be classified as a viable colony. The usual criterion is 50 cells, equivalent to 5–6 generations of cell division. If in the control dishes an average of approximately 20 colonies is found, the plating efficiency (PE) is  $20/100=0.2$ . If the irradiated cells yield an average of approximately eight colonies, then their plating efficiency is lower:  $8/400=0.02$ . The *surviving fraction* is calculated as the ratio of these plating efficiencies:

$$\text{Surviving fraction} = \frac{\text{PE}_{\text{treated}}}{\text{PE}_{\text{control}}} = \frac{0.02}{0.2} = 0.1$$

The assumption here is that  $\text{PE}_{\text{control}}$  indicates the detection efficiency of clonogenic cells, and is unaffected by irradiation. Using this equation, the colony counts from the irradiated cells can be corrected for this detection efficiency. Surviving fraction is often given as a percentage (10% in this case).

The above description started with a suspension of tumour cells. In order to measure *in vivo* cell survival, two groups of experimental tumours (i.e. in mice or rats) are taken. One is irradiated and the other is kept as a control. At some time after irradiation cell suspensions are made from both groups, treated identically, and plated as before. The difference here is that the cells are irradiated under *in vivo* conditions.

Irradiation not only reduces the colony numbers; it also produces non-lethal effects that shift the colony-size distribution to smaller values. Some of these small colonies may represent clones that eventually die out; others may arise from cells that, as a result of non-lethal injury, have a reduced colony growth rate. Unless they reach the usual cut-off of 50 cells, they will not be counted. However, the implication of these partially viable colonies for the evaluation of radiation effects on tumours may be worthy of greater attention.

**FIGURE 7.2**

A typical cell survival curve for cells irradiated in tissue-culture, plotted (a) on a linear survival scale; (b) shows the same data plotted on a logarithmic scale.

## 7.3 CELL-SURVIVAL CURVES

A cell survival curve is a plot of surviving fraction against dose (of radiation, cytotoxic drug, or other cell-killing agent). Figure 7.2a shows that when plotted on *linear* scales, the survival curve for cells irradiated in tissue culture is often sigmoid: there is a shoulder followed by a curve which asymptotically approaches zero survival. To indicate the sensitivity of the cells to radiation, the  $ED_{50}$  or  $ED_{90}$  values could be read off from the graph. ( $ED_{90}$  is the dose necessary to kill 90% of the cells.) In doing this no assumptions are made about the shape of the curve.

There are two reasons why survival curves are usually plotted on a *logarithmic* scale of survival as in Figure 7.2b. If cell killing is the result of random *single-hit* radiation events then survival will be an *exponential* function of dose. This will be a straight line on a semi-log plot\*. Secondly, a logarithmic scale more easily allows effects at very low survival levels to be shown and compared. This is important because, as indicated in the next section, the cure of a tumour requires many orders of magnitude of cell kill.

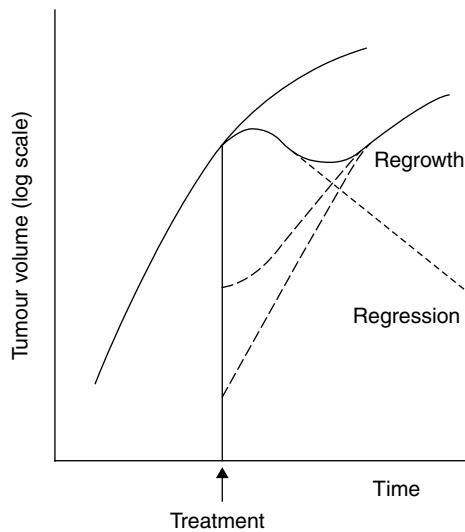

## 7.4 THE RELATIONSHIP BETWEEN CELL SURVIVAL AND GROSS TUMOUR RESPONSE

The objective of clonogenic cell survival studies is to be able to understand, or to make predictions about, the main features of tumour response to therapy: these are tumour growth delay (or in clinical terms *duration of remission*) and local tumour control.

### 7.4.1 TUMOUR GROWTH DELAY

Incomplete treatment of a tumour leads to a temporary phase of tumour regression which is subsequently followed by tumour recurrence. This pattern is illustrated in Figure 7.3.

\* The linear-quadratic model of cell killing involves both *single-hit* and *double-hit* mechanisms and will be introduced later in Section 7.13.

**FIGURE 7.3**

The volume response of an uncontrolled tumour is the resultant of two processes: regression and regrowth. Repopulation during the period of regression may take place at a rate that may differ from the growth rate of the untreated tumour.

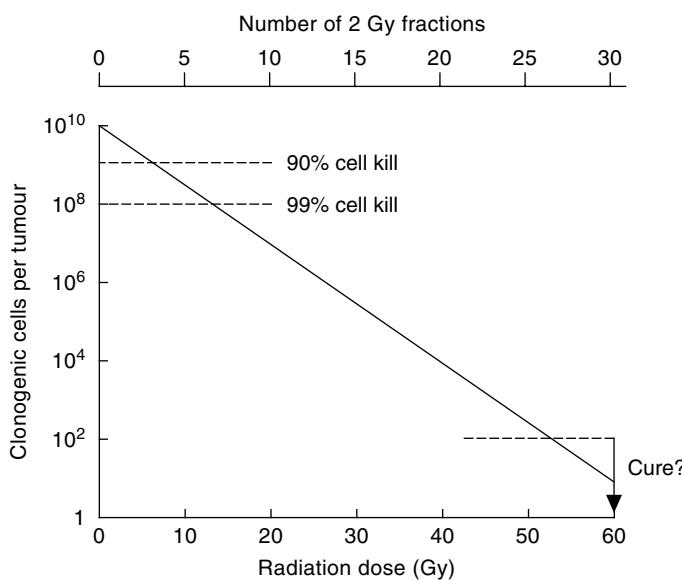

Regression is due to the death and disappearance of cells killed by radiation and also of differentiated (i.e. maturing) cells of limited life-span which would have been produced by the killed stem cells.

The rate of tumour regression differs widely from one tumour to another. Some tumours shrink during a course of radiation therapy, whereas others regress very slowly. This process strongly influences the patient's and the clinician's perception of the effectiveness of the treatment. But it is important to stress (as illustrated by Figure 7.3) that the effectiveness of treatment (as judged by the time-scale of tumour recurrence) depends on the *regrowth component* and not on the regression component.

The regrowth component in Figure 7.3 is due to repopulation by surviving clonogenic cells. The speed of regrowth varies considerably from one tumour to another, and the upper of the two broken lines in the figure illustrates the possibility of a lag period before repopulation fully gets under way. There is also evidence that once it begins, the speed of repopulation may resemble the higher growth rate of a very small untreated tumour. This is sometimes known as *accelerated repopulation*.

#### 7.4.2 LOCAL TUMOUR CONTROL

The eradication of every clonogenic tumour cell will lead to tumour cure; however, this is a very difficult objective. Every gram of tumour may contain  $10^9$  cells of which as few as 1%, may be clonogenic. A human tumour at presentation will have a mass of tens or hundreds of grams, and thus the total number of clonogenic cells could exceed  $10^9$ . Figure 7.4 illustrates the response of a tumour that initially contains  $10^{10}$  clonogenic cells to radiotherapy. Each radiation dose is assumed to result in a surviving fraction of roughly 0.5, thus approximately halving the number of clonogenic cells. Consequently, cell kill is exponential with cumulative dose. This assumption implies *constant effect per fraction*, for which there is some experimental evidence. In this example around 30 fractions of 2 Gy are required to reduce the initial number of clonogenic cells to ten surviving cells ( $0.5^{30} \approx 10^{-9}$ ). When treatment has reduced survival to 1% of the original number of clonogenic cells, this might, in a rapidly shrinking tumour,

**FIGURE 7.4**

Illustrating the treatment of a tumour that initially contains  $10^{10}$  clonogenic cells with a sequence of 2 Gy radiation doses; each roughly reduces survival by half.

lead to a complete disappearance of all *visible* tumour. The diagram indicates that four or five times this dose is expected to be needed in order to eradicate the last surviving clonogenic tumour cell thereby reaching a curative level.

Whether it is always necessary to eradicate the last clonogenic tumour cell in order to achieve local tumour control has been a matter of intense debate. During the 1970s there was a widespread belief that the immune responses of patients against their tumours might be strong, and this gave rise to many attempts at immunotherapy. Unfortunately, it has subsequently been realised that the animal tumours used to support the optimistic claims for immunotherapy were not truly syngeneic (i.e. genetically identical to their hosts). They had developed an artificially strong immune response against the hosts they were growing in, and consequently the results obtained with them were misleading. Although it is possible that weak tumour-directed immune responses may exist within cancer patients, perhaps sufficient to eradicate a few of the surviving tumour cells, this cannot be relied on.

The key point that is illustrated in Figure 7.4 is that a course of radiotherapy which kills 99% of clonogenic cells and which might lead to complete tumour regression is very far from achieving local tumour control. Hence the adage, “99% tumour cell kill is complete failure” (see [Section 36.1](#) on the mathematical modelling of tumour control probability).

### 7.4.3 SELECTIVITY IS THE NAME OF THE GAME

The very considerable *log cell kill* that is required to control a tumour has to be achieved without exceeding the tolerance of critical normal tissues which are within or adjacent to the high-dose volume. This is a daunting task for it is known that organs such as the small intestine will fail (for instance, by ulceration of the mucosa) if the proportion of stem cells is reduced below around 1% (see [Figure 8.5](#)). This implies that  $\sim 10$  logs of cell kill in the tumour must be achieved without exceeding  $\sim 2$  logs in the normal tissues. This requires a factor of 5 in dose selectivity, i.e. the dose to the tumour must be *five times* the dose to the sensitive normal tissue. Radiotherapy goes a long way toward achieving this by physically *focusing* the radiation and reducing the amount of normal structures which are within the high-dose volume. If this is not achieved, radiotherapy will almost always fail. Incidentally, this is the predicament of cancer

chemotherapy. When it is given as a systemic treatment, critical normal tissues such as the bone marrow and intestines receive a full drug dose and success is only possible when (as is rarely the case) the drugs or drug combinations have a very high level of selectivity for tumour cell kill (see also Wilson et al. 2006).

---

## 7.5 WHY CELLS DIE WHEN THEY ARE IRRADIATED

Exposure of biological tissues to ionising radiation immediately leads to ionisation and excitation of their constituent atoms. The molecules where these atoms reside then tend to fall apart, resulting in so-called *free radicals*. Water is the most prevalent molecule within the cell so most of the free radicals are produced by the radiolysis of water. Free radicals are highly unstable. They react with other nearby molecules, thereby transferring chemical damage to them; these free-radical processes are usually complete within a millisecond under physiological conditions. All components of the cell will be damaged in this way: proteins, enzymes, membrane components, etc. However, such molecules are present in vast numbers in every cell and damage to a few of them probably has little impact on the cell's viability; they will be quickly regenerated. But there is one cellular component which is almost unique: DNA. DNA is a very long double-helix molecule consisting of a repeated sequence of bases, and every chromosome has approximately 200 million bases. Groups of bases form the genes that contain instructions for proteins and thus for all aspects of cellular function. There is usually some duplication of genes, but even so there is a serious risk that radiation damage may lead to the loss (or modification) of some genes and thus to a loss of specific functions (some of which may be essential for survival). This is the reason why DNA is the most vulnerable part of a cell to radiation damage. Cells have evolved to withstand such damage, however; they have a formidable armoury of sophisticated repair enzymes which are continually monitoring the integrity of the DNA, recognising damage, and repairing it. A radiation dose of 1 Gy produces, in every cell nucleus, roughly  $2 \times 10^5$  ionisations, leading to around 1000 single-strand breaks in DNA and possibly 40 double-strand breaks. But repair processes are so efficient that, in spite of all this damage, most cells survive.

Direct evidence that damage to DNA is in most cases the critical event for cell survival has come from experiments showing that when short-range Auger-emitting isotopes are incorporated into DNA they are far more toxic than when the same type and amount of radioactivity is bound to other parts of the cell.

When they are fatally damaged by radiation most cells do not immediately die; after a dose-dependent delay in progression through the cell cycle they usually proceed to mitosis. Damaged cells often fail to complete mitosis, or they may go through one or more further cell cycles before getting stuck at a subsequent cell division (Figure 7.1). However, lymphocytes as well as some other cell types die before reaching mitosis. This is called *intermitotic cell death*. It is closely related to what has come to be called *programmed cell death* or *apoptosis* which has been the focus of much cancer research, the aim being to manipulate this process for therapeutic benefit (Haimovitz-Friedman et al. 1996).

---

## 7.6 CELLULAR RECOVERY FROM RADIATION DAMAGE

Experimental methods have been devised to detect the recovery of cells and tissues from radiation exposure, and these recovery processes are of direct relevance to clinical radiotherapy.

1. *Split-dose experiments.* The effect of a given dose of radiation is less if it is split into two fractions that are delivered a few hours or more apart. This effect has been termed recovery from *sublethal damage* (SLD), or *Elkind recovery*. Almost all cells show this effect. The basis for

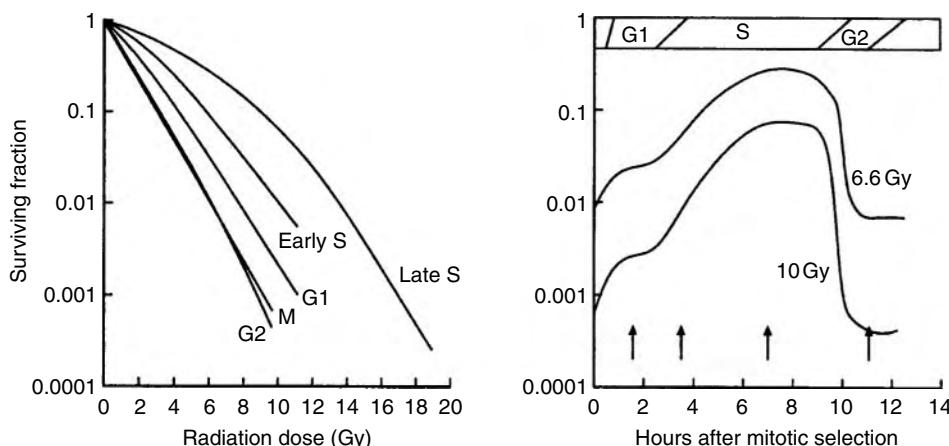

this is that if after giving one pulse of damage to a cell, a time delay is allowed before a second pulse, repair will enable the cell to withstand the second pulse more readily. Giving both together may, in contrast, produce an unreparable level of damage.

2. *Delayed-plating experiments.* If cells are irradiated in a non-growing state and left for increasing periods of time before assaying for survival, an increase in survival is often observed. This has been termed recovery from *potentially lethal damage* (PLD). The rationale is that assay involves cell proliferation and cells which are made to replicate using a non-repaired genome are more likely to die. The kinetics of PLD recovery and SLD recovery are similar.
3. *Dose-rate effect.* The sparing of radiation damage as the dose rate is reduced to around 1 Gy/h is primarily due to cellular recovery. What happens is that at low dose rates each cell that suffers a particle traversal will, on average, experience a considerable delay before a second particle comes along. As in the split-dose situation, this will lead to less overall damage.
4. *Fractionation.* The sparing effect of *fractionating* radiation treatment within a relatively short overall time is primarily due to recovery (see [Section 9.1](#)). With daily dose fractions, there is a gap of  $\sim$ 24 h after each fraction during which repair can occur. This is the reason why, in clinical radiotherapy, the total radiation dose required for tumour control must be increased as the number of fractions increases (see [Section 9.2](#)).

The speed of cellular recovery has been measured in many cell- and tissue types. There is evidence, mainly from DNA repair studies, that recovery is a multi-exponential process with a first component half-time of a few minutes, a main component whose half-time may be approximately 1 hour, and perhaps also an even slower component. The clinical implication of this is that when treatment is given with multiple fractions per day, it is important to allow full recovery between fractions. This may require an inter-fraction gap of at least 6 hours (see [Section 9.4](#)).

## 7.7 VARIATION OF CELL KILLING THROUGH THE CELL CYCLE

The radiosensitivity of cells varies considerably as they pass through the cell cycle. A cell's life is conventionally divided into four phases: its birth at mitosis, a period of DNA synthesis known as the S-phase, preceded by G1, and followed by G2 (see [Figure 7.5](#)). Although this has not been studied in a large number of cell lines, there seems to be a general tendency for cells in

**FIGURE 7.5**

The variation of radiosensitivity with the phase of the cells in the cell cycle; the surviving fraction varies by a factor of almost 100. (From Sinclair, W. K. and Morton, R. A., *Biophys. J.*, 5, 1–25, 1965.)

the S-phase, in particular the latter part of the S-phase, to be the most resistant and for cells in G2 and mitosis to be the most sensitive. The reason for the resistance in S may be related to the *conformation* of DNA at that time. The sensitivity in G2 probably results from the fact that those cells have little time to repair radiation damage before being called upon to divide. The analysis of the radiation response of synchronized cells by the linear-quadratic model could shed additional light on the underlying mechanisms (Chapman 2003).

The effect of the variation in sensitivity during the cell cycle is that a degree of *synchrony* is created in the cells that survive irradiation. Immediately after a dose of x-rays, all the cells will still be at precisely the same point in the cell cycle as they were before irradiation; some will have lost their reproductive integrity, and the greatest number of viable cells will tend to be in the S-phase. The implication for clinical radiotherapy is that when radiation doses are given close together in time, the extent of cell-cycle progression will influence the overall amount of cell kill. If surviving cells have time to move out of their resistant phase into a more sensitive one, then the effect of a second radiation dose will be greater. This process is called *reassortment* or *redistribution*.

---

## 7.8 THE 5 Rs OF RADIOTHERAPY

The biological factors that influence the response of normal and neoplastic tissues to fractionated radiotherapy can be summarised as:

*Repair* As evidenced by cellular recovery during the few hours after exposure

*Reassortment* Cell-cycle progression effects. Cells that survive a first dose of radiation will tend to be in a resistant phase of the cell cycle, and within a few hours, they may progress into a more radiosensitive phase

*Repopulation* During a 4- to 6-week course of radiotherapy, tumour cells that survive irradiation may proliferate and thus increase the number of cells which must be killed

*Reoxygenation* In a tumour the radioresistant hypoxic cells will selectively survive after a dose fraction, but thereafter, when their oxygen supply improves, their radiosensitivity will increase

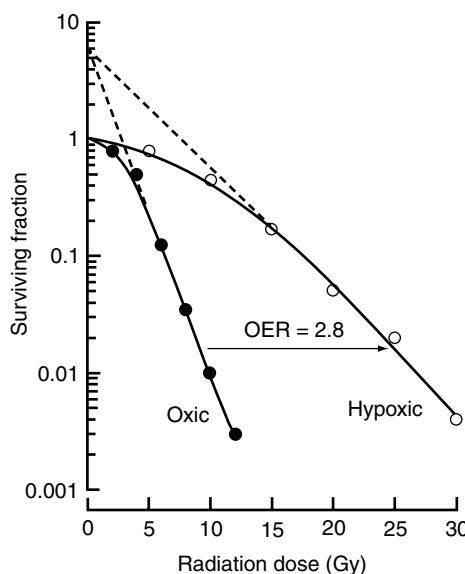

*Radiosensitivity* For a given fractionation course (or for single-dose irradiation), the haemopoietic system shows a greater response than the kidney, even allowing for the different timing of response. Similarly, some tumours are more radioresponsive than others to a particular fractionation schedule, and this is largely due to differences in radiosensitivity

Note that two of these processes (*repair* and *repopulation*) will tend to make the tissue more *resistant* to a second dose of radiation; two others (*reassortment* and *reoxygenation*) tend to make it more *sensitive*. The first four factors given above were christened the *4 Rs of Radiotherapy* by Withers (1975).

---

## 7.9 THE IMPORTANCE OF OXYGEN

The response of cells to ionising radiation is strongly dependent upon oxygen. This is illustrated in [Figure 7.6](#) for mammalian cells irradiated in culture. Cell surviving-fraction is shown as a function of radiation dose administered either under normal aerated conditions or under hypoxia which is generally achieved by passing nitrogen gas over the cell suspension for

**FIGURE 7.6**

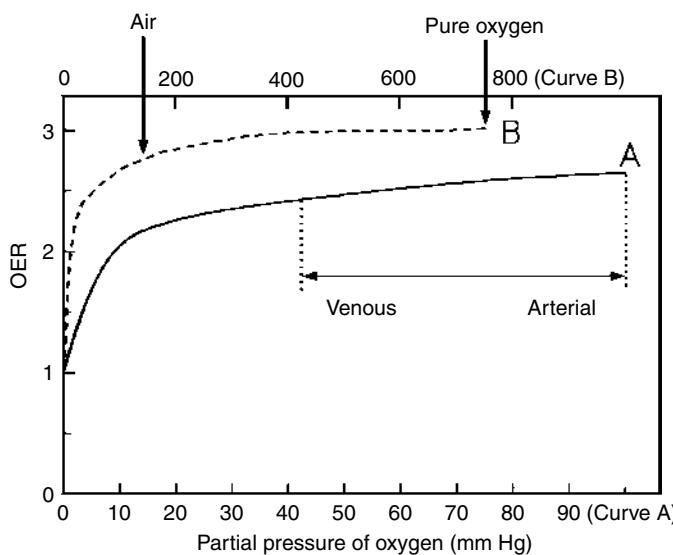

Survival curves for cultured mammalian cells exposed to x-rays under oxic or hypoxic conditions. Note that the dose level is  $\approx 10$  Gy, SF  $\approx 0.015$  where the OER value equals 2.8, i.e. far in excess of the clinically relevant 2 Gy.

a period of 15–30 min. The enhancement of radiation damage by oxygen is *dose-modifying*, i.e. the isoeffective dose is reduced by the same factor at all levels of survival (note that in Figure 7.6 the broken lines extrapolate to the same point on the Y-axis). This allows calculation of an *oxygen enhancement ratio* (OER) that is simply the ratio of the radiation dose in hypoxia to the dose in air needed to achieve the same biological effect. For most cells, the OER for x-rays is around 3.0. However, certain studies have shown a *lower* OER for the single-hit mechanism relative to the double-hit mechanism of the linear-quadratic model so that at radiation doses of 3 Gy or less, the OER is actually *reduced* (Palcic and Skarsgard 1984; Chapman 2003; Nahum et al. 2003). This is an important finding because this is the dose range for the overwhelming majority of fractionated treatments.

It has been demonstrated from rapid-mix studies that the oxygen effect only occurs if oxygen is present either during irradiation or within a few milliseconds thereafter. This occurs because the effect of oxygen is to modify free-radical reactions, leading to greater fixation of DNA damage. The dependence of OER on oxygen tension is shown in Figure 7.7. By definition, the OER under anoxic conditions is 1.0. As the oxygen level increases, there is a corresponding increase in radiosensitivity and therefore in the OER. The greatest change occurs from 0 to about 20 mm Hg; further increase in oxygen concentration, even up to that seen in air (155 mm Hg) or to 100% oxygen (760 mm Hg), has little influence on radiosensitivity. Also shown in Figure 7.6 are the oxygen partial pressures typically found in arterial and venous blood. Therefore, from a radiobiological standpoint, most normal tissues can be considered to be well-oxygenated, although it is recognised that the response of some normal tissues may increase if their oxygen supply is improved.

## 7.10 HYPOXIA IN TUMOURS

Oxygen also plays an important role in the radiation response of tumours. Solid tumour growth requires the induction of new blood vessels, a process that is referred to as *angiogenesis*. This new blood supply is primitive in nature, and it may be inadequate for meeting all the needs of the growing tumour. Nutrient-deprived and oxygen-deprived regions often develop,

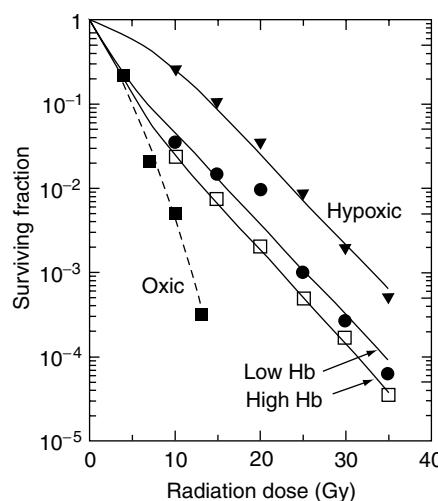

**FIGURE 7.7**

Variation of oxygen enhancement ratio (OER) with oxygen tension. The dashed curve shows the same curve plotted on the upper scale. The range of blood oxygen tensions is indicated. (From Denekamp, J., in *The Biological Basis of Radiotherapy*, 2nd ed., Steel, G. G., Adams, G. E., and Horwich, A., Eds., Elsevier Science, Amsterdam, 1989. With permission.)

yet the hypoxic cells existing in these areas may still be viable. The first real indication that hypoxia could exist in tumours was made in 1955 by Thomlinson and Gray from their observations on histological sections of fresh specimens from carcinoma of the bronchus (Thomlinson and Gray 1955). They observed viable tumour regions surrounded by vascular stroma where the tumour cells obtained their nutrient and oxygen requirements. As these regions expanded, areas of necrosis appeared at the centre. The thickness of the resulting 'shell' of viable tissue was found to be similar to the calculated diffusion distance of oxygen in respiring tissues; it was suggested that as oxygen diffused from the stroma, it was consumed by the cells. Although those cells beyond the diffusion distance were unable to survive, cells immediately bordering the necrotic regions might be viable, but hypoxic.

Tannock (1968) made similar observations in mouse mammary tumours. The extent of necrosis in these tumours was much greater, and each patent blood vessel was surrounded by a 'cord' of viable tumour cells outside which there was necrosis. Cells at the edge of the cords are thought to be hypoxic and are often called *chronically hypoxic cells*. Tannock showed that because the cell population of the cord is in a dynamic state of cell turnover, these cells will have a short lifespan. More recently, it has been suggested that some tumour blood vessels may open and close, leading to *transient* or *acute* hypoxia. The mechanisms responsible for intermittent blood flow in tumours are not entirely clear. They might include vessel-plugging by white blood cells, red blood-cell *rouleaux* or circulating tumour cells, vessels collapsing in regions of high tumour interstitial pressure, or spontaneous vasomotion in incorporated host arterioles affecting blood flow in downstream capillaries.

Since hypoxic cells are resistant to radiation, their presence in tumours is critical in determining the response of tumours to single treatments with large doses of radiation. The presence of such cells in experimental tumours can be easily demonstrated as seen in Figure 7.8. This shows (from left to right) the radiation survival response of EMT6 mouse mammary tumours irradiated (a) as single cells in monolayer culture under oxic conditions; (b) *in situ* in air-breathing mice (having high or low haemoglobin (Hb) levels); or (c) hypoxic (*in nitrogen-asphyxiated* mice). Cell survival was estimated immediately after irradiation using an *in vitro* assay. The figure shows that the survival curves in air-breathing mice were biphasic;

**FIGURE 7.8**

The survival of an EMT6 mouse sarcoma irradiated under aerobic or hypoxic conditions. The dashed curve shows the in vitro survival of oxic cells. (From Hill, R. P., et al., *Br. J. Radiol.*, 44, 299–304, 1971. With permission.)

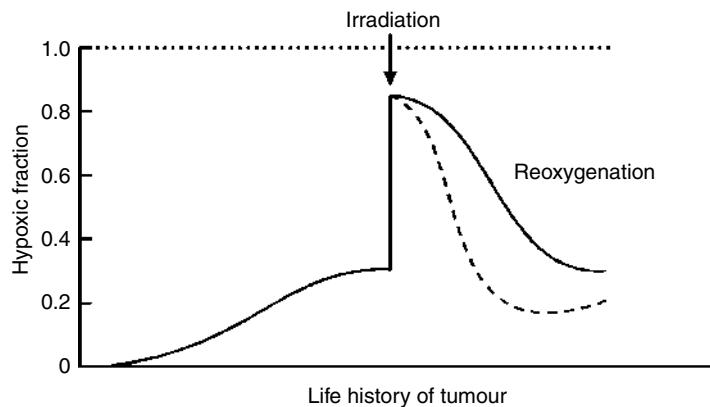

for doses under 5 Gy, the curves followed that for oxic cells, but above this dose level, the curves are parallel to the hypoxic curve. High single doses of radiation wipe out the oxic cells, and the surviving cells are almost all hypoxic.

### 7.10.1 HYPOXIC FRACTION

The term *hypoxic fraction* refers to the fraction of clonogenic tumour cells that have a radiosensitivity which is characteristic of hypoxic cells. Figure 7.8 shows the standard way in which this has been measured. In air-breathing animals, the survival curve will have the biphasic form mentioned above, reflecting the radiosensitivity of a mixture of oxic and hypoxic cells. In the killed animals, only the hypoxic component will be seen. The fact that the two survival curves are parallel confirms that they are both characteristic of hypoxic cells. If a vertical line is drawn at any point where the lines are parallel, then the ratio (survival in air-breathing mice)/(survival in dead mice) gives the hypoxic fraction of the tumours in air-breathing mice. The example shown in Figure 7.8 also illustrates the therapeutically important conclusion that the hypoxic fraction of a tumour may be greater in patients whose blood has a reduced haemoglobin content. Smoking reduces blood oxygen tension and is particularly inadvisable for patients undergoing radiotherapy.

### 7.10.2 REOXYGENATION

The time-course of changes in the hypoxic fraction of a tumour before and after irradiation is illustrated in Figure 7.9. Tumour nodules whose diameters are less than about 1 mm have been found to be fully oxygenated. Above this size, the hypoxic fraction increases until it reaches between 10% and 50% of clonogenic cells. Irradiation of a tumour will inevitably kill more oxic than hypoxic cells, and after a single large radiation dose, the hypoxic fraction may approach 100%. The *number* of surviving hypoxic cells will be low, but their *fraction* of all surviving clonogenic cells will be high. The term *reoxygenation* refers to the process by which these hypoxic cells become better supplied with oxygen. Reoxygenation has been studied by measuring the hypoxic fraction (as described above) at various times after a

**FIGURE 7.9**

The time-course of changes in the hypoxic fraction during the life history of a tumour.

priming dose of radiation. The experiments are difficult because they involve assaying the increase in cell kill from adding one radiation dose to another. The results of these studies have indicated that some tumours reoxygenate quickly (the hypoxic fraction falling from 100% to 10% within approximately one day), whereas, other tumours reoxygenate slowly (taking a week or more).

During the 1960s and 1970s, tumour hypoxia was perceived to be one of the principal causes of failure in radiation therapy, and much research effort was directed at developing ways of selectively killing hypoxic cells: high-LET radiations (see Chapter 49), hyperbaric oxygen, chemical radiosensitizers, etc. The disappointing results from these approaches have led to a widespread view that reoxygenation may be quite efficient in many clinical situations. Tumour cells that are hypoxic at the time of one radiation-dose fraction may be oxic by the time a subsequent dose fraction comes along. Therefore, provided fractionated radiotherapy is given over a conventional period of time, the presence of hypoxia may be less serious than had been previously believed. When the overall treatment time is shortened, as with brachytherapy or accelerated external-beam treatment, hypoxia may still be a significant problem.

Several clinical studies performed throughout the 1990s with the Eppendorf pO<sub>2</sub> micro-electrodes have confirmed that hypoxia identified prior to the start of radiotherapy does significantly predict for the treatment failure of cervical, head-and-neck, and prostate carcinomas and of sarcomas (Hockel et al. 1993; Nordmark et al. 1996; Movsas et al. 2002). Indeed, the use of the hypoxic-cell radiosensitizer Nimorazole has been shown to increase local control in supraglottic larynx and pharynx carcinoma in a phase-III clinical trial (Overgaard et al. 1998).

## 7.11 TUMOUR CONTROL PROBABILITY

The main factor determining success in clinical radiotherapy is radiation dose. Low doses are ineffective, but if it is possible to give a very large total radiation dose then, in principle, any tumour can be (locally) controlled. Between these extremes is a probability of tumour control which varies with dose according to a sigmoid relationship (see [Figure 8.2](#) and [Figure 8.3](#); see also [Section 36.1](#) on the mathematical modelling of tumour control probability). For any particular type of cancer, the characteristics of this curve are crucial to the success of therapy, and this is stressed in [Section 8.5](#).

The position of such a dose-response curve on the dose scale depends on the various biological factors that have been discussed above. Its steepness is also clinically important and depends on:

1. An underlying Poisson relationship ([Section 8.6](#)).
2. Variation in the possibility of cure among tumours of the same type, arising from differences in bulk, cellular radiosensitivity, repopulation, hypoxia, etc. All forms of variability will tend to make dose-response curve less steep (cf. the parameter  $\sigma_\alpha$  in [Section 36.1](#) on TCP modelling).
3. Inter-patient variation in the actual radiation dose delivered.

Quantification of the steepness of dose-response curves is dealt with in [Section 8.6.1](#) and [Section 36.2.1.3](#).

---

## 7.12 EXPERIMENTAL TUMOUR SYSTEMS

Research into the radiation response of tumours has been performed on a wide variety of tumour cell systems, including the following:

*In-vitro tumour cell lines.* These are cells derived from rodent or human tumours that have been induced to grow in tissue culture. They usually grow rapidly and have to be *passaged* (i.e. a small sample of the culture is transferred to new culture medium) every few weeks. They may be stored for long periods in a tissue bank, and they are useful for model experiments where simplicity and good reproducibility are important.

*Multicellular spheroids.* Small fragments of a tumour tissue culture can be grown under culture conditions where the cells stay together and grow as spherical balls of cells. As the spheroids grow, they develop a hypoxic centre. They have been used as in-vitro models of solid tumours.

*Transplanted tumours in experimental animals.* Within a highly inbred strain of mice or rats (i.e. syngeneic animals), tissues can be readily transplanted from one animal to another. A tumour that has arisen within such animals can be indefinitely *passaged*. For any one experiment, a large number of identical tumours can be produced and this greatly aids the experimental design. A disadvantage is that such tumours tend to drift away from their original characteristics, often growing more rapidly. Both the tumour and the mouse strain may drift genetically which leads to the development of immune rejection mechanisms and to potential artefacts.

*Primary animal tumours.* These may spontaneously arise or be induced by chemicals. They are real tumours with less artificiality than the systems described above, but they are expensive, often available only in small numbers, and are less easy to use than transplanted tumours.

*Human tumour xenografts.* *Xenograft* refers to transplantation across a species barrier. This is facilitated by the production of mice that almost completely lack an immune response. There are congenitally immune-deficient mouse strains such as the nude or SCID mice, but it is also possible using whole-body irradiation and immuno suppressive drugs to make conventional mice receptive to the subcutaneous transplantation of human tumour fragments. Xenografts maintain many of the biological characteristics of the source tumour and are useful for some aspects of tumour radiobiology. But the artificiality of the immunological situation of xenografts may lead to artefacts.

*Tumours in patients.* All experimental models of human cancer have drawbacks, and in many respects, the ideal is to work directly on cancer patients. However, practical and

ethical considerations seriously limit the scope for such research. Clinical trials as the endpoint of research development are, of course, established. The quantification of treatment response, both of tumours and normal tissues, is an important research area. There are also some opportunities to perform experimental therapy on small groups of patients in order to test the feasibility of using radiosensitizers, hyperthermia, etc.

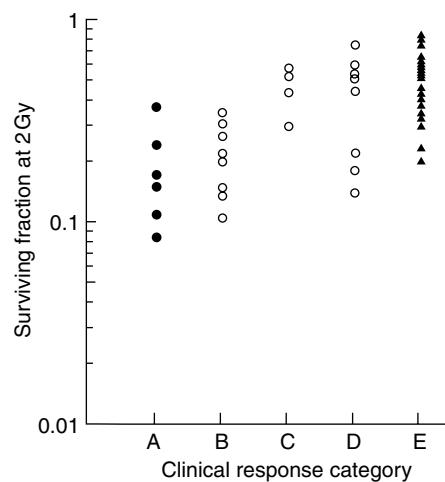

These experimental tumour systems have been listed in order of increasing closeness to cancer in patients. As we move down the list we come closer to the reality that we seek to understand but the scope for precise and sophisticated experimentation decreases.

## 7.13 THE RADIOSENSITIVITY OF HUMAN TUMOUR CELLS

### 7.13.1 THE INITIAL SLOPE OF THE CELL-SURVIVAL CURVE

Two key questions in radiation biology applied to radiotherapy are: how radiosensitive are human tumour cells, and how does this relate to clinical radiocurability? Prior to 1980, there was little information on these issues, but interest was aroused by Fertil and Malaise (1981) who surveyed the published literature on in-vitro human tumour cell survival curves. They found evidence for a correlation with clinical response. This survey was repeated by Deacon et al. (1984) who summarised data on 51 non-HeLa cell lines. These covered 17 different histopathological tumour types that were placed into five categories of local tumour radiocurability: A: lymphoma, myeloma, neuroblastoma; B: medulloblastoma, small-cell lung cancer; C: breast, bladder, cervix carcinoma; D: pancreas, colo-rectal, squamous lung cancer; and E: melanoma, osteosarcoma, glioblastoma, renal carcinoma. The placing of tumour types in this list is somewhat controversial, and the underlying clinical data do not allow this to be unequivocally done. However, the ranking A–E broadly reflects clinical experience.

The published in-vitro data for each cell line were analysed to determine the surviving fraction at 2 Gy (which Deacon et al. termed SF<sub>2</sub>): chosen as a measure of the initial slope of the cell survival curves. The result is shown in Figure 7.10. Within each category of clinical

**FIGURE 7.10**

Surviving fraction at 2 Gy for 51 human tumour cell lines arranged in five categories of clinical radioresponsiveness.

radioresponsiveness there is a considerable scatter (not surprising in view of the many different sources, cell lines, and techniques used). In confirmation of Fertil and Malaise's conclusions, there was a significant trend in the data towards Group A having lower and Group E having higher SF<sub>2</sub> values. This important conclusion underlies the belief that the steepness of the initial slope is a significant factor in the clinical response of tumours to radiotherapy. One should note that, while there is some evidence of a trend for average tumour radiosensitivity, the intra-group heterogeneity is so large that the most radioresistant tumour cells in Group A (the sensitive group) are more resistant than the most sensitive tumour cells in Group E (the resistant group).

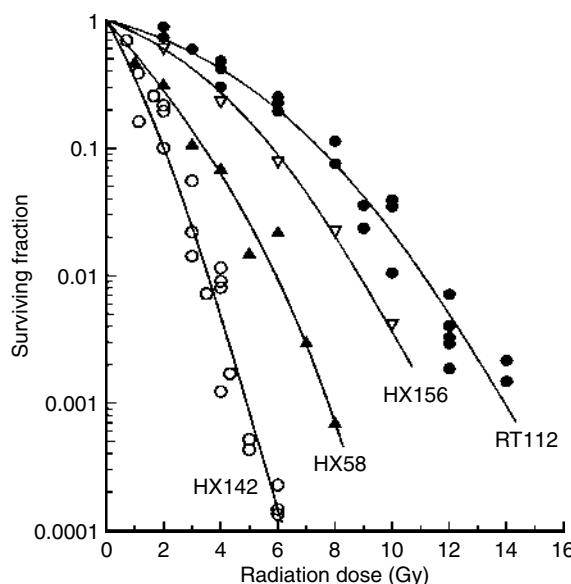

### 7.13.2 CELL-SURVIVAL CURVES FOR HUMAN TUMOUR CELLS

The survival curves shown in Figure 7.11 illustrate the range of radiosensitivity commonly found among human tumour cell lines. The range of doses that correspond to a survival of 1% of cells varies by approximately a factor of three. The range of steepness of the initial slopes of these curves is even wider. The full lines in Figure 7.11 are *linear-quadratic* curves fitted to the data

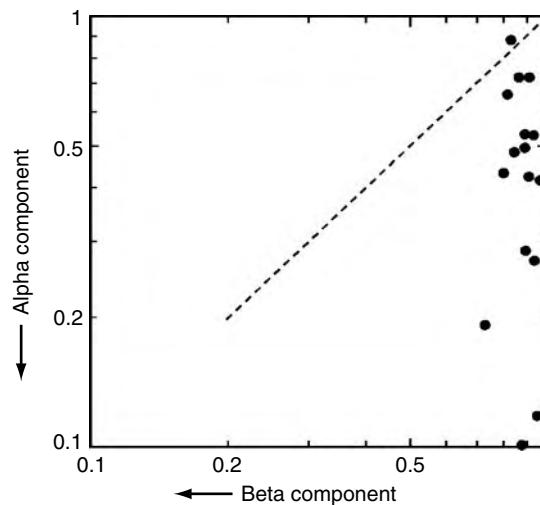

$$\text{Surviving fraction} = e^{-\alpha d - \beta d^2} \quad (7.1)$$

where  $d$  is the radiation dose. With these and other data sets, the fit is good; there is a clear initial slope, and the data are consistent with a *continuously-bending* curve. This is usually the case when cells of *homogeneous* radiosensitivity are irradiated at *low* temperatures where the repair of sublethal damage is minimized (Chapman 2003).

Because there may be a molecular basis for regarding the separate terms of the linear-quadratic equation as mechanistically distinct, it is interesting to examine their relative

**FIGURE 7.11**  
Cell survival curves for four representative human tumour cell lines irradiated at high dose rate. HX142 neuroblastoma; HX58 pancreatic; HX156 cervix; RT112 bladder carcinoma. (From Steel, G. G., *Radiother. Oncol.*, 20, 71–83, 1991. With permission.)

**FIGURE 7.12**

Contributions to the surviving fraction at 2 Gy from the linear and quadratic components of radiation cell killing for 17 human tumour cell lines. The dotted line indicates equality of the two components. (From Steel, G. G. and Peacock, J. H., *Radiother. Oncol.*, 15, 63–72, 1989. With permission.)

contributions to cell killing. Therefore, they are separated as:

$$\text{Linear or alpha component} = \exp(-\alpha d)$$

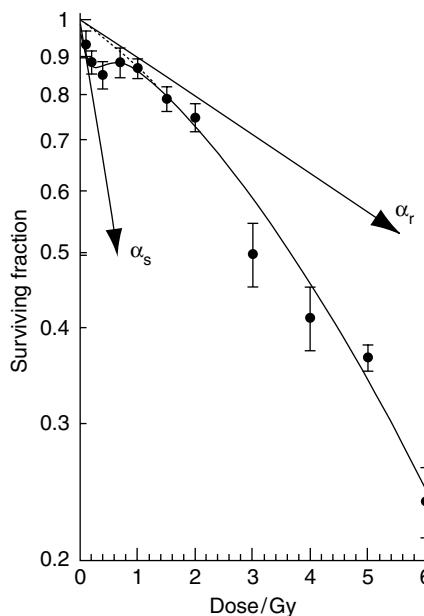

$$\text{Quadratic or beta component} = \exp(-\beta d^2)$$

Having fitted the data with the linear-quadratic (LQ) expression (Equation 7.1), as shown in Figure 7.11, the values for  $\alpha$  and  $\beta$  are known, and for any chosen dose, these two components can be calculated. This has been done in Figure 7.12 for 17 human tumour cell lines for a radiation dose of 2 Gy, a typical dose per fraction in clinical radiotherapy. It can be seen that the calculated points lie down the right-hand border of this diagram; the dispersion in radiosensitivity among these cell lines at 2 Gy is entirely due to differences in the steepness of the *linear* component of cell killing. The small amounts of cell kill because of the *beta* component (indicated by the distance of the point from the right-hand boundary) do not seem to correlate with the *alpha* sensitivity. The conclusion is one that is derived from most of the models of radiation cell killing: *cell killing at clinically realistic doses per fraction is dominated by the steepness of the linear component of the cell-survival curve*. An excellent review of cell-killing mechanisms in radiation therapy has been written by Chapman (2003).

### 7.13.3 DEPARTURES FROM THE LQ MODEL FOR DOSES BELOW 1 Gy

There is now a large body of experimental evidence (e.g. Marples and Joiner 1993; Short et al. 1999; Joiner et al. 2001) that for many mammalian cell lines, the surviving fraction at doses below around 1.0 Gy is not well predicted by the LQ expression (Equation 7.1). This low-dose behaviour is illustrated in Figure 7.13, which shows the survival of *asynchronous* T98G human glioma cells between 0 Gy and 6.0 Gy measured by Short et al. (1999).

As the figure clearly shows, the cells exhibit increased radiosensitivity at doses up to around 1.0 Gy, and this phenomenon has become known as *low-dose hyper-radiosensitivity* (HRS). This important behaviour has only come to light relatively recently because of the difficulty of making measurements at doses less than 1 Gy; effective techniques involve either a so-called fluorescence-activated cell sorter (FACS) to plate a predetermined number of cells, or microscopic scanning to identify an exact number of cells after plating (Joiner 2003; see also Section 7.1.3).

**FIGURE 7.13**

Experimental data on the survival of human glioma cells showing hypersensitive behaviour, clearly departing from the linear-quadratic expression (dashed curve), at doses below around 1.0 Gy. The radiation quality used was 240 kV x-rays. The solid line is a fit of the Induced Repair Model (IndRep) to the data (see Equation 7.2). The initial slope parameter of the IndRep model is indicated as  $\alpha_s$  that is clearly much greater than that of the LQ model,  $\alpha_r$ . The surviving fraction between  $\approx 0.2$  Gy and  $\approx 1.1$  Gy is approximately constant at  $\approx 0.87$ ; whereas, the LQ model would predict that it should vary between  $\approx 0.98$  and  $\approx 0.87$ . (From Short, S. C., et al., *Int. J. Radiat. Biol.*, 75, 847–855, 1999. With permission.)

A modified form of the LQ expression has been proposed (Joiner 2002a) which is known as the induced repair (IndRep) model

$$\text{Surviving Fraction} = \exp\left\{-\alpha_r D [1 + (\alpha_s/\alpha_r - 1) \times \exp(-D/D_c)] - \beta D^2\right\} \quad (7.2)$$

where  $D_c$  (about 0.2 Gy) is the dose at which the transition from hypersensitive behaviour to the increased radioresistance (IRR) associated with following the LQ model begins (see Figure 7.13). Inspection of Equation 7.2 shows that for  $D \gg D_c$ ,  $\exp(-D/D_c) \rightarrow 0$ , and the right-hand side reduces to the LQ expression (Equation 7.1) with parameters  $\alpha_r$  and  $\beta$ . At very low doses, ( $D \ll D_c$ ),  $\exp(-D/D_c) \rightarrow 1$ , and the expression also reduces to the LQ model with parameters  $\alpha_s$  and  $\beta$ .

The mechanism behind this intriguing low-dose behaviour of the surviving fraction has not yet been fully elucidated. Joiner et al. (2001) suggest that an increase in DNA repair capacity occurs in the IRR region. Other radiobiologists have hypothesized that it is a manifestation of the widely differing radiosensitivities of cells in different phases of the cell cycle in an asynchronous cell population (see Section 7.7); the much steeper initial slope corresponds to the response of these highly radiosensitive cells undergoing mitosis (Chapman, private communication). However, simple modeling of this variable radiosensitivity in the cell cycle yields too small a deviation from LQ behaviour.

Is there any evidence that the hypersensitivity observed from in-vitro experiments also exists in vivo? Joiner et al. (2001) concluded that such evidence does exist; the total dose required to produce a given level of damage in mouse skin, kidney and lung decreases when the fraction size is reduced below 1 Gy. They termed this a *reverse fractionation* effect. Short et al. (2001) found that a 3-hour interfraction interval was sufficient for HRS recovery between fractions. Joiner et al. (2001) have discussed how HRS might be clinically exploited, e.g. by giving dose fractions around 0.5 Gy (which they termed *ultrafractionation*). Clearly a greater

excess of radiosensitivity is required in the tumour than in the surrounding organ(s)-at-risk for there to be a therapeutic gain (see [Section 8.5](#)).

Fractional doses of the order of 0.2 Gy to 1.0 Gy correspond to the 10–50% isodoses in a treatment plan, (for a 2 Gy per fraction prescription dose) and consequently the presence of HRS in the cells in certain organs-at-risk could have consequences for complication rates. In particular, the rapidly emerging field of predicting complication probability by analysing dose distributions and DVHs in organs at risk (normal-tissue complication probability modeling—see [Section 36.3](#)) may need to take account of HRS. To give a simple example, if a certain conformal or intensity-modulated technique *reduces* the volume of normal tissue irradiated at around 1 Gy per fraction, but at the same time *increases* the normal-tissue volume irradiated at around 0.2 Gy per fraction, and if the cells involved exhibit HRS, then this may not lead to any net reduction in cell killing at all and thus not reduce the complication probability. Honore (2002) has explored scenarios of this nature.

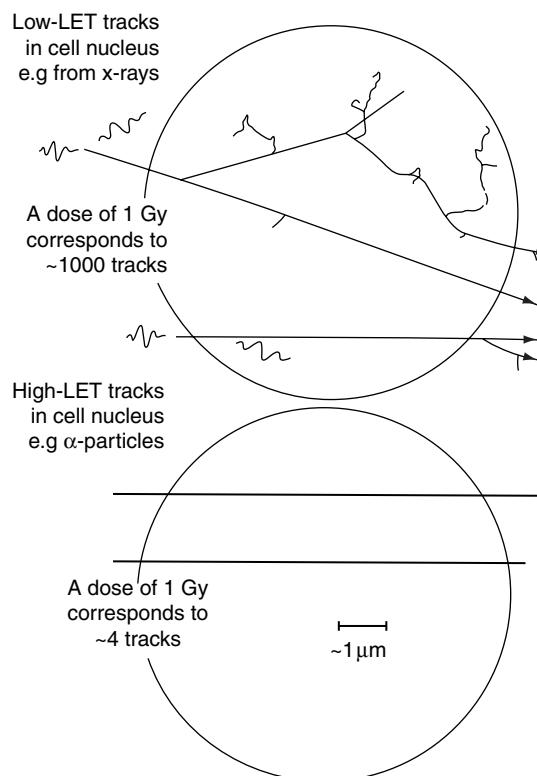

## 7.14 THE EFFECT OF DIFFERENT RADIATION QUALITIES OR LET

There has so far been very little mention of the effect of the *quality* of the radiation employed, i.e. whether this be photons (x- or  $\gamma$ -rays), electrons (linac-produced or  $\beta$ -rays), neutrons, protons,  $\alpha$  particles, etc. or of their energy or energy spectrum. This is a complex and important issue, but it is possible to simplify it inasmuch as the radiobiological effect over the radiation-quality range employed in modern radiotherapy, i.e. overwhelmingly megavoltage beams from linear accelerators or cobalt-60  $\gamma$ -radiation, exhibits entirely negligible variations (for the same total dose delivered in a given fractionation pattern at a given dose rate). This is also true of the high-energy end of the kilovoltage x-ray range (approx. 50 kV and above) and is very nearly the case even for high-energy proton beams. All of the above radiation qualities are classed as *low-LET*. This refers to the fact that the ionisation density along the tracks of the secondary charged particles (overwhelmingly electrons) is relatively low. LET stands for *Linear Energy Transfer* which is another term for (collision) Stopping Power (see Chapter 3). However, this constancy of biological effect over a wide quality range does not extend to neutrons or charged particles heavier than protons which are often known as *light ions* (see Chapter 46 and Chapter 49). Such qualities are classed as high LET. In fact, one could justifiably add a 6th R to the 5 Rs previously discussed: Radiation Quality.

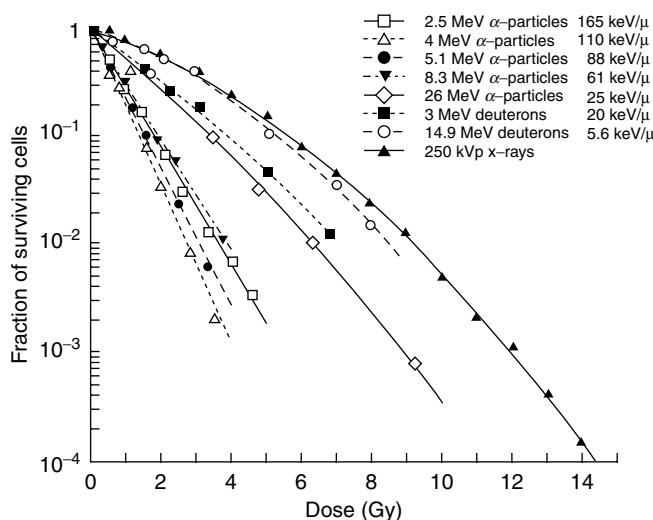

The considerable difference between low- and high-LET charged-particle tracks is illustrated in [Figure 7.14](#). An absorbed dose of 1 Gy corresponds to around 1000 electron tracks but only about 4 from  $\alpha$ -particles (in a volume equal to that of the cell nucleus). This shows how much more *energy* is transferred *per unit distance* along the high-LET  $\alpha$ -particle tracks compared to that transferred by the low-LET electrons.

A huge number of cell irradiation experiments have been carried out over the years with different qualities of radiation (e.g. Barendsen 1968; Raju 1980; Fowler 1981; Joiner 2002b). From these experiments, a clear picture has emerged. As the LET increases, more cell killing is generally produced per Gy. [Figure 7.15](#) shows experimentally derived surviving fraction vs. dose curves for human kidney cells irradiated by radiation ranging from 250 kV x-rays, representing low-LET radiation (LET = 2 keV/ $\mu$ m), through to 2.5 MeV  $\alpha$ -particles at the high-LET end (LET = 165 keV/ $\mu$ m)\*. Several things can be observed in Figure 7.15. First, the curves

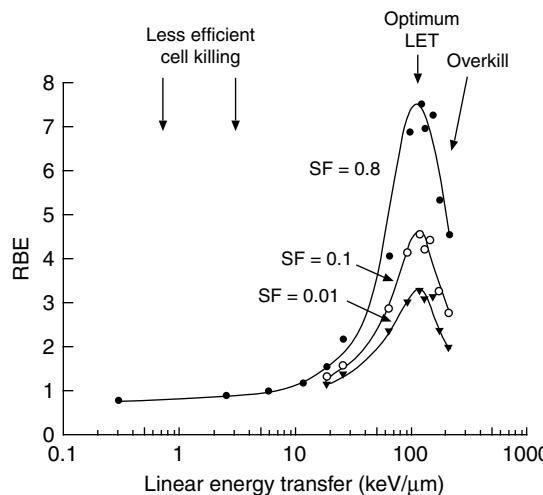

\* To characterize a radiation quality by a single value for LET is a gross simplification (ICRU 1970). All radiations give rise to a broad spectrum of charged-particle energies in irradiated media; this is especially true of megavoltage photons or electrons, which produce electron energies from several MeV down to tens of eV, with  $S_{\text{col}}$  values in water (see Chapter 3), i.e. with LET in water, ranging between 2 MeV/cm (0.2 keV/ $\mu$ m) and 250 MeV/cm (25 keV/ $\mu$ m). An example of the complete electron-fluence spectra produced in water by megavoltage radiation can be found in Nahum (1976, 1999).

**FIGURE 7.14**

Particle track structure for low-LET radiation (upper picture) and for  $\alpha$ -particles (lower picture). The circles represent the size of the nucleus of a typical mammalian cell. The tortuous nature of the (low-LET) secondary electron tracks are in complete contrast to the high-LET particles, of which only around four are required to deposit a dose of 1 Gy in that small volume. (From Goodhead, D. T., *Health Phys.*, 55, 231–240, 1988. With permission.)

**FIGURE 7.15**

Surviving fraction measured in vitro for human kidney cells exposed to radiations with a wide range of (mean) LET. (From Barendsen, G. W., *Curr. Top. Radiat. Res. Q.*, 4, 293–356, 1968. With permission.)

**FIGURE 7.16**

The relationship between RBE, for cell killing, and (mean) LET. The three curves correspond to different levels of cell survival, showing how RBE depends on exactly how it was determined. The low-LET qualities overwhelmingly employed in radiotherapy correspond to the mean values of  $\text{keV}/\mu\text{m} < 1.0$  where the RBE is essentially constant. (From Barendsen, G. W., *Curr. Top. Radiat. Res. Q.*, 4, 293–356, 1968. With permission.)

become progressively steeper with increasing LET, corresponding to increased radiosensitivity. Second, these curves also become progressively straighter (or there is less *shoulder*). This corresponds to higher and higher  $\alpha/\beta$ -ratios. Or, in other words, more of the cell killing is by the  $\alpha$ - or single-hit (non-repairable) mechanism (see [Section 7.13.2](#) and Chapman 2003) and correspondingly less by the  $\beta$ - or repairable mode. This can be understood from the very different track structures illustrated in [Figure 7.14](#); a hit on the DNA in the cell nucleus from a densely ionising high-LET track will almost always cause major, irreparable damage, whereas, the vast majority of the low-LET hits are much less damaging because much less energy is transferred. Such considerations fall under the scope of *Microdosimetry* (e.g. ICRU 1983; Goodhead 1988).

The radiotherapeutic implications of the higher  $\alpha/\beta$ -ratio for high-LET radiation will be understood by referring to Chapter 9; briefly, for a given total dose, one would expect much *less* dependence of either tumour control probability or normal-tissue complication rate on *fraction size*. This has certainly been observed, at least in mice and rats, for the case of neutron radiation (Withers et al. 1982) which is a high-LET quality because the secondary charged particles are low-energy protons and these are high-LET particles (unlike the very high-energy proton beams required for proton radiotherapy).

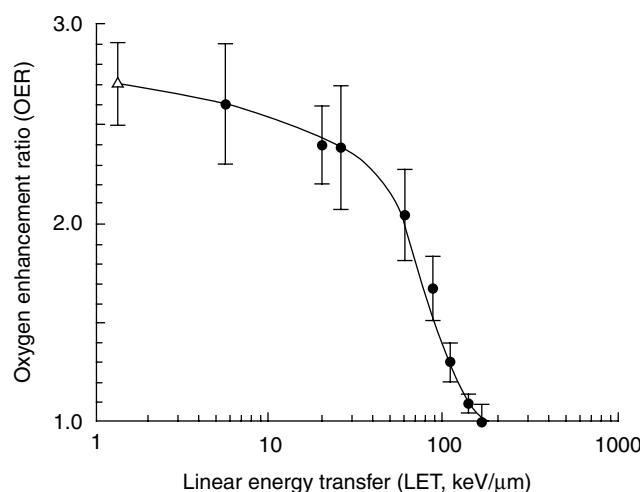

The differing biological effectiveness of various radiation qualities is generally expressed through the quantity RBE (*relative biological effectiveness*). RBE is defined as

$$\text{RBE} = \frac{\text{dose of reference radiation}}{\text{dose of radiation under investigation}} \quad (7.3)$$

to give the same biological effect (i.e. in this case, surviving fraction)\*. The standard reference radiation is usually a low-LET quality such as 250 kV x-rays.

Figure 7.16 shows the relationship between RBE and (mean) LET. Over a range of low LET values, between 0.3 and about 5.0, there is little change. The maximum is a characteristic

\* Another frequently encountered endpoint is cancer induction (see Part L; Sachs and Brenner 2005); RBE values can be very different for the two endpoints of cell killing and carcinogenesis.

**FIGURE 7.17**

The relationship between OER and (mean) LET; the closed circles correspond to monoenergetic  $\alpha$ -particles and deuterons and the open triangle to 250 kV x-rays; the dose levels where these OER were determined was not stated. Note that OER  $\approx 2$  at the mean LET of therapeutically useful carbon ions. (From Barendsen, G. W., *Curr. Top. Rad. Res. Q.*, 4, 293–356, 1968. With permission.)

feature of such curves and corresponds to a type of saturation, or overkill, effect. It should be noted that different values result from determining the RBE at different cell survival levels; SFs of 0.01, 0.1, and 0.8 were used by Barendsen (1968) in constructing Figure 7.16.

Another important radiobiological difference between radiations of differing LET concerns the effect of oxygen on cellular radiosensitivity. In Section 7.9, the concept of Oxygen Enhancement Ratio (OER) was introduced in the context of the low-LET qualities commonly employed in radiotherapy. As pointed out in Section 7.9 and Section 7.10, OER values are sufficiently high in low-LET radiation (between  $\approx 2$  and  $\approx 3$ ) that one would not expect to achieve uncomplicated tumour control in situations where the tumour contains an appreciable fraction of hypoxic clonogens. There is clinical evidence that this is, in fact, the case (e.g. Brizel et al. 1999; Movsas et al. 2002). With high-LET radiation, there is evidence from cell-survival curves obtained in vitro that the OER is reduced below its low-LET value with the degree of reduction being dependent on mean LET as Figure 7.17 illustrates.

However, as Dasu and Denekamp (1998), Nahum et al. (2003), and others have pointed out, the effective OER for the 2-Gy fraction size commonly used in megavoltage photon or electron (i.e. low-LET radiotherapy) is closer to 2 than to 3. Therefore, the theoretical advantage of high-LET over low-LET radiotherapy in hypoxic tumours (e.g. through the use of high-energy carbon-ion beams, which have a mean LET of around 80 keV/ $\mu$ m in the spread-out Bragg peak region) (Suzuki et al. 2000; see also Chapter 49), may turn out to be negligible in practice.

## 8.1 NORMAL-TISSUE REACTIONS TO RADIOTHERAPY

The damage caused by radiation treatment in the various normal tissues of the body varies widely, both in type and in severity. Many patients testify to their experiences that the morbidity associated with cancer therapy is very distressing, and it substantially detracts from the therapeutic benefits. Some tissues, such as the lungs, intestine, and bone marrow, are vital to life; severe radiation damage to these tissues may lead to death. Damage to other tissues, such as the skin, limbs, or gonads, is not usually life-threatening; nevertheless, it can lead to significant impairment of life.

---

## 8.2 WHAT DETERMINES THE SEVERITY OF NORMAL-TISSUE DAMAGE?

Many factors are involved in determining the severity of normal-tissue damage; these may be divided into two categories: controllable factors and uncontrollable factors.

### 8.2.1 CONTROLLABLE FACTORS

The term *controllable factors* principally refers to total radiation dose and treatment volume. Radiation effects are always more severe or more likely to occur as the radiation dose is increased. They also become more frequent as the *size* of the radiation field is increased; this is called the *volume effect* (Section 8.9). Related to this is the question of which normal structures are contained within the radiation field, as enlargement of the field may result in the inclusion of a structure that otherwise would not have been irradiated. A number of other controllable factors influence radiation damage to normal tissues. The choice of fractionation parameters is important: damage tends to increase with increasing dose per fraction (for a given total dose) and is often greater for short overall treatment times (see Section 9.3 and Section 9.4). If the interval between fractions is reduced below 24 h (and especially to below 6 h), then repair of radiation damage may be incomplete and the damage is increased. Concomitant therapy, especially with cytotoxic drugs, also often leads to increased normal-tissue complications.

### 8.2.2 UNCONTROLLABLE FACTORS

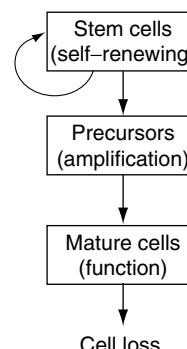

Uncontrollable factors include the age and clinical status of the patient, concurrent disease, genetic make-up, and to some extent, lifestyle. Patients who are older, or in poor health, often have reduced tolerance of radiation treatment. Smoking and excessive alcohol consumption are examples of lifestyle factors that increase the effect of radiation on normal tissue. The issue of genetic make-up is highly topical at the present time. Some radiotherapy patients *burn* more easily than others, just as some individuals react more to sunlight than others. There are a number of recognised inherited syndromes that are associated with an increased risk of damage by radiotherapy, especially ataxia-telangiectasia, Fanconi's anaemia, and Cockayne's syndrome. Genes associated with these and other syndromes are now being identified, and the range of responses seen within the *normal* population may be partly because some people carry these

genes. The term *heterozygote* means a person who is carrying a copy of a particular gene in a *recessive* mode, i.e. without expressing the disease itself. Heterozygotes for a radiosensitivity gene do not show the same level of sensitivity as the *homozygote* (who carries two identical copies of a particular gene), but they may show a tendency towards increased radiation damage. Efforts are being made to develop screening procedures for genes that could influence radiation sensitivity, and this might lead to tests that enable unduly sensitive individuals to be identified prior to radiation treatment.

## 8.3 THE PROLIFERATIVE STRUCTURE OF TISSUES

Most tissues consist of a complex variety of cell types. Often there is a principal functional cell type that is referred to as the *parenchymal* component of the tissue. Invariably, there is also a connective-tissue component made up of fibroblasts, blood vessels, nerve cells, and mobile cells such as macrophages. The epithelial tissues that cover the outside of the body (i.e. epidermis) and the lining of the gut are structurally the easiest to understand. Here the parenchymal component is a sheet of cells, one or more cells thick, lying on supportive connective-tissue structures. When this type of tissue is exposed to radiation, all cell types are damaged and this damage may be expressed in different ways. Some epithelial tissues are in a state of rapid cell turnover in which the structure shown diagrammatically in Figure 8.1 can clearly be seen. There are *stem cells* that have the dual ability to renew themselves and also to *differentiate* into mature cells. *Differentiation* means changing into a special type of cell with the ability to perform a specialised function. In the small intestine, this function is to absorb nutrients from the gut; in the skin, the function is to act as a waterproof and physical barrier.

When stem cells begin to differentiate, they usually proliferate faster and tend to be more sensitive to proliferation-dependent cytotoxic agents and may be more radiosensitive. Irradiation tends to stop cell proliferation, and if the dose is high enough, the production of new cells may fail to keep up with cell loss. The parenchymal cell population will, therefore, decline, and the tissue may eventually break down. In the epidermis, this leads to the loss of the superficial layers of the skin, *moist desquamation*, and even ulceration. Skin that has been damaged in this way may heal (if the dose is not too high) but problems may develop at later times as a result of the radiation damage to connective tissues underlying the epidermis. Damaged blood vessels may become permanently swollen and visible to the eye as the disfiguring appearance of *telangiectasia*. The skin may become hard and less flexible. In an extreme case, the tissue may break down into a deep ulcer (i.e. necrosis), a serious clinical problem. In tissues other than the skin, more than one manifestation of radiation injury may also develop, again attributable to damage to the various cell types that are present.

**FIGURE 8.1**

Schematic outline of the structure of a hierarchical tissue such as the skin.

## 8.4 EARLY- AND LATE-RESPONDING TISSUES

The effects of ionising radiation on the various tissues of the body vary considerably, both in terms of the radiation dose required to produce damage and in the timing of the expression of damage. Broadly speaking, tissues are divided into two categories: early-responding tissues and late-responding tissues.

### 8.4.1 EARLY-RESPONDING TISSUES

Early-responding tissues show the effects of radiation damage within a few weeks of being irradiated. Examples of such tissues are skin, oral mucosa, intestines, bone marrow, and testis. Each of these tissues contains functional cells (*epithelial* cells in the case of the surface tissues and *haemopoietic* cells in the case of the marrow) and also connective-tissue cells. The early reactions are due to damage to these parenchymal components which usually have a short functional life-span.

### 8.4.2 LATE-RESPONDING TISSUES

Late-responding tissues show their response to radiation damage over months to years after exposure. Examples of late-responding tissues are lung, kidney, and spinal cord. Damage to these tissues may often be the result of damage to connective tissues, especially blood vessels. Furthermore, some of the early-responding tissues mentioned above may subsequently show a late response that is either due to direct damage to connective-tissue cells or to connective-tissue damage that arises as a result of a very severe loss of parenchymal cells (the so-called *consequential late effects*).

Whereas damage to early-responding tissues tends to heal, damage to the late-responding tissues tends to be more permanent. Although patients can die from severe early reactions, these are usually transient and can be managed by appropriate treatment and nursing. It is the possibility of irreversible late reactions that is usually perceived by the radiation oncologist to be the main limiting factor on treatment. Therefore, it is these reactions that determine the maximum radiation dose that can be given. For instance, damage to the spinal cord appears as paralysis. This is nonrecoverable and a serious impediment to health, and the radiation oncologist will seek to avoid it at all costs.

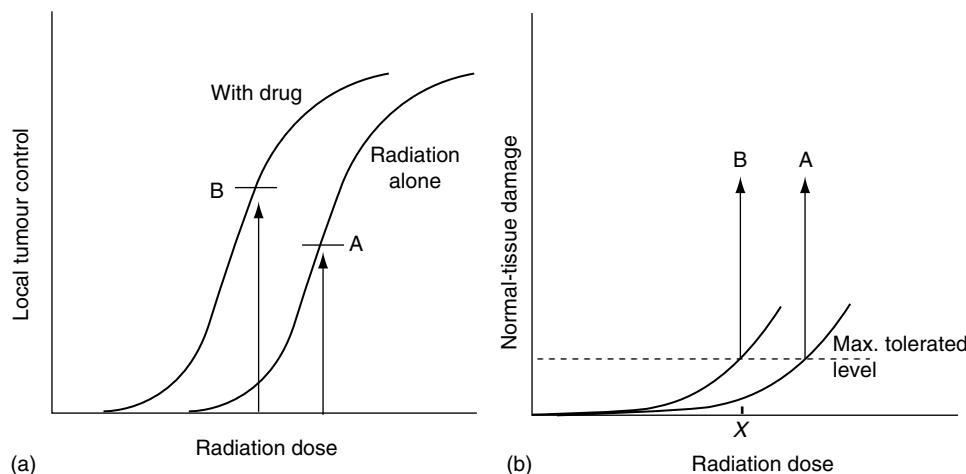

The distinction between early- and late-responding tissues has become more important as a result of the recognition that time-dose relationships are systematically different between them (see [Section 9.3](#)).

---

## 8.5 CONCEPTS OF NORMAL-TISSUE TOLERANCE AND THERAPEUTIC GAIN

Basic to curative radiotherapy is the concept of *treating to tolerance*. As the radiation dose is increased, the effects on the tumour and on normal tissues both increase. The greater the dose of radiation, the greater the likelihood of controlling the tumour. But some types of radiation-induced morbidity are so serious that they must be avoided, and the risk of these also increases with radiation dose. How should the radiation oncologist decide where to stop? In principle, the first step is to decide what level of normal-tissue damage (early or late) the patient can tolerate and the radiation dose is then increased until this level is reached. The level of tumour response will be determined by this maximum dose.

The probability of local tumour control by radiotherapy increases with dose according to a sigmoid relationship (see [Figure 8.2a](#), right hand curve). The probability of normal-tissue damage also increases with dose (see [Figure 8.2b](#), right hand curve). This curve may also be

**FIGURE 8.2**

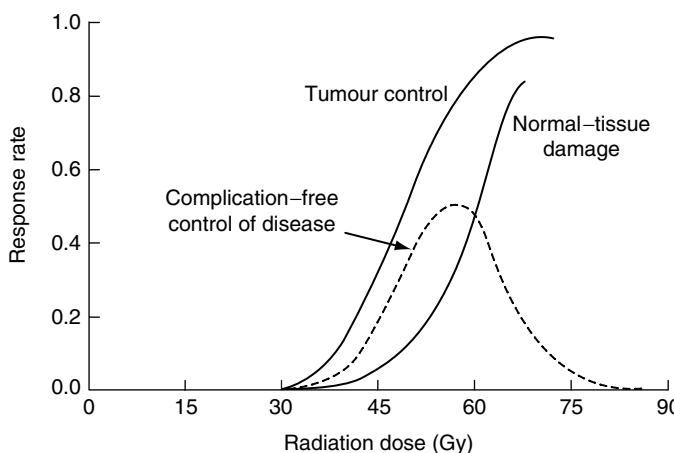

Illustrating the procedure by which an improvement in therapeutic index might reliably be identified as a result of adding chemotherapy to radiotherapy.

sigmoid in shape, but for serious complications only the bottom part of the curve is of interest. The radiation oncologist must decide the maximum level of complications that can be permitted (the *tolerance* level). This, in turn, fixes the level of tumour control that can be achieved (i.e. point A in Figure 8.2a).

Figure 8.2 also illustrates a very important principle: the concept of *therapeutic index* or *therapeutic gain*. For example, if chemotherapy is added to treatment that is initially by radiotherapy, how can it be known if a significant gain has been made? This is a complicated question that in clinical practice is seldom satisfactorily answered. The complication comes from the fact that chemotherapy, when given with radiotherapy, commonly increases not only the tumour response but also many types of radiation-induced normal-tissue damage. Therefore, an observed increase in tumour control is often at the expense of increased radiation morbidity. How do we know whether the same gain could not also have been obtained just by increasing the radiation dose?

The strategy to deal with this problem is illustrated in Figure 8.2, and it goes as follows: In the patients who are being given the combined (drug + radiation) treatment, a range of radiation doses is explored in order to identify the radiation dose ( $X$ ) which, when combined with chemotherapy, gives the *same* incidence of treatment complications as chosen for radiotherapy alone (the assumed tolerance level). The expectation shown in Figure 8.2 is that this will lead to a level of tumour control at point B. If it can be statistically shown that point B is higher than point A, then there has been a proven *therapeutic gain* by adding the chemotherapy. Tumour response has been increased without increasing the treatment-induced morbidity (for radiation dose  $X$ ), and such a gain could *not* have been obtained by merely increasing the radiation dose.

This concept is clear in theoretical terms. Unfortunately it is very difficult to put into practice. In the clinic it is impractical and unethical to explore a range of radiation doses in order to plot out the curves shown in Figure 8.2. This can be, and has been, done in experimental animals where the ethical constraints are not (yet) as stringent. Furthermore, the numbers of patients available for such a study is invariably too small to allow more than a three-arm clinical trial, and the precision that can be expected on the data (i.e. incidence of tumour control and complications) at each dose level is usually too low to allow it to be clearly shown that Point B is different from point A. But if this cannot be done, then there is no way of knowing whether a claimed benefit of adding chemotherapy could not have also been gained just by increasing the radiation dose. In addition, the large variations in tumour parameters

**FIGURE 8.3**

Illustrating the idea of complication-free tumour control. See text for a warning about this concept.

(volume, site, histology, gene expressions, etc.) of patients recruited to clinical trials will further confound the outcomes. The broader aspects of the combination of radiotherapy and chemotherapy are dealt with in Steel (2002a, b), Stewart and Bartelink (2002) and Wilson et al. (2006).

Figure 8.3 shows a similar type of representation of therapeutic index. From the dose-response curves for tumour control and normal-tissue damage respectively, the *probability of complication-free tumour control* has been calculated as shown by the dashed line. This is a bell-shaped curve against radiation dose. Although this is an interesting notion, it does not provide an appropriate approach for clinical practice: it would be wrong to suppose that the correct treatment policy is to prescribe a radiation dose that is at the peak of the dashed curve because, in some situations, this might be a dose that greatly exceeds an acceptable level of normal-tissue damage. Furthermore, calculation in this way assumes that the therapeutic *value* of tumour control can be equated to the *penalty* of a complication. There is no practical basis for such an assumption, and it is better to recognise that a key part of the judgement of a radiation oncologist in any individual case is to balance the risks and severity of radiation responses, both in the tumour and in the surrounding normal tissues.

## 8.6 STEEPNESS OF DOSE-RESPONSE CURVES

As previously demonstrated, if the total dose given to a patient is increased, it is expected that both local tumour control and normal-tissue damage will increase. Whether there will be a therapeutic advantage in doing this depends on the steepness of the dose-response curves for these two endpoints. Dose-response curves are, therefore, fundamental to clinical radiobiology.

Dose-response curves are usually sigmoid in shape (see Figure 8.3). At a low dose, such a curve is shallow and there is only a slow increase in the effect with dose. At a high dose, the same is also true. The steepness of the curve reaches a maximum at the point of 50% response. The theory and significance of dose-response curves has been further described by Brahme et al. (1988) and Bentzen (2002).

### 8.6.1 BASIC PROPERTIES OF DOSE-RESPONSE CURVES

In an ideal model situation where there is no variability between tumours or patients and no host response against residual cancer cells, tumour control would be achieved when the last

**TABLE 8.1**

Steepness of Dose–Response Curves from Studies in Clinical Radiotherapy

Normal-Tissue Damage	$\gamma_{50}$	Tumour Control	$\gamma_{37}$
Type of Damage		Tumour Type	
Frozen shoulder	4.8	Head and neck	2.8
Larynx oedema	4.3	Larynx	1.7–2.8
Rectal complications	0.4	Nasopharynx	1.6–1.8
Subcutaneous fibrosis	3.7	Neck nodes	1.4
Telangiectasia	2.2–3.5	Base of tongue	0.5, 0.9
		Supraglottic larynx	0.6, 0.8

Steepness is indicated by  $\gamma$ -values (see text). Ranges show the range of mean values from a number of clinical studies. From Bentzen (1997), where error estimates and original references will be found.

clonogenic cell is sterilized. The probability of cure will then be based on Poisson statistics (see Equation 36.5). If  $m$  is the mean number of clonogenic cells that survive the treatment, then the tumour control probability (TCP) is given by the zero-order term of a Poisson series:

$$\text{TCP} = e^{-m} \quad (8.1)$$

If there is a cell-survival curve that is accurate down to such small survival levels, then how  $m$  depends on dose is known and a TCP vs. dose curve can be calculated (see Section 36.2.1.2 for a detailed explanation of how this can be done). Such a curve is steep, but not infinitely steep. A similar argument applies to dose–response curves for normal-tissue damage where the endpoint is a reduction in the number of stem cells (or, more accurately, tissue-rescuing units) below a critical threshold.

The conventional way of expressing the steepness of a dose–response curve is to indicate, at the steepest point of the curve, the *percentage increase in effect for 1% increase in dose*. This dimensionless quantity is called the  $\gamma$ -value (Brahme et al. 1988). To be more precise,  $\gamma_{50}$  is the steepness at the 50% effect level,  $\gamma_{37}$  at the 37% level, and the appropriate choice between these depends on the form of the dose–response curve. Under the ideal circumstances just described, the maximum value for  $\gamma$  is around 7. Some values calculated from actual clinical data are shown in Table 8.1. For the head and neck tumours,  $\gamma_{37}$  ranges from 0.5 to 2.8. For various types of normal-tissue complication, the  $\gamma_{50}$  values range from below 1 to 4.8. Of course, these values are subject to various types of experimental error, but the following conclusions can be drawn from the body of data so far accumulated:

- Dose–response curves for complications of radiotherapy are often very steep with  $\gamma$ -values exceeding 3. There is a tendency for  $\gamma$ -values to be higher, and for the curves to be steeper, for *late* responses than for damage to *early*-responding tissues.
- The steepness of tumour control curves is often less than that for late complications.

## 8.6.2 WHAT DETERMINES THE STEEPNESS OF DOSE–RESPONSE CURVES?

In practice, a tumour control curve has to be obtained by recording success or failure in a large number of patients treated with different radiation doses. Such a clinical study cannot, for ethical reasons, be planned to obtain these data in a well controlled way; the data usually have to be accumulated from trials with different doses performed over a clinical *learning period*. Therefore, the results are subject to the sources of error that always accompany such noncontrolled trials.

More importantly, inter-patient and inter-treatment variation will always tend to make the dose-response curve shallower\*. If, for example, there is a mixture of sensitive and more resistant tumours, then the sensitive subgroup will have a dose-response curve that lies to the left of that for the more resistant tumours. The overall dose-response curve will, therefore, be a composite of steep curves at different points on the dose scale, and it will be flatter than any single one of them. Factors which may vary from one patient to another and which will contribute to such flattening include the quality of dose delivery and variation in various biological factors: cellular radiosensitivity, tumour hypoxia, speed of repopulation, etc. There is a growing realisation that these biological factors may, to a greater or lesser extent, be under genetic control and that, by genetic testing, it might be possible to identify sensitive and resistant subgroups of patients. If this could be done, then the dose-response curve for each subgroup would be steeper than for the patient group as a whole and there might be the possibility of improved therapeutic management.

The value of  $\gamma$ , either for tumour or treatment complications, also depends on whether, it is the *fraction number* or the *dose per fraction* that is kept constant as the dose is increased (Bentzen 2002). If it is the number of fractions then as the total dose increases so does the dose per fraction, and because *biological effectiveness* increases with dose per fraction (see [Section 9.3](#)), this will make the dose-response curve steeper. This is a manifestation of what has come to be called *double trouble*.

---

## 8.7 RADIATION PATHOLOGY

Each major tissue of the body shows a characteristic series of reactions to radiation exposure. They may be classified as stochastic or nonstochastic (also called deterministic, see [Section 59.1.1](#)).

### 8.7.1 STOCHASTIC EFFECTS

Stochastic effects are those for which the *incidence*, but not the *severity*, of damage increases with radiation dose. A prime example is radiation carcinogenesis, i.e. the induction of second tumours by radiation. The key biological event is neoplastic transformation, the probability of which is radiation-dose dependent, but the eventual development of a tumour is an *all-or-nothing* event. The induction of tumours by radiation was long thought to follow a bell-shaped curve against dose because the probabilities of transformation and the killing of transformed cells both increase in a nonlinear way with radiation dose. High radiation doses produce more transformants, but even more of these will be killed, and the actual frequency of viable transformants was thought to eventually decrease with increasing dose. However, Sachs and Brenner (2005) have put forward an alternative hypothesis which predicts a slow continuous increase with dose at high doses.

### 8.7.2 NONSTOCHASTIC EFFECTS

Nonstochastic effects are the more common and more clinically important effects, in which the *severity* of damage increases with radiation dose. Whether the *incidence* also increases with dose depends on how the data are presented. A common practice is to count the number of cases where the severity of a reaction exceeds a defined level. When this is done, it will usually be found that the incidence (e.g. of grade-3 effects) increases with dose for such nonstochastic effects. The following are examples of nonstochastic effects in three selected tissues.

---

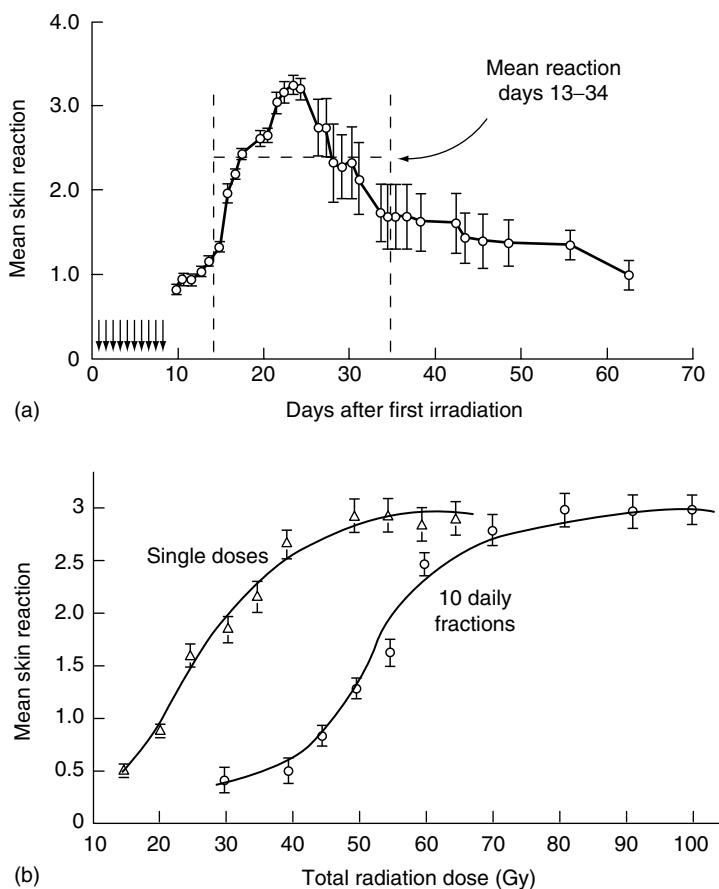

\* The  $\sigma_x$  parameter was introduced by Webb and Nahum (1993) into their TCP model precisely in order to account for such *interpatient* differences in radiosensitivity ([Section 36.2.1.2](#)).

### 8.7.2.1 Skin and Mucosae

Effects in the skin are easily visible to the eye, both to the doctor and to the patient. Therefore these attract attention. As radiation dose is increased, the first evidence of damage is reddening (*erythema*), shortly followed by scaling (*dry desquamation*), and then by weeping (*moist desquamation*). After high radiation doses, the skin may finally break down in *necrosis*. The mucosal lining of the mouth cavity is a stratified epithelium, like the skin, and damage to this mucosal lining is a significant limiting factor in head-and-neck radiotherapy. Skin damage begins to appear at the end of the second week of radiotherapy, and reaches a peak between four and eight weeks after the start of treatment (see Figure 8.4a). This is an *early reaction* as described in Section 8.4. Skin damage will eventually heal unless it is very severe, but it may be followed by more persistent types of late damage. The skin may become hard and inflexible (i.e. *fibrosis*), and there may be long-term damage to blood vessels as evidenced by the visible and disfiguring appearance of *telangiectasia*.

### 8.7.2.2 Lung

The lungs are among the most radiosensitive of anatomical structures and are essential to life. The first evidence of damage is *pneumonitis*, which appears three to six months after irradiation. Lung function is impaired in a dose-dependent manner to an extent that may

**FIGURE 8.4**

(a) The time-course of radiation-induced skin damage in mice irradiated with ten fractions of 6 Gy. (From Brown, J. M., Goffinet, D. R., Cleaver, J. E., and Kallman, R. F., *J. Natl. Cancer Inst.*, 47, 75–89, 1971.) (b) Dose–response curves calculated from such data as in panel A for irradiation with a single dose or with ten fractions.

lead to death. Patients who survive this first phase may suffer a second phase of damage a year or more after irradiation. This is due to a progressive and irreversible fibrosis of the lung that also manifests itself in breathing problems.

### 8.7.2.3 Brain and Spinal Cord

These are tissues which have a very low rate of cell turnover, and damage is only manifested many months to years after irradiation. In less severe cases there may be neurological effects that eventually resolve, but above a critical dose threshold the damage progresses to permanent radiation myelopathy or necrosis. In the cord this presents as paralysis, and the severity of this effect on the patient is such that radiation oncologists take great care to reduce the risk of it happening to below 1%.

---

## 8.8 QUANTIFICATION OF NORMAL-TISSUE DAMAGE

Radiobiologists have developed a wide range of techniques for quantifying the effects of radiation on normal tissues. These include visual scoring methods, assays of tissue function, and stem-cell cloning techniques; most have been developed in the context of laboratory studies on mice or rats, but some are applicable to humans.

### 8.8.1 VISUAL SCORING METHODS

Each manifestation of damage to a tissue such as the skin can be scored, by eye, using an arbitrary scale. For instance, for the skin one may set erythema as 1.0 and necrosis as 4.0 with intermediate scores for other types of damage. [Figure 8.4a](#) illustrates effects on mouse skin measured in this way. The ordinate is the average reaction score obtained in a group of mice given a dose of 60 Gy in 10 daily fractions. The reaction starts around days 7–10 (probably days 14–17 in humans); it rises to a peak after 4 weeks and then declines slowly over the next couple of months. During this *wave* of response, the character of the skin reaction changes: erythema is an early factor, and necrosis, if reached, comes in later and takes a long time to heal. Radiobiologists have quantified the effects on the skin by calculating the area under such a curve within a defined time interval (13–34 days in this example). By performing experiments at various radiation doses it is then possible to build up a *dose-response curve*. [Figure 8.4b](#) shows two such curves: for single-fraction and multiple-fraction irradiation. These curves are sigmoid in shape, and they clearly show the sparing effect of fractionation. Visual scoring may seem ‘low-tech’ and of dubious precision, but it has proved to be a valuable method which has made an important contribution to normal-tissue radiobiology.

### 8.8.2 ASSAYS OF TISSUE FUNCTION

In tissues where a relevant assay of tissue function is available, this may be a valuable endpoint for radiobiological studies. The lung is a good example. During the expression of radiation pneumonitis there is a decrease in lung function that can be detected by standard clinical lung-function tests. In mice, there is a rise in breathing rate above the normally very fast rate of around 350 breaths per minute. This can be detected in an enclosed chamber by a microphone, displayed as breathing rate on a pen recorder, and quantified electronically. A wide range of radiobiological studies has been made in this way.

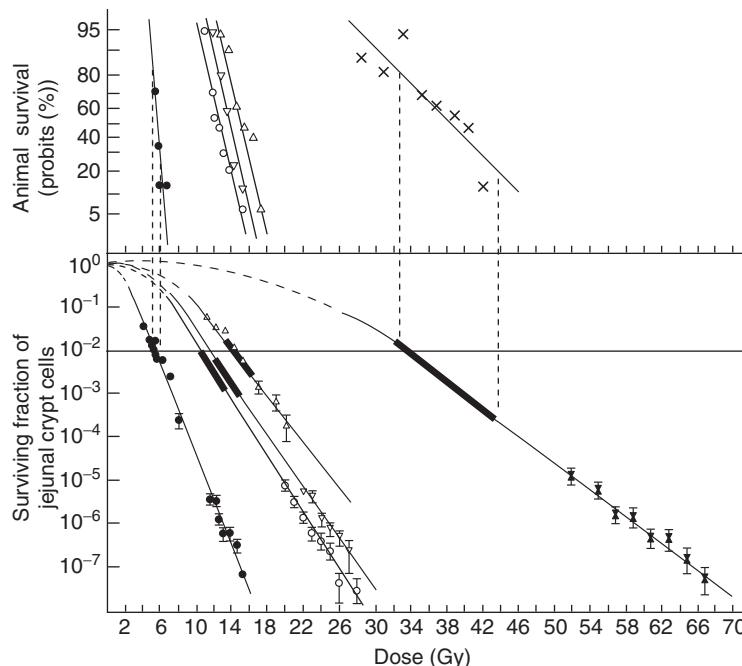

The kidney is another example of a tissue where physiological function can easily be measured. A common technique is to study the excretion rate of a radioactively labelled tracer, such as  $^{51}\text{Cr}$ -labelled EDTA (ethylenediaminetetraacetic acid).

Damage to the bladder has been documented by measuring urination frequency. Mice are placed in a cage that has a grid base; paper towels on a roller are automatically passed at a constant rate under the cage, and urine spots on the towel are counted or sized. Damage to the large intestine and rectum has been documented by measurements of faecal size, shape, and composition. The ingenuity of radiobiologists to invent clever and sensitive (but unsavoury) endpoints of normal-tissue damage knows no bounds.

### 8.8.3 STEM-CELL CLONING TECHNIQUES

In experimental animals, it is possible to look deeper into the biology of damaged tissues. For the skin, intestine and a few other tissues methods have been developed which allow colony formation by stem cells (Section 8.3) to be detected. Many early developments in normal-tissue radiobiology were made using these methods. For some tissues, it is possible to transplant irradiated cells into genetically identical recipient animals as a way of studying the radiosensitivity of stem cells. Best-known are the applications to blood-forming tissues. In classic studies on mouse bone marrow, Till, McCulloch, and their colleagues in the Ontario Cancer Institute intravenously transplanted marrow cells from test-irradiated animals into mice whose endogenous marrow had been destroyed by whole-body irradiation (Till and McCulloch 1961). The transplanted marrow stem cells grew to form colonies in the spleen that could be counted by eye. The number of colonies exponentially decreased with the radiation dose that the test cells had received, and it was possible to conclude that the mean inactivation dose for marrow stem cells was around 1 Gy.

An example of cloning studies on the mouse small intestine is shown in Figure 8.5. Hornsey (see Alper 1973) irradiated mice under a variety of conditions and measured both the effects on the whole animal (i.e. lethality) as well as the survival of intestinal stem cells using a colony assay.

**FIGURE 8.5**

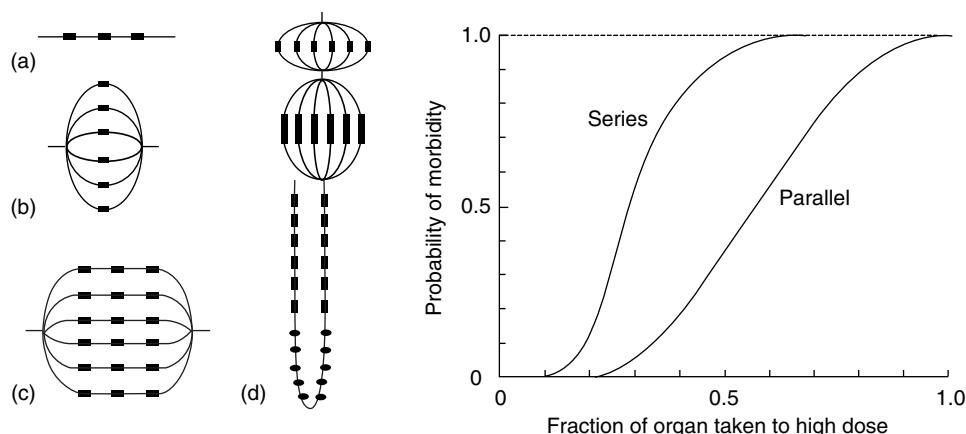

Survival of mice five days after irradiation (upper panel) matched with survival curves for intestinal stem-cells. From left to right, the irradiations were with neutrons, electrons (high and low dose rate), x-rays, and electrons under hypoxic conditions. (Reproduced from Alper, T., *Br. Med. Bull.*, 29, 3–6, 1973. With permission.)

The figure shows a remarkable observation: for each condition of irradiation, the radiation dose that caused around 50% lethality (upper panel) reduced the survival of intestinal stem cells to around  $10^{-2}$  (i.e. 99% cell kill). This not only shows that the stem-cell assay produces realistic estimates of radiation damage, but it also indicates that, as a general rule, the intestine can tolerate the loss of no more than 99% of its stem cells. Less damage than this can be made up by rapid repopulation after irradiation; greater damage will lead to intestinal failure. As indicated in [Section 7.4.3](#), this observation illustrates the predicament of the radiation oncologist: to achieve tumour control requires perhaps nine or ten decades of killing of tumour cells, but this must be achieved without exceeding around two decades in the critical normal tissues.

## 8.9 THE VOLUME EFFECT

### 8.9.1 INTRODUCTION

The severity of radiation-induced normal-tissue damage depends, to a very large extent, on the volume of tissue irradiated. *Volume effects* differ among the various organs of the body, depending on their structural organisation (see left-hand side of Figure 8.6) and on the migration characteristics of the surviving stem cells. Some tissues, in spite of having cells that are inherently radiosensitive, may nevertheless have a large volume effect and, therefore, are resistant to partial irradiation. Examples of this are the kidney or lung, both of which are among the most sensitive organs when the whole of the organ is irradiated but where partial volumes can be treated to far higher radiation doses. This occurs because there is considerable reserve capacity in these organs, and only one quarter to one third of the functional organ volume is required to sustain life under normal physiological conditions. In contrast, other more tube-like structures such as the spinal cord have a different volume effect: inactivation of a short segment causes loss of function of the whole organ (i.e. paralysis). Such tissues are sometimes said to have a *serial* organisation (lung and kidney would be described as having a *parallel* organisation).

**FIGURE 8.6**

Clinical benefit from a reduction in field size may depend upon how morbidity increases with field size. The *left-hand* picture illustrates the concepts of (a) series (or serial), e.g. the spinal cord; (b) parallel, e.g. the lungs; (c) serial-parallel, e.g. the heart; and (d) a combination of parallel and serial structures, e.g. a nephron (From ICRU, *Prescribing, Recording and Reporting Photon Beam Therapy*, Report 62, ICRU, Bethesda, MD, 1999). The form of the complication probability vs. partial high-dose volume relationship can be expected to differ between series- and parallel-type tissues as indicated in the *right-hand* picture.

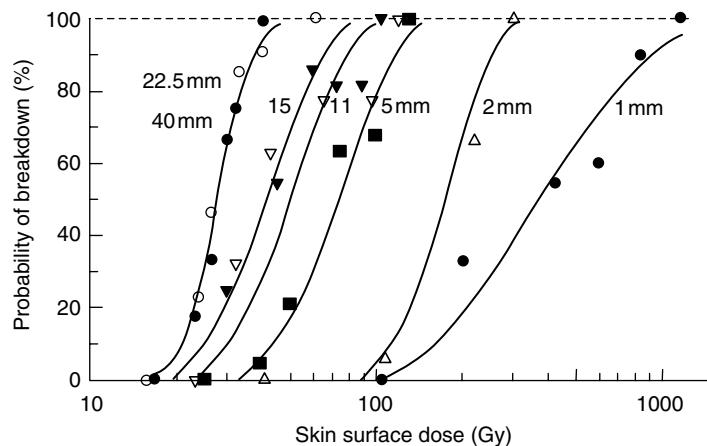

Intermediate between the *parallel* or *serial* organisation types are tissues composed of specialised elements, each carrying out very specific functions such as parts of the brain. Radiation damage even to a small area of this tissue leads to a permanent deficit for that particular function since the uninjured components may be unable to take over the functions of the affected elements. As a consequence, the *tolerance* dose of such tissues is only influenced to a small extent by the volume of the tissue irradiated. However, irradiating a larger volume may result in a more severe functional failure because of the elimination of a larger number of functional elements.

The magnitude of the volume effect is of critical importance to the development and success of *conformal radiotherapy* (see [Chapter 43](#) and [Part I](#) generally). If there is a large volume effect, then reducing the volume of normal tissue taken to a high radiation dose should allow a considerable escalation in dose with the expectation of an improved tumour response. If the volume effect is low, then there is little to be gained in this way. Models for normal-tissue complication (see [Section 36.3](#)) must accurately reflect the volume effects of the various organs if they are to make reliable predictions of complication probability for arbitrary dose distributions.

### 8.9.2 BASIS OF THE VOLUME EFFECT

In spite of considerable attention by researchers, the biological basis for the volume effect is still unclear in most tissues. A major limitation has been the fact that most laboratory research has been on small animals (rats and mice) in which clinical-sized radiation fields cannot be used, and there is a serious scaling problem. A mouse is roughly 1/20 the *height* of a man: can it be assumed that changing a field diameter from 5 mm to 10 mm in the mouse is equivalent to changing from 10 cm to 20 cm in the clinic? Such scaling is unlikely to be valid because one component of the volume effect may be cell migration to replace damaged cells, and although this could occur faster in mice, it is unlikely to be twenty times faster. There may be other (e.g. vascular) factors that also do not scale with body size. The *fractional* volume of an organ that is irradiated may be important, but this also may not scale well over a wide range of body sizes.

Figure 8.7 shows data on the volume effect in pig skin (Hopewell 1986). The pig was chosen for these studies because the structure of its skin is similar to that of man. Strontium-90

**FIGURE 8.7**

The volume effect in pig skin. The skin was irradiated with circular  $^{90}\text{Sr}$  sources ranging in diameter from 1.0 to 40 mm. The percentage of skin fields showing moist desquamation is shown as a function of the skin surface dose. (From Hopewell, J. W., *Br. J. Radiol.* (Suppl. 19), 39–51, 1986. With permission.)

plaques of differing diameter were placed on the skin, and dose-response curves were generated as shown. As the plaque diameter was decreased from 40 mm to 2 mm, the skin dose that was required to produce moist desquamation increased from around 26 Gy to over 150 Gy. This indicates that there is a very large volume effect in skin over this small range of field sizes. Such an effect may well be due to the ability of undamaged epithelial cells to migrate into the irradiated area from its periphery and repopulate it, an effect that will clearly be more effective over millimetre than centimetre distances. Changing the field size in the clinical situation from 20 cm to 15 cm may show a volume effect, but *ingrowth* from the edges of the field could be a minor factor and is probably ineffective at these large field sizes. More important could be the discomfort, pain, and potential for infection of a large radiation burn compared with a smaller one. In other tissues such as the spinal cord, marked volume effects have also been seen in small animals over millimetre dimensions (Hopewell et al. 1987).

The basis of the volume effect may differ from one normal tissue to another, and in a body region such as the pelvis, a number of different organs will be involved. A basic characteristic may be how the probability of morbidity depends upon the *fraction* of the organ that is irradiated ([Figure 8.6](#)). *Series*-type tissues (e.g. spinal cord) will show a steeper curve in this type of plot than in *parallel*-type tissues (e.g. lung), and for the latter, there could be greater benefit from volume reduction. However the concept of *morbidity*, as used here, will depend not only on measurable biological factors but also on patient perception. The reader should refer to [Section 36.3](#) on modelling normal-tissue complications where attempts to formulate a mathematical relationship between dose-volume and complication probability for different organs are described.

## 9.1 WHY WE FRACTIONATE IN RADIOTHERAPY

During the last twenty years, important new insights have been gained into the principles of dose fractionation in radiotherapy. The linear-quadratic (LQ) approach (see [Section 7.13](#)) provides a new understanding of why fractionation works and how it may be optimised; this approach has now become the standard method of calculation in modern radiotherapy departments, and it will be described in detail below. The *practical* basis of fractionation was established many years ago, well before the introduction of the LQ approach, through the skill, observation, and wisdom of radiotherapists in France, Austria, and other countries. These historical aspects have been well described by Thames and Hendry (1987), Bentzen (2002) and Fowler (2006).

The most direct reason why fractionation is routinely used in clinical radiotherapy is that it was *empirically* established. The early radiation oncologists began using single-dose treatments, but they soon realised that giving daily doses over a period of weeks also resulted in good tumour control with less severe side effects. In retrospect, this must have occurred because the normal-tissue reactions that limit radiation therapy have a greater recovery or repair capacity than most tumours.

Since those early days there have been some decades of intensive laboratory and clinical research into the scientific basis of radiation fractionation. This is a key area in clinical radiotherapy, and there is evidence that the optimisation of time-dose relationships is crucial to the achievement of a good clinical outcome.

---

## 9.2 HISTORICAL APPROACHES TO FRACTIONATION

### 9.2.1 THE APPROACHES OF STRANDQVIST AND ELLIS

The attempt to provide a quantitative basis for changes in dose fractionation began with the work of Strandqvist and Cohen (among others) in the 1940s. They documented their success or failure in controlling skin tumours by radiotherapy and recorded the incidence of skin necrosis. They found that the total dose required for tumour control increased with the number of fractions. At that time, it was the custom to treat with five daily doses per week, and it was not possible to separate the effects of time from the number of fractions. For individual patients with skin cancer, Strandqvist plotted, using double-logarithmic coordinates, the total radiation dose against the overall treatment time. Using different graph symbols he recorded the outcome in terms of local control or skin necrosis. He was able to draw straight lines that broadly divided the two types of symbol: these lines sloped upward (total dose increasing with overall time), and they are often referred to as *Strandqvist curves* (Strandqvist 1944). This was the first quantitative demonstration of recovery in tumours and normal tissues. Strandqvist curves are early examples of *isoeffect* curves which have an important place in thinking about radiotherapy optimisation. There was some uncertainty about the slope of the Strandqvist curves; Strandqvist believed it was 0.22, but with additional data, Cohen (1952) found a value of 0.33, giving rise to what was known as the *cube root law*. If a radiation oncologist wished to change the overall treatment time, he could read off from the Strandqvist curve a new total dose that should give the same treatment outcome.

Working in Oxford, Ellis (1969) developed the hypothesis that data such as those used by Strandqvist and Cohen could be summarised in a simple formula. Their straight lines on logarithmic coordinates implied a power-law relationship between total dose and overall time for a constant level of effect. Although accurate data on the relative roles of fraction number ( $N$ ) and overall treatment time ( $T$ ) were not available, Ellis used his intuition to separate the exponents for  $N$  and  $T$  as follows:

$$D = NSD \times N^{0.24} \times T^{0.11} \quad (9.1)$$

where  $D$  is the (isoeffective) total dose, and  $NSD$  (the *nominal standard dose*) determines the *intensity* of treatment and is assumed constant for any particular clinical situation. Note that Ellis had divided the 0.33 slope of Cohen into two exponents that roughly give the same result for the case of daily treatments. He included an adjustment to allow for daily (i.e. five) treatments per week.

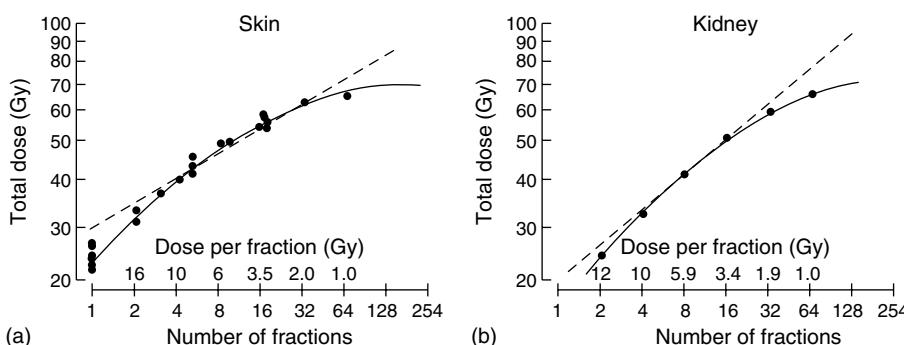

The NSD formula was used for many years as the standard method for adjusting total dose in response to a change in fractionation, but it is an astonishing thought that its scientific basis was very weak. The original data that the slopes of Strandqvist curves were determined from showed considerable scatter, and there was uncertainty in how to represent single-dose data on a logarithmic scale of time. The original data related only to the treatment of skin tumours, but it later began to be used more widely in the absence of adequate alternative data. It gradually became clear that the formula only worked for certain well-defined conditions and within a limited range of fraction numbers. Examples of poor therapeutic results began to accumulate, especially when a fraction number greater than approximately 30 or less than approximately 10 was chosen. Detailed animal studies were performed which showed that a power-law relationship was usually not satisfactory in representing the data, and the slopes sometimes differed substantially from those in the original NSD formula.

As a result, efforts were made to adjust the NSD formula. Variants of it (known as CRE and TDF) were introduced and widely used, and these may have been easier to use and safer. Around 1980, it began to be appreciated that the basic power-law relationship was inappropriate to represent time-dose relationships in radiotherapy. Furthermore, there was a pressing need to tailor the formulae to individual clinical situations. A critique of the Ellis formula and the background to these developments have been described by Bentzen (2002).

### 9.2.2 THE CONTRIBUTION OF EXPERIMENTAL RADIobiOLOGY

Ethical and logistical considerations inevitably preclude clinical experiments exploring a wide range of fractionation regimes. This has led to extensive research using laboratory animals which has borne fruit in improved clinical dose schedules. Of course, laboratory animals have limitations mainly because the time-scale of tumour and normal-tissue effects in rodents is usually much shorter than in man.

An important observation in animals was that Strandqvist curves are usually not straight. Good examples of this are shown in Figure 9.1. In mouse skin, it is possible to make

**FIGURE 9.1**

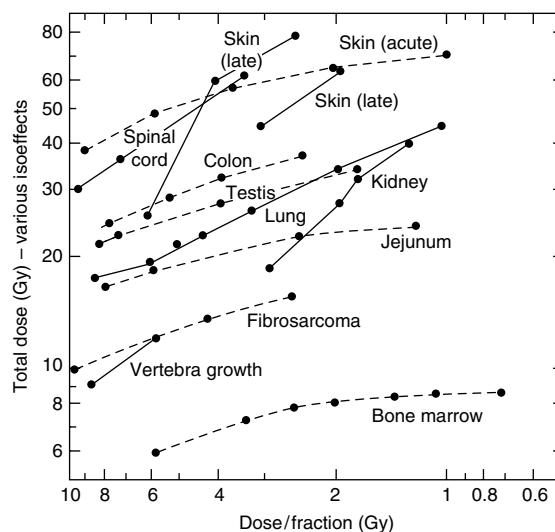

Isoeffect curves in the skin and kidney of the mouse. (a) Acute skin reactions (Douglas, B. G. and Fowler, J. F., *Radiat. Res.*, 66, 401–426, 1976.); (b) late injury in the kidney (Stewart et al., *Radiat. Res.*, 98, 407–420, 1984). Note that the relationship for kidney is steeper than for skin. The broken lines are NSD formulae fitted to the central part of each data set. The solid lines show the LQ model, from which the guide to the dose per fraction has been calculated.

fractionation experiments covering fraction numbers from 1 to 64, all delivered within eight days. Dose-response experiments were performed for each schedule, and this allowed the total radiation dose that gave an arbitrarily chosen isoeffect to be identified (clearly an experiment that is impracticable in the clinic). These are the doses that are plotted in Figure 9.1a. The data define an isoeffect curve that is convex upwards. As indicated in the figure, the data falls below the NSD line both for small and large fraction numbers. Why the NSD formula was unsafe in these conditions is immediately seen: the formula predicts a higher isoeffective dose than is actually tolerable, and treatment with such doses would lead to increased normal-tissue damage.

Figure 9.1b shows the results of similar experiments in the kidney, a late-responding tissue. Here again, for each fraction number, dose-response experiments were performed that allowed the total radiation dose for a selected isoeffect to be read off. These were large experiments that have produced very precise data. Once again, the isoeffect curve is clearly convex upwards.

### 9.3 THE FRACTIONATION RESPONSE OF EARLY- AND LATE-RESPONDING TISSUES

A major development in thinking about fractionation was the realisation by Thames et al. (1982) that in fractionation studies in mice, there is a systematic difference between *early*-responding and *late*-responding normal tissues (see Section 8.4). They summarised published isoeffect curves for fractionation effects on normal tissues in mice, considering only those studies where the overall time was kept short in order to minimise the effects of repopulation on the data. Their key result is shown in Figure 9.2. This shows a collection of isoeffect curves for various tissues as a function of the dose-per-fraction plotted from *right* to *left* (note that fraction number increases from left to right along the abscissa as in the case of the Strandqvist

**FIGURE 9.2**

A collection of isoeffect curves for damage to normal tissues of the mouse following fractionated radiation treatment. Number of fractions increases to the right along the abscissa; dose per fraction, therefore, decreases. Full lines are for late-responding tissues; dashed lines for early-responding tissues. (From Thames, H. D., et al., *Int. J. Radiat. Oncol. Biol. Phys.*, 8, 219–226, 1982.)

curves). Many of these lines show evidence for the upward convexity shown by the data in Figure 9.1. But the most significant observation by the authors was that there is a systematic tendency for late-responding tissues to have *steeper* isoeffect lines than the early-responding tissues (i.e. effects on late-responding tissues are more sensitive to changes in fraction size). The position of the lines on the vertical scale covers a wide range of dose and this reflects two main factors. First, some tissues are more radiosensitive than others for any chosen dose per fraction; second, for each tissue studied, an isoeffect has been chosen, and the level of cell kill necessary to produce this effect differs among the tissues.

The collection of data shown in Figure 9.2 was discussed by Thames et al. (1990) in terms of the linear-quadratic model of cell killing (see Section 7.13). They went on to show that the form of isoeffect relationships for normal tissues is usually consistent with this model and that the difference in steepness of isoeffect curves between early- and late-responding tissues can be described by a single parameter: the  $\alpha/\beta$  ratio. Their approach is described in what follows.

### 9.3.1 THE LINEAR–QUADRATIC APPROACH TO FRACTIONATION

It is believed that the effect ( $E$ ) of a single radiation dose ( $d$ ) is given by

$$E = \alpha d + \beta d^2 \quad (9.2)$$

This is a linear-quadratic equation that can be considered to derive from a cell-survival relationship of the form: surviving fraction,  $S = \exp(-\alpha d - \beta d^2)$ , i.e. identical to Equation 7.2, where *log cell kill* is regarded as the *effect* of irradiation, i.e.  $E = -\log_e[S]$ .

For  $n$  fractions

$$E = n(\alpha d + \beta d^2) = \alpha D + \beta dD$$

where the total dose  $D = nd$ . This can be rearranged in the form

$$\frac{E}{\alpha} = D \left( 1 + \frac{d}{\alpha/\beta} \right) \quad (9.3)$$

$E/\alpha$  is a quantity that has the units of dose ( $E$  is dimensionless, and  $\alpha$  has units  $\text{Gy}^{-1}$ ). Note that in the limit  $d \rightarrow 0$ ,  $E/\alpha \rightarrow D$ . Therefore,  $E/\alpha$  can be described as the *Extrapolated Response Dose* (i.e. the dose that would produce the effect  $E$  when given in many small-dose fractions).

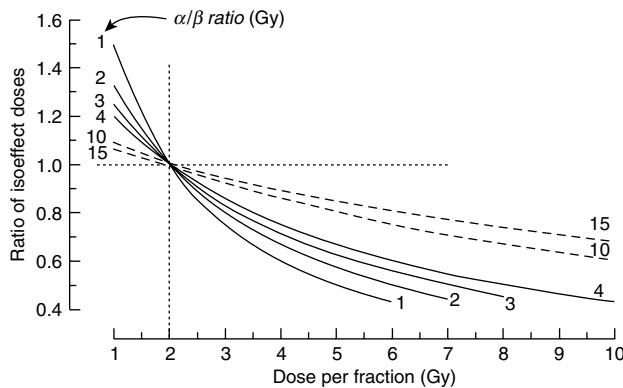

Fowler (1989a) has suggested that  $E/\alpha$  be called the *Biologically Effective Dose* (BED). It is a measure of effect ( $E$ ), in dose units, and for a given biological tissue (where  $\alpha$  and  $\beta$  are constant). BED values indicate how much *damage* a particular fractionation regime will do; it can be written as

$$\text{BED} = D \times RE \quad (9.4)$$

where BED is the total dose which, if given in *infinitely small fractions*, is equivalent to the actual fractionated regimen with fraction size  $d$  and total dose  $D$ , and

$$RE \text{ is the Relative Effectiveness} = \left( 1 + \frac{d}{\alpha/\beta} \right)$$

Consider now an isoeffect calculation where it is asked: for a given tissue, if the dose per fraction is changed, how must the total dose be adjusted? It is presumed that a reference schedule is used where the total dose is  $D_{\text{ref}}$  and the dose per fraction is  $d_{\text{ref}}$ . For *iseffect*,

**FIGURE 9.3**

Compared with a reference treatment using 2 Gy per fraction, the diagram shows how the total dose must be changed in order to maintain a constant level of effect when dose per fraction is modified. Full lines are for low  $\alpha/\beta$  ratios (as in late-responding normal tissues), and broken lines are for early-responding normal tissues or for most tumours.

$E$  (Equation 9.3) is a constant, as are  $\alpha$  and  $\beta$  for a given tissue type and given endpoint. Therefore

$$D \left( 1 + \frac{d}{\alpha/\beta} \right) = D_{\text{ref}} \left( 1 + \frac{d_{\text{ref}}}{\alpha/\beta} \right)$$

where  $D$  is the new total dose. The resulting simple *isoeffect* relationship:

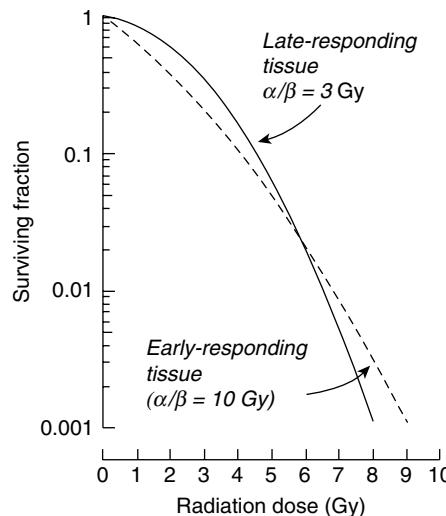

$$\frac{D}{D_{\text{ref}}} = \frac{d_{\text{ref}} + (\alpha/\beta)}{d + (\alpha/\beta)} \quad (9.5)$$

was first proposed by Withers et al. (1983); the form of this relationship is shown in Figure 9.3\*.

### 9.3.2 RATIONALE OF THE LQ APPROACH

The rationale underlying the linear-quadratic approach to fractionation can be stated as follows. Normal tissues and tumours respond differently to a change in dose fractionation. In part, this may be due to differences in repopulation, but if this is ruled out by suitable choice of overall treatment times, such differences probably arise largely from different intrinsic radiosensitivities related to different  $\alpha$ -components. These differences can be seen in data of the type shown in Figure 9.2. As can be seen from Equation 9.4, they can be described in terms of a single parameter: the  $\alpha/\beta$  ratio. Late-responding normal tissues show greater changes in sensitivity in response to a change in dose per fraction than do early-responding tissues (i.e. they have a higher *fractionation sensitivity*), and this is consistent with a lower  $\alpha/\beta$  ratio (or lower  $\alpha$ -coefficients). The survival curves for target cells in early- and late-responding normal tissues can be envisaged to have systematic differences in shape as illustrated in Figure 9.4. The  $\alpha$ -value determines the initial slope of this curve, whereas,  $\beta$  determines the degree of curvature; a lower  $\alpha/\beta$  ratio means a more *bendy* curve.

\* It should be noted that the use of the  $\alpha$  and  $\beta$  parameters in these analyses is far removed from their original intent to define specific mechanisms of cell killing for homogeneous cell populations (Section 7.13) though it may be possible to identify the effective value of  $\alpha/\beta$  with certain 'target' cells in the normal tissue in question.

**FIGURE 9.4**

Cell survival curves for the putative target cells in early- and late-responding normal tissues. A lower  $\alpha/\beta$  ratio produces a more *bendy* curve.

In the years since the original publication by Thames et al. (1982), a considerable literature has appeared, making it clear that the linear-quadratic approach to dose fractionation is more reliable than the NSD approach (see Section 9.2.1). It must be emphasised that NSD should no longer be used and should be regarded as being of historic interest only. Values for the  $\alpha/\beta$  ratio have been obtained for many tissues in experimental animals, some also in man, and values are given in Table 9.1 (Bentzen and Baumann 2002; Joiner and Bentzen 2002).

There is a general tendency for the  $\alpha/\beta$  ratio to be high in early-responding tissues and to be low in late-responding tissues. Fowler (1989a) has expressed the view that because the

**TABLE 9.1**

Some Examples of  $\alpha/\beta$  Ratios for Human Normal Tissues and Tumours

Tissue reaction	$\alpha/\beta$ ratio (Gy)
Early reactions	
Skin desquamation	~11
Mucosa	8–15
Late reactions	
Spinal cord	<3.3
Brachial plexopathy	~2–3
Skin, telangiectasia	2.5–3
Skin, subcutaneous fibrosis	~1.7
Lung, pneumonitis	3.3
Tumours:	
Head and neck	7–16
Skin	~8.5
Melanoma, liposarcoma	~0.5

uncertainties in  $\alpha/\beta$  ratios are considerable and because the values for some tissues have not been shown to be different from those of others, for the time being, it is logical to assume standard values for  $\alpha/\beta$  of 3 and 10 Gy for most late-responding and early-responding tissues, respectively. A prudent approach to these uncertainties is to make calculations for a range of  $\alpha/\beta$  ratios, seeking to get a feel for what effect the uncertainty in  $\alpha/\beta$  has on dose prescription. And if the variation in  $\beta$ -kill is much less than that for  $\alpha$ -kill (as shown for tumour cells in [Figure 7.12](#)), then research should be directed towards more clearly defining and then manipulating the underlying mechanisms of this  $\alpha$ -kill process (Chapman 1980, 2003).

Data on human tumours is sparse, but it is generally believed that most tumours resemble early-responding normal tissues in their fractionation sensitivity, thus having high  $\alpha/\beta$  ratios. However, there are exceptions to this general rule: melanomas, some sarcomas, and possibly prostate tumours (Brenner and Hall 1999; Fowler et al. 2001; Brenner 2003) seem to have very low  $\alpha/\beta$  ratios; although, this low prostate  $\alpha/\beta$  has been challenged by Nahum et al. (2003) and others. The basis of the Nahum et al. case is that prostate tumours are not infrequently hypoxic (Movsas et al. 2002; Parker et al. 2004), and it is this, rather than low  $\alpha/\beta$ , that explains the approximately equal biochemical control rates for external-beam radiotherapy and low dose-rate brachytherapy (for which  $\beta$  can be set approximately equal to zero; see [Section 9.7](#) and also [Chapter 55](#)). In general it is prudent to be cautious in areas where there is insufficient clinical data or where these data are open to more than one interpretation.

### 9.3.3 HYPOFRACTIONATION

*Hypofractionation* means the use of a *reduced* number of fractions, or a *larger* dose per fraction. Equation 9.5, illustrated in [Figure 9.3](#), indicates that if the dose per fraction is *increased* above the reference value of 2 Gy, then the total dose (for an isoeffect) must be *reduced* as indicated by the appropriate line in this chart. Many clinical studies have confirmed that such a dose reduction is required. The curves for late reactions (low  $\alpha/\beta$  ratio) are steeper than for early reactions or for tumours (high  $\alpha/\beta$  ratio). As an example, if the dose per fraction is increased to 5 Gy and the  $\alpha/\beta$  ratio for late reactions is 3 Gy, then the total dose must be reduced to roughly 0.625 of its reference value (i.e. by 37.5%). If the tumour has an  $\alpha/\beta$  ratio of 10 Gy, then at 5 Gy per fraction, the isoeffective total dose, say 70 Gy, should only be reduced by 20% to 56 Gy. A reduction by 37.5% is underdosing the tumour by 17.5% and this will almost certainly result in a significant loss in local control. The general rule is that the use of a large dose per fraction is radiobiologically sub-optimal (accepting that  $\alpha/\beta$  is appreciably lower for late complications than for tumour-cell kill). Such large fraction sizes are widely used in palliative radiotherapy where factors of cost and convenience may predominate over radiobiological principles.

However, the use of large fraction sizes in situations other than palliative is on the increase, despite the above. So-called *extra-cranial* or *body* stereotaxy, with lung tumours often as the target, is one such area (Blomgren et al. 1995; Shiu et al. 2003 and [Section 45.13](#)); a summary of this work is given by Fowler et al. (2004b), Grau et al. (2006) and SBRT (2006). Shiu et al. (2003) treated paraspinal metastases in 5 fractions to 30 Gy, stating that their superior dose distribution (7–9 intensity-modulated beams) under CT image guidance was responsible for limiting the spinal cord dose to less than 10 Gy. The use of fraction sizes larger than 2 Gy is under intensive exploration also for treating the breast (Ash et al. 1995; Shelley et al. 2000; Whelan et al. 2002). The FAST trial has been launched in the United Kingdom (Yarnold 2004) and will test five 5.7 Gy or 6.0 Gy fractions to total doses of 28.5 and 30 Gy, respectively, in a total duration of either 35 or 15 days. The control arm in this prospective randomised clinical trial is 50.0 Gy in 25 fractions of 2.0 Gy in 35 days. The FAST trial is based on a recently completed trial that showed no difference in tumour control or normal tissue complications between 39 Gy in either 3 or 3.3 Gy fractions and 50 Gy in  $25 \times 2$  Gy fractions, which corresponds to  $\alpha/\beta = 4.0$  Gy for tumour control (Owen et al. 2006).

The contention that the  $\alpha/\beta$  ratio is of the order of 1.5 for prostate clonogens (Brenner 2003) has led several investigators to propose hypofractionation schedules for prostate radiotherapy given that the  $\alpha/\beta$  ratio for the principal organ at risk, the rectum, is believed to be considerably higher than 1.5. Therefore, the standard situation of low  $\alpha/\beta$  for normal tissues, high  $\alpha/\beta$  for tumours is effectively reversed, and giving a large number of small fractions is, at least theoretically, a disadvantage (i.e. is clearly suboptimal). Proposals for prostate hypofractionation schedules have been worked out by Fowler et al. (2003): assuming that  $\alpha/\beta=1.5$  Gy, they calculate that 10 fractions of 4.69 Gy should yield bNED\* = 89.6% compared to only 69.2% for 72 Gy conventionally delivered in  $36 \times 2$  Gy fractions for isoeffective normal-tissue response using  $\alpha/\beta=3.0$  Gy. Amer et al. (2003) have carried out a similar exercise, but they use, as a reference, the schedule of 50 Gy in 16 fractions of 3.13 Gy that has long been standard at the Christie Radiotherapy Department in Manchester. However, if  $\alpha/\beta \approx 8.3$  and a significant proportion of the more advanced (pre-treatment PSA > 20 ng ml<sup>-1</sup>) prostate tumours are hypoxic as Nahum et al. (2003) claim, then these hypofractionation schedules may actually lead to poorer control rates than those currently obtained with 2 Gy fractions rather than the considerably improved outcome predicted by Fowler et al. and others.

## 9.4 EFFECT OF OVERALL TREATMENT TIME

A conventional overall treatment time of 5–7 weeks is long enough to allow considerable cell proliferation to take place, both in the tumour and in the critical normal tissues.

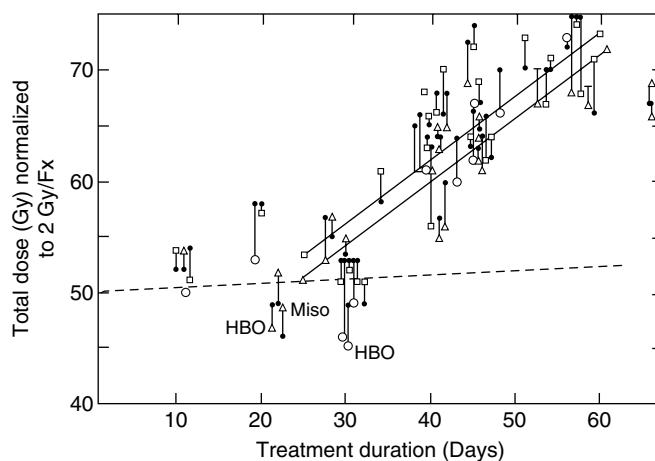

*Early reactions.* The early-responding normal tissues (see [Section 8.4.1](#)) usually have a relatively high rate of cell proliferation, and part of their ability to withstand irradiation is due to the extensive repopulation that they undergo over a period of weeks. If the overall treatment time is shortened, then there will be less time for repopulation to occur and the early reactions will be more severe.

*Late reactions.* The target cells for late reactions usually proliferate slowly. Changes in overall time have less effect on late than on early reactions. The usual advice is that for modest changes in overall time, it is unnecessary to adjust the total radiation dose.

*Tumours.* Repopulation rates in tumours vary widely. In view of the fact that most human tumours grow very slowly (volume doubling times for carcinomas average around three months), it might be supposed that there would be little growth within a 5–7 week period. This is not so. It seems that when a tumour is damaged and begins to shrink, there is usually a considerable increase in repopulation rate, and doubling times for repopulation have been estimated often to be less than seven days. Consequently overall treatment time is very important for tumour response. A one-week extension (for instance, because of a gap in treatment) may significantly reduce the chance of tumour control. Conversely, even a modest shortening of overall time, if it can be achieved without lowering the total dose, could improve the chance of local control.

The strongest evidence for tumour cell repopulation has come from analysis of clinical data where overall time has been changed. A classic example is the review by Withers et al. (1988) of data on the local control of head and neck cancers ([Figure 9.5](#)). As overall time is increased, there is a corresponding increase in the *isoeffective* total dose. The slope of the full lines in this figure is 0.6 Gy per day. This is a remarkably high number for it implies that every 2 Gy daily fractional dose is counteracted by a loss of 0.6 Gy because of repopulation, so that the effective dose is only 1.4 Gy.

\* bNED means no biochemical evidence of disease and is based on monitoring the patient's PSA value; it is often used as a surrogate for local control.

**FIGURE 9.5**

Tumour control dose ( $TCD_{50}$ ) in head and neck tumours as a function of treatment duration. (From Withers et al., *Acta Oncol.*, 27, 131–146, 1988. With permission.)

*The lag period.* Both in early-responding tissues and in tumours, it takes time for repopulation to start. Lag periods vary and are seldom accurately known, but there is evidence that they may (in normal tissues or tumours) be in the region of 2–3 weeks. This is only of practical importance for very short treatment times, but it is one of the rationales for the CHART protocol\* (Dische et al. 1997; Saunders et al. 1997, 1999) where treatment is over a 12-day period.

At the present time, the speed and time-course of repopulation in normal tissues and tumours are poorly understood (but see Fenwick 2006). They also vary between different tissues and from one patient to another. There is no simple equation to correct for the effect of a change in overall time. The lack of such an equation is sometimes used as a criticism of the LQ approach as compared with the NSD equation (see Section 9.2.1). This criticism is unfounded for although the Ellis formula allowed the effects of overall time to be calculated, it is now thought that these predictions were often inaccurate and misleading. In the commonest situation where late reactions are regarded as the dose-limiting factor, the usual recommendation is *not* to correct for overall time. Any correction will always be small and to ignore it is, in many cases, the safest option.

## 9.5 HYPERFRACTIONATION AND ACCELERATED FRACTIONATION

Two new approaches to radiotherapy fractionation were developed during the 1980s. Both involve the delivery of multiple fractions per day, but they are based on very different radiobiological principles.

### 9.5.1 HYPERFRACTIONATION

*Hyperfractionation* means using an increased number of fractions so that the dose per fraction is reduced below the conventional level of 1.8–2.0 Gy. In order to achieve the required

\* Continuous Hyperfractionated Accelerated Radiotherapy.

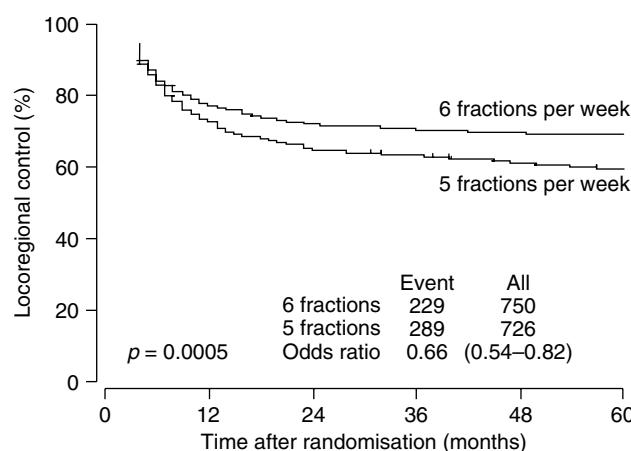

total dose without extending the overall time, it is necessary to give more than one radiation dose per day (usually 2 or 3 fractions per day); the prostate study by Valdagni et al. (2005) is an example of this.

The aim of hyperfractionation is to exploit the greater recovery capacity of late-responding normal tissues. This is illustrated, on the basis of the LQ model, by Figure 9.3. As indicated in Section 9.3, the isoeffective total dose for late-responding normal tissues rapidly changes with change in dose per fraction. Increasing the dose per fraction above 2 Gy (i.e. hypofractionation) leads to a decrease in therapeutic index; however, by the same argument, there should be a therapeutic gain if dose per fraction is reduced below 2 Gy. This occurs because as dose per fraction is reduced, the isoeffective total dose for an  $\alpha/\beta$  ratio of 3 Gy representing normal tissue increases faster than it does along the curve for  $\alpha/\beta$  ratio = 10 Gy representing tumour. The dose difference between these curves indicates the magnitude of the potential therapeutic gain for any chosen dose per fraction.

### 9.5.2 ACCELERATED FRACTIONATION

*Accelerated fractionation* means reducing the overall duration of radiation therapy, using a conventional dose per fraction. The aim is to reduce the impact of tumour-cell proliferation during treatment. As with hyperfractionation, in order to deliver the prescribed total dose within a short overall time (without increasing dose per fraction), it is necessary to give more than one dose-fraction per day.

Both of these novel approaches to radiotherapy fractionation are showing some evidence of clinical benefit in current trials, and hybrid schedules between hyperfractionation and accelerated fractionation are also being used. As an example, Dische et al. (1997) obtained similar local control in head and neck cancer with the CHART schedule of 54 Gy given in 36 fractions over 12 days and with the 66 Gy given in 33 fractions over 6.5 weeks. Overgaard et al. (2003) reported on a comparison between five and six fractions per week of conventional (2 Gy fraction size) radiotherapy for squamous-cell carcinoma of the head and neck. 1476 patients were randomly assigned to one schedule or the other at the same total dose and fraction number. Their findings are shown in Figure 9.6.

**FIGURE 9.6**

Primary locoregional tumour control as a function of the number of fractions per week in squamous-cell carcinoma of the head and neck, 66 Gy in 33 fractions or 68 Gy in 34 fractions, with all patients receiving the hypoxic radiosensitiser nimorazole. (From Overgaard, J., et al., *Lancet*, 362, 933–940, 2003. With permission.)

This constitutes convincing evidence for tumour-cell proliferation and for the advantage of an accelerated schedule.

### 9.5.3 WHAT INTERFRACTION INTERVAL FOR MULTIPLE FRACTIONS PER DAY?

Accelerated- and hyper-fractionation both require the delivery of multiple fractions per day. It is essential that sufficient time is allowed between fractions to allow full repair of sublethal damage. The reason for this is that the rate of repair in late-responding normal tissues tends to be slower than in tumour cells. If fractions are given close together, repair may be less complete in the normal tissue than in the tumour, and this is a therapeutic disadvantage. It is usually recommended that dose fractions not be given closer than six hours apart, but this may be too close together when tissues such as the spinal cord are at risk.

---

## 9.6 HOW TO RESPOND TO GAPS IN TREATMENT

A substantial proportion of radiotherapy patients suffer an interruption in their prescribed course of treatment. This may arise for many reasons: some that derive from the patient (e.g. severe acute reactions, concurrent disease), and others that are unconnected with the patient (e.g. machine breakdown, transport difficulties, public holidays, etc.). How should the rest of the course be adjusted in response to such a gap? There are a number of options with some that are more advisable than others:

- a. Ignore the missed fractions. This would be the worst response because it would reduce the total dose and seriously compromise local tumour control.
- b. Add the missed fractions at the end of the course. This is frequently done, but its disadvantage is that the overall treatment time is extended, allowing greater tumour-cell repopulation. The usual practice is to make a correction for the loss of effectiveness that results from the gap. This can be done by adding one or more fractions (of the same or a similar size) or by increasing the dose per fraction, but neither is ideal.
- c. Increase the dose per fraction for the rest of the course in order to complete treatment in the prescribed overall time. This avoids the repopulation problem but suffers from the radiobiological disadvantage of an increased dose per fraction (see [Section 9.3](#)).
- d. Add the missed fractions to the remainder of the course either by treating at weekends or by giving multiple fractions per day. This option seeks to maintain the dose per fraction and overall treatment time as prescribed. It is thought to be the best option, but if the gap occurs toward the end of the treatment course, it may be logistically difficult to implement. If 2 or 3 fractions have to be given on a single day, they should be separated by at least six hours as indicated above.

The radiobiological and other considerations in the response to treatment gaps have been considered (in the United Kingdom) by a committee of the Royal College of Radiologists (Hendry et al. 1996).

## 9.7 LOW DOSE RATE: RATIONALE FOR BRACHYTHERAPY

A low dose rate can be viewed as the limiting case of hyperfractionation: many small fractions are given very frequently. Brachytherapy (i.e. radiation treatment using implanted radioactive sources) has distinct radiobiological advantages as well as potential disadvantages (see [Chapter 55](#)).

*Advantages:*

1. At a sufficiently low dose rate, this ultimate form of hyperfractionation maximally spares late-responding normal tissues.
2. It is usually achieved within a short overall treatment time, giving minimal time for tumour-cell repopulation.
3. The geometric form of the radiation field exploits the volume effect in normal-tissue damage; compared with external-beam treatment, the volume of normal tissue taken to high dose is usually smaller.
4. Cell killing around an implanted source is very intense and provides a form of tumour debulking.

*Disadvantages:*

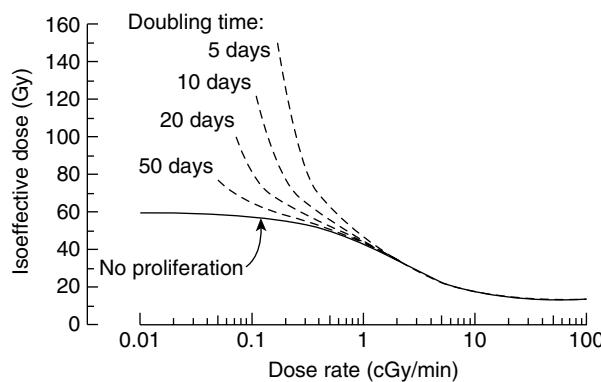

1. The very non-uniform dose distribution risks the *geometric miss* of some tumour cells.
2. The short overall treatment time may be inadequate to allow full re-oxygenation of hypoxic tumour cells.
3. Particularly with pulsed high dose-rate brachytherapy, there is a temptation to treat too fast, losing the advantage listed as (1) above.

The effect of a single, low dose-rate exposure will differ from that of the same dose given at high dose rate because the extended treatment time allows a number of biological processes to take place. These are the 4 Rs of radiotherapy listed in [Section 7.8](#). Over what range of dose rates will these biological processes act? This depends on their speed. A fast recovery process can compete with rapid infliction of damage and will produce effects at high dose rate. As a rough guide, the time the process takes (for example, after a brief radiation exposure) can be compared with the exposure time at low dose rate. Repair is a fast process with a half-time in the region of 1 h in mammalian cells. At a dose rate of 100 cGy/min or more (typical of high dose-rate exposures in clinical and experimental radiotherapy), a dose of, for example, 2 Gy is delivered in 2 min, and little recovery can occur during exposure. Therefore, dose rate will have little effect. Lowering the dose rate to 10 cGy/min increases the exposure time for 2 Gy to 20 min, and some recovery will occur. Reduction by a further factor of 10, to 1 cGy/min, gives an exposure time of over 3 h for 2 Gy. At this dose rate, recovery will be almost complete.

In contrast, proliferation is a much slower process. Cell cycle times for human cells are in the region of 2 to 4 days, and only when the exposure time becomes a day or more will this produce a significant effect. [Figure 9.7](#) illustrates this in the form of calculated isoeffect curves for a cell population that has an  $\alpha/\beta$  ratio of 3.7 Gy. The full line shows the sparing effect of repair (half-time 0.85 h) which has its main effect over the dose-rate range from around 20 cGy/min down to 0.2 cGy/min. The dashed lines show the effect of proliferation at various rates; these indicate the substantial sparing that may occur at very low dose rates in proliferating tissues.

The effect of changing the dose rate on cell survival is shown in [Figure 9.8](#). For any given dose (imagine a vertical line in this figure), cell survival increases as the dose rate is reduced\*. This reflects the effect of cellular recovery during irradiation. The shouldered survival curves at high dose rate become straight at a dose rate of around 1 cGy/min. This occurs because the time-dependent processes that produce the shoulder can then proceed during exposure and even go to completion.

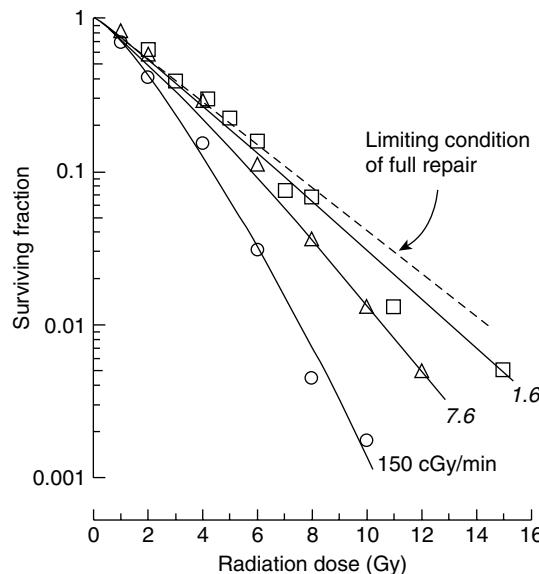

\* Wang et al. (2003) and Fowler et al. (2004a) have discussed the dose-rate issue in the context of the relatively prolonged delivery of certain intensity-modulated external-beam techniques; Fowler et al. concluded that any technique requiring more than 30 min for delivery could lead to a decrease in biological effect and tumour control probability.

**FIGURE 9.7**

Theoretical isoeffect curves, showing the effect of changing dose rate for a single exposure either in the absence of proliferation or assuming proliferation with a doubling time in the range 5 to 50 days.

Wide variation is seen among different tumour cell lines in their sensitivity to low-dose-rate irradiation. This occurs because the low-dose-rate sensitivity is largely determined by the magnitude of the  $\alpha$  component in the LQ equation, and this widely varies from one cell line to another (see Figure 7.11 and Figure 7.12). Studies on experimental animals have also found that the magnitude of the dose-rate effect differs from one normal tissue to another. Many tissues recover well from radiation damage and show a strong dose-rate effect. The bone-marrow is perhaps the extreme example of a tissue whose stem cells show little dependence on dose-rate since  $\alpha$ -killing dominates (see Section 7.13; Chapman 2003).

In evaluating the therapeutic implications of these observations, it must be realized that the clinical use of low-dose-rate irradiation (in interstitial or intracavitary therapy) is not primarily for radiobiological reasons, but because these approaches lead to a better dose distribution within the tumour. Furthermore, the clinical choice is not between a single exposure at high dose rate or at low dose rate, but between fractionated high-dose-rate treatment and a single

**FIGURE 9.8**

Cell survival curves for a human melanoma cell line irradiated at dose rates of 150, 7.5, or 1.6 cGy/min, illustrating the effect of dose rate on radiosensitivity.

(or a few) low-dose-rate exposures. As indicated above, both of these ways of protracting radiation treatment exploit the same biological processes (principally recovery and repopulation) and in broad terms tissues that are well spared by one will also be spared by the other\*. Fowler (1989b) has calculated, on the basis of the linear-quadratic model, equivalence relationships between fractionated and low-dose-rate irradiation. For a tumour with an  $\alpha/\beta$  ratio of 10 Gy and a late-responding normal tissue with  $\alpha/\beta=3$  Gy, the relative effects of continuous exposure at approximately 50 cGy/h will be equivalent to 30 high-dose-rate fractions of 2 Gy. The advantage of the continuous exposure is that it would be complete in only five days. Low-dose-rate radiotherapy is the most efficient way of maximizing recovery while keeping the treatment duration as short as possible. It is theoretically attractive where tumour-cell repopulation is thought to be rapid. For a more detailed description of dose-rate effects in brachytherapy, see Steel (2002a) and also [Chapter 55](#).

---

\* This equivalence between continuous low dose rate and small-fraction (at high dose rate) treatment is expanded upon in Chapter 55.

## INTRODUCTION

This part deals with the equipment used in external beam radiotherapy. The treatment devices used for radiation production are either *kilovoltage x-ray units*, or *megavoltage linear accelerators*, or *cobalt-60 machines*. *Kilovoltage x-ray units*, described in [Chapter 10](#) were historically the first to be used and they played an important role in the early development of radiotherapy, mainly between 1910 and 1950. Although still useful for the treatment of superficial lesions, they have been superseded for most treatments by *linear electron accelerators*, emitting megavoltage x-ray beams and possibly electron beams. These accelerators, which started to be used clinically in the late 1960s, are described in [Chapter 11](#) with a brief reference to *betatrons* and *microtrons*, which were other types of electron accelerator developed for radiotherapy. *Cobalt-60 machines*, described in [Chapter 12](#), provide penetrating  $\gamma$ -ray beams emitted from a radioactive source. They were introduced as a replacement for kilovoltage x-ray units in the 1950s. It is only in the last decade of the past century that the superiority of linear accelerators became evident and that the number of cobalt-60 machines started to decrease all over the world, except in developing countries where they are still considered as the best option, mainly because of their reliability. Equipment for radiotherapy using proton or high LET particle beams are dealt with in [Chapter 46](#) and [Chapter 49](#) respectively.

For the treatment devices considered in this Part, a description is given of the physical principles involved and of practical considerations relating to machine construction. For a radiation beam to be clinically useful, the beam must be collimated and filtered in order to provide the radiation characteristics appropriate for use in radiotherapy treatment. These aspects are only touched on briefly in this Part, but they will be dealt with more fully in [Part E](#).

Beside the equipment used to treat patients, specialist imaging devices are required to perform treatment preparation and verification. These are the so called *simulators* and *portal imaging devices* dealt with in [Chapter 13](#) and [Chapter 14](#) respectively. Standard diagnostic imaging devices, which also make an essential contribution to treatment preparation (see [Chapter 30](#) and [Chapter 31](#)) are not described in this book and the reader interested in this subject should refer to other books dedicated to imaging equipment.

## 10.1 INTRODUCTION

Kilovoltage x-rays have been used in radiotherapy from the earliest attempts at external beam treatments. Their use has gradually diminished over the years because of the widespread availability of high energy photons, and more recently, of electrons generated from high energy linear accelerators. Nevertheless, kilovoltage x-rays still provide an important option in the range of treatments available within many departments.

In principle, kilovoltage x-rays are generated by stopping electrons accelerated across the potential difference between a cathode and an anode. The energy or *quality* of the beam can generally be described in terms of the magnitude of this potential difference. However, the spectrum of radiation can be significantly altered by placing metal filters in the beam, and beams of different penetrative quality can be produced from the same accelerating potential. For this reason, it is customary to define the beam quality in terms of the thickness of a given material (usually aluminium or copper) that will reduce the beam intensity to half of its initial value. This is called the *half value layer* or HVL. This is discussed further in [Section 21.2](#).

The kilovoltage range covers x-ray beams generated between 10 kV and 400 kV and is usually subdivided into categories according to increasing beam penetration. These reflect the type of treatments that each range is suited for as well as other physical considerations such as equipment design, beam characteristics, and the method employed in determining the dose rate (Klevenhagen et al. 2000).

1. *Grenz rays* (10 kV to 20 kV, 0.02 mm to 0.15 mm Al HVL) lie between the hardest ultraviolet rays and x-rays and are named from the German word *Grenze* (meaning *boundary*). They are sometimes also called *border* x-rays. At such energies, absorption in air can be appreciable. This range is rarely used in modern radiotherapy.
2. *Short distance or contact therapy*. (10 kV to 60 kV, 0.02 mm to 3.3 mm Al HVL) was originally developed to reproduce the conditions of surface Radium treatment. The very short source skin distance (SSD) of typically 1.5 cm to 5.0 cm ensures a rapid fall-off in depth dose, even over a wide range of qualities, providing a useful treatment depth up to several millimetres (BIR 1996).
3. *Superficial therapy* (50 kV to 150 kV, 1 mm to 8 mm Al HVL). This energy range has probably been least affected by the introduction of high energy linear accelerators providing the treatment of choice for many superficial lesions, and in many other cases, an adequate alternative to electrons. The beam characteristics enable lesions to a depth of around 5 mm to be encompassed by 90% of the surface dose.
4. *Orthovoltage therapy or deep therapy* (150 kV to 400 kV). Most clinical units in this range are operated with generating potentials from 160 kVp to 300 kVp corresponding to 0.5 mm to 4 mm Cu HVL for typical filtrations. The 90% dose in this range lies 1 cm to 2 cm beneath the incident skin surface at the usual treatment distance of 50 cm SSD. The percentage depth dose gradually varies with applied tube potential in this range. It changes by 2% or less of the local dose down to 50% of the peak dose per 50 kV change in tube voltage (BIR 1996). Multi-energy units covering both the *superficial* and *orthovoltage* ranges are now used in many departments.

---

## 10.2 PRINCIPLES OF X-RAY GENERATION

### 10.2.1 X-RAY PRODUCTION

As discussed in [Chapter 3](#), when a high speed electron penetrates a target material, as explained in Chapter 3, three main interactions can occur.

1. The electron is subjected to small deflections by the electron cloud of the target material. These energy losses cause excitation and heat production, and they account for the majority of interactions.

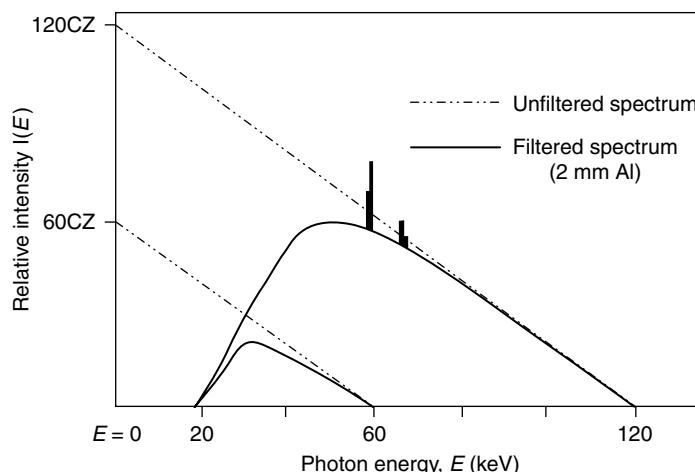

2. The incoming electron interacts with an inner shell orbital electron and has sufficient energy to eject it. The resultant vacancy is filled by an electron from an outer shell that emits a photon of energy equal to the difference in energy between the two shells. This is termed *characteristic radiation* as the energy difference between orbital shells depends on atomic number and is characteristic of the target material. An electron from a shell still farther from the nucleus will then fill this new vacancy. This process is repeated, leading to the emission of a series of discrete lines of characteristic x-rays. Characteristic radiation accounts for only a small percentage of the x-rays produced. An electron must have an energy of 69.5 keV to eject a K shell electron from tungsten. The principal K-line emission for tungsten is 59.3 keV (range 58 keV to 69.1 keV).
3. *Bremsstrahlung (braking radiation)* accounts for the majority of x-ray photons emitted, and it occurs when the incoming electron passes close enough to the positive charge of the target nucleus to be attracted and, consequently, decelerated. The energy lost because of this braking effect is emitted as an x-ray photon. The electron can lose all of its incident energy in a single collision with a nucleus.

### 10.2.2 THE X-RAY SPECTRUM

The bremsstrahlung energy spectrum emerging from the target shows a continuous distribution of energies with characteristic x-rays at discrete energies superimposed upon this. In the absence of any filtration, the calculated energy spectrum emerging from a thick target will be a straight line given by the following equation (Johns and Cunningham 1983)

$$I(E) = CZ(E_{\max} - E)$$

where  $I(E)$  is the bremsstrahlung intensity at energy  $E$ ,  $C$  is a constant that will include the number of electrons bombarding the target (proportional to tube current), and  $Z$  is the atomic number of the target material. The maximum energy of emitted photons ( $E_{\max}$ ) equals the maximum energy lost by the bombarding electrons that is determined by the peak kV (kVp) applied across the tube. To increase beam intensity a high-atomic-number target material is required that should also be capable of withstanding the very high temperatures generated. Tungsten satisfies this criterion ( $Z=74$ , melting point  $3380^{\circ}\text{C}$ ). As shown in Figure 10.1, the maximum intensity of  $CZE_{\max}$  at  $E=0$  decreases linearly to zero at  $E=E_{\max}$ . The total emitted x-ray energy given by the area under the line increases

**FIGURE 10.1**

Unfiltered and filtered bremsstrahlung spectra from a tungsten target ( $Z=74$ ) for peak applied tube potentials of 60 kVp and 120 kVp. The K-line characteristic emissions are superimposed on the filtered spectrum.

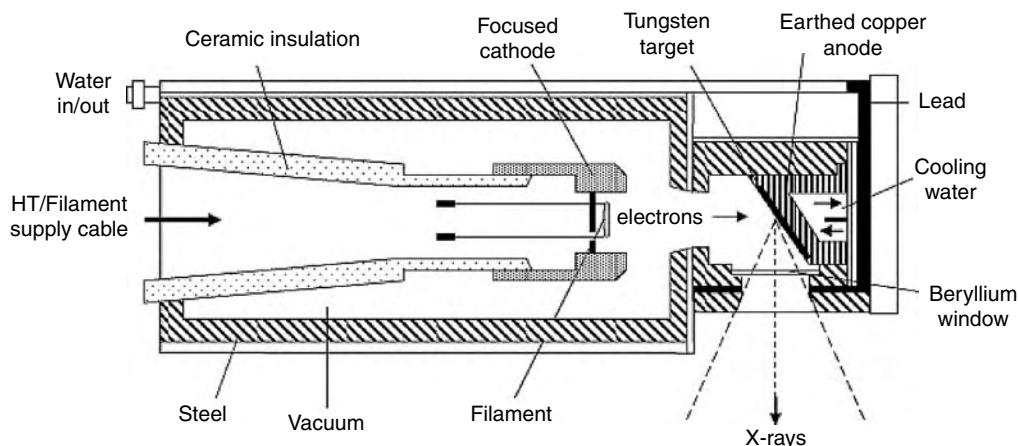

according to  $E_{\max}^2$  and with *applied kVp*<sup>2</sup>. For filtered beams, this proportionality may be raised to an even higher power of kVp, highlighting the importance of stable and reproducible kV control for accurate dose delivery. In practice, the emergent spectrum is attenuated by *inherent* and added filtration that preferentially absorb the lower energy components producing the filtered spectrum as shown in Figure 10.1. The thickness and type of filtration determines the minimum energy. As before, the maximum photon energy (keV) equals the applied kVp.

## 10.3 PRACTICAL X-RAY GENERATORS

### 10.3.1 THE X-RAY TUBE

In recent years, there have been numerous developments in the equipment associated with kV x-ray units. These include the widespread replacement of the glass enveloped x-ray tube by the more efficient and robust metal–ceramic tube, the introduction of high frequency HT generators, and the use of microprocessors for monitoring and controlling generator parameters.

Conventional kilovoltage x-ray units are designed around a stationary anode tube of which there are several possible designs depending on the age and type of equipment. The standard glass enveloped stationary anode tube has largely been superseded by the metal–ceramic tube (Figure 10.2) that offers numerous advantages over its predecessor. The basic radiotherapy x-ray tube consists of a cathode and anode assembly inside an evacuated tube. The cathode is a tungsten filament that, when heated by passing a current through it, emits electrons by the process of thermionic emission. The filament is set into a focusing cup that concentrates the electrons onto a small area of the target several centimetres away called the focal spot. The anode consists of a tungsten target embedded within a block of copper. A high voltage difference applied between the cathode and anode accelerates the electrons emitted from the cathode toward the anode where they deposit their energy in the target as outlined above. Most of this energy is deposited as heat, but a small percentage (ranging from 0.5% at 60 kVp to 1% at 200 kVp [Meredith and Massey 1977]) is converted to x-rays.

**FIGURE 10.2**

Schematic cross-section of a metal–ceramic x-ray tube (Comet MXR 161) for superficial therapy.

### 10.3.1.1 Metal–Ceramic Tube Design

The earthed anode is welded to the metal tube envelope to form a robust unit, facilitating simple and efficient direct cooling. The target is recessed within the copper anode, providing an integral anode hood that absorbs unwanted stray x-rays. The negative HT supply to the cathode is made by a connector from the HT generator that locates into a ceramic receptacle, reducing the likelihood of electrical discharge across this extended insulating surface. Metal–ceramic tubes are manufactured with an integral beryllium window (2 mm to 5 mm thick) that has a low atomic number ( $Z=4$ ) and physical density. For the same tube operating conditions, this lower inherent filtration results in increased output compared with glass envelope tubes. Consequently, metal–ceramic tubes can be run at lower tube currents and allow lower beam qualities to be produced for a given tube kVp.

### 10.3.1.2 Contact Therapy Tubes

The design of contact therapy tubes is based on bringing the target as close as possible to the treatment surface. This leads to quite different configurations that have involved the use of both transmission targets (Chaoul unit) and reflection targets (Philips unit) (Birch and Blowes 1990). This equipment is not commonly used today, and the reader is referred to earlier texts for more information.

### 10.3.1.3 Target Angle and Radiation Distribution in Air

The inverse-square law and the amount of oblique filtration through attenuating materials in the beam path will govern the directional distribution of the beam. The beam profile perpendicular to the anode–cathode direction should be symmetric. This is unlikely to be the case in the anode–cathode direction where x-rays will be differentially absorbed within the target depending on the angle where they emerge. This *heel effect* can result in increased or reduced beam intensity on the anode side of the beam axis compared with that on the cathode side (Klevenhagen et al. 2000). The magnitude of this effect depends on both the target angle and applied kV, and it is additionally constrained by the need for a large useful beam at relatively short SSDs. The target angle, defined as the angle between the incident electrons and the normal to the target, is typically 40° for superficial x-rays and 30° for orthovoltage equipment. For multi-energy equipment, the larger target angle is chosen so that the useful field size at the superficial energy is not significantly reduced by the heel effect.

## 10.3.2 X-RAY TUBE HOUSING

The x-ray tube housing consists of a metal shield that encloses and protects the tube providing shielding from unwanted x-rays. Permissible leakage levels through the shield at 1 m from the focal spot are 1 mGy/h and 10 mGy/h for equipment running up to 150 kVp and 300 kVp, respectively (IEC 1987). A filter holder and applicator mount are attached to the tube housing at the beam exit aperture. The filter holder usually contains one or more micro-switches to enable the system control unit to recognise coded external metal filters. For orthovoltage equipment with applicators of SSD above 40 cm, a radiation monitor should be provided to indicate the tube output rate (IEC 1987). This typically takes the form of a transmission ionisation chamber placed downstream of the filter holder. Such equipment can be calibrated to deliver the intended dose in terms of monitor units rather like a linear accelerator (Gerig et al. 1994).

## 10.3.3 TUBE COOLING SYSTEM

The requirement for tube cooling results from the inefficiency of x-ray production in the kilovoltage energy range with about 99% of the energy of the electrons striking the target

being dissipated as heat. Heat is conducted through the target into the copper anode block and, in the case of the metal–ceramic tube, efficiently removed by direct water (or oil) cooling of the copper block. Some units may also incorporate secondary cooling of the pumped coolant using a remote heat exchanger. Interlocks prevent the beam from running if the coolant temperature gets too high or if its flow rate drops below an acceptable level.

#### 10.3.4 HT GENERATOR AND RECTIFICATION

The HT step-up transformer, filament transformer, and any rectification circuitry are located in a separate oil filled earthed metal tank. The HT transformer has a fixed turns ratio whose voltage output is directly proportional to the input. Modern systems supply a high frequency (25 kHz) sine wave input voltage to the step-up transformer. The high frequency HT output from this transformer is then fed into a voltage multiplier circuit that consists of a network of diodes and capacitors. The HT voltage across the output capacitors of this multiplier network is essentially constant (less than 1% ripple) and can be dynamically monitored and regulated with high precision (0.1%) by external control circuits. The HT supplied to the x-ray tube from the voltage multiplier network requires no further rectification. A low voltage transformer is used to supply the filament current because the filament is at the cathode potential relative to earth and must be isolated from the primary input voltage.

---

### 10.4 ANCILLARY EQUIPMENT

#### 10.4.1 TUBE SUPPORT STAND

A good tube support stand is vital for accurate radiotherapy, and it may be floor or ceiling mounted. Treatments should not be compromised because the tube stand is unable to support the tube in the desired position. Independent lockable movements should enable most beam orientations to be attained. Fine adjustment of the tube position should be possible. Because it is normal for the applicators to be touching the patient skin, it is essential that fail-safe mechanisms exist to interrupt motor driven tube movements in the event of a faulty drive switch. In addition all movements must be locked in case of a power failure.

#### 10.4.2 SYSTEM CONTROL UNIT AND USER INTERFACE

The system control unit must allow complete and safe control of important generator parameters and system timers, and it will normally include a start, stop, and emergency shut-off switch. Modern microprocessor based control systems are interfaced to the HT generator and dynamically monitor parameters such as tube kV and filament current. When an exposure is started, the voltage supplied across the tube ramps to the desired value over a period of up to several seconds. Some control units are able to detect unusual ramp-up cycles, and they terminate the beam before the full tube potential is applied. During this ramp-up period, the dose rate from the x-ray tube will increase from zero to its steady state value. For timer-based systems, the treatment timer will be started as soon as the start button is depressed or at some time during the ramp-up stage. As it is usual for the steady-state dose rate to be used to calculate treatment times, the ramp-up region could lead to a dose deficit or excess, depending on the precise point where the timer was started. This correction is called the *timer error* and should be dosimetrically determined for all combinations of kV and mA (Heales et al. 1998 and see [Section 38.8.4](#)). For machines delivering dose based on monitor ionisation chambers, this is not a problem as the treatment is defined and terminated by the control unit according to transmitted dose (Gerig et al. 1994; Aukett et al. 1996). The control

unit will also be linked into treatment unit and room safety interlocks only permitting treatment when these are all successfully completed. Display requirements for the user interface, which may be integral to or independently communicate with the control unit, are outlined in IEC 601-2-8 (1987). Modern microprocessor-based user interfaces provide more functionality, including automated tube run-up routines and recording of patient-specific treatment parameters.

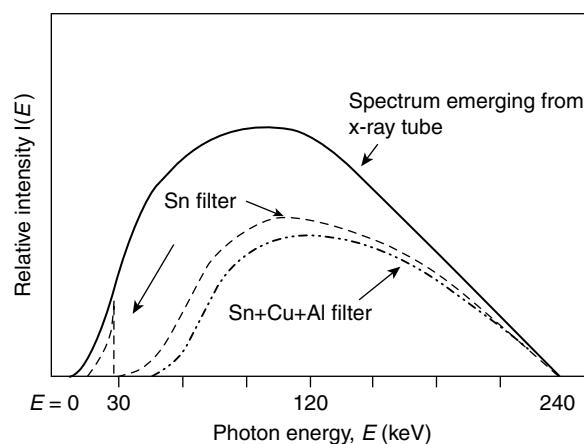

### 10.4.3 MACHINE INTERLOCKS

As with all radiotherapy equipment, necessary interlocks must be provided to ensure correct and safe operation of the equipment and to reduce exposure of the operator and patient to any undue hazard (IEC 1987). The main interlocks and safety features are as follows: emergency stop, start, and stop switch; last person out/treatment door closed; cooler over-temperature; cooler flow-rate; filter in place; filter selection confirmation; HT generator interlocks (over-current, over-voltage, power limit); x-ray warning; ready lights; and audible alarm.

---

## 10.5 BEAM FILTRATION

The spectrum of radiation emitted from an x-ray tube includes a considerable low-energy component. These lower-energy photons will be quickly attenuated in tissue and contribute little dose at greater depths. Depending on the intended depth of treatment, this low-energy component needs to be substantially reduced as it increases dose in superficial tissue without clinical benefit. In order to achieve preferential absorption of the lower-energy component, metal filters are placed in the path of the beam. In this energy range, the probability of a photon undergoing a photoelectric interaction decreases with increasing energy according to an approximate inverse cube relationship (see Equation 4.7). The lower-energy photons are attenuated more than those at a higher energy, so the mean energy of the spectrum will increase or *harden* (Figure 10.3). The filter will attenuate the spectrum at all energies, but it should not lead to an unacceptable overall reduction in transmitted intensity. The metal should have no photoelectric absorption edge occurring within the required useful energy range as this will

**FIGURE 10.3**

Beam hardening effect of a single Sn (0.4 mm) and composite Sn (0.4 mm)+Cu (0.25 mm)+Al (0.5 mm) filter on the intensity spectrum emerging from an x-ray tube at 240 kVp applied generating potential. Note that the curves are to illustrate the effect only—more accurate curves are shown in [Figure 21.1](#).

lead to preferential absorption of higher energy photons in this region. The resultant filter must be mechanically stable, easy to handle, and of uniform thickness. It is important to verify the thickness and integrity of all filters at commissioning as irregularities in thickness across the filter could have an undesirable effect on the uniformity of the transmitted beam.

### 10.5.1 SUPERFICIAL ENERGIES

Although metals of high atomic number tend to harden the beam more efficiently, the resultant filter is often too thin to be mechanically stable, and an absorption edge is likely to be present within the required energy range. Aluminium is normally used (0 mm to 2.5 mm thick, depending on the amount of inherent filtration). Copper and aluminium composite filters may be used at the higher end of this range (120 kVp to 150 kVp).

### 10.5.2 ORTHOVOLTAGE ENERGIES

Higher atomic number filters of adequate thickness can be used at orthovoltage energies. Because of the production of characteristic radiation and incomplete removal of some parts of the lower energy spectrum by these filters, composite filters are used. These consist of additional metal filters of lower atomic number placed immediately downstream of the first filter. These filters preferentially remove the residual lower energy photons with a minimal effect on overall beam intensity. Examples include Cu + Al or Sn + Cu + Al (Thoraeus) filters ([Figure 10.3](#)). The order of composite filters is vital, and it must not be possible to administer treatment with the filter upside down.

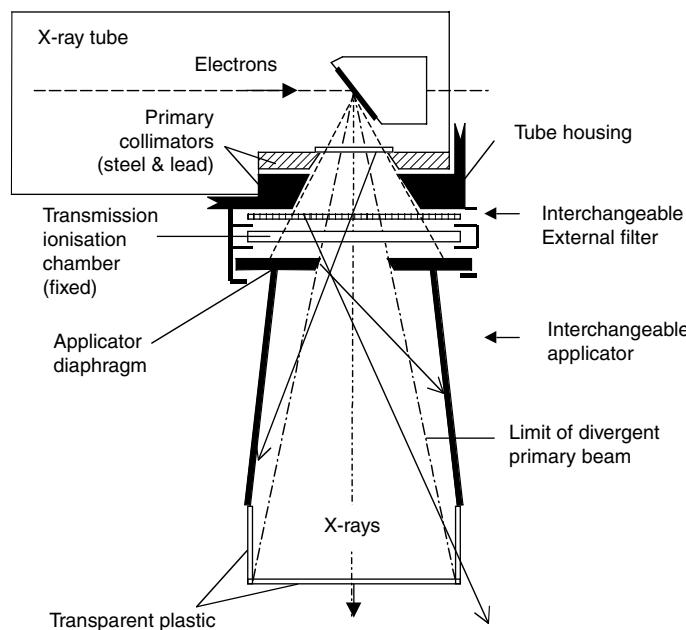

### 10.5.3 FILTER BOX

Most units have a filter storage box that contains interchangeable filters that can be inserted beneath the beam exit aperture to produce beams of different qualities. Mechanical shaping of the filter and their holders within the box can limit individual filters to a unique place in the box. The box can be interlocked so that the system control unit can detect the removal of any filter and indicate an error condition if two or more filters are removed. A thick lead filter is normally provided for times when the tube is being run up or is not in use.

---

## 10.6 BEAM COLLIMATION AND APPLICATORS

The primary collimator usually consists of a conical hole within a block of lead, or other heavy metal, set into the tube housing and/or the x-ray tube. Although distant collimating systems with a projected light field are also used, secondary collimation is normally accomplished using a set of interchangeable applicators covering the range of available treatment sizes ([Figure 10.4](#)). The main collimation from an applicator is provided by a diaphragm of the correct size and shape that slides beneath the filter holder and is thick enough to reduce the unwanted beam to less than 1% of its incident intensity. The size of the divergent beam passing through the diaphragm must closely match the treatment field size as defined by the end of the applicator. The finite focal spot size means there will be a penumbra region at the beam edge that may be *trimmed* by making the edges of the divergent beam graze the applicator walls just before the end of the applicator. The *cone* part of the applicator consists of a rigid structure normally made from stainless steel. No primary radiation should strike the applicator walls, and any scattered radiation will usually be incident on the wall at an oblique angle as shown in [Figure 10.4](#). Applicator walls can be made thinner than the diaphragm, keeping their overall weight down. The measurement technique and permissible levels of leakage radiation through

**FIGURE 10.4**

Schematic cross-section of the beam collimation system on an orthovoltage unit. Superficial units will be similar, but they will have no transmission ionisation chamber or plastic applicator end plate. The scattered radiation is schematically represented by solid-line arrows.

applicators are given in IEC 601-2-8 (1987). For a 10 cm circular applicator, this corresponds to 2% of the air-kerma rate on the radiation beam axis at a lateral distance between 2.5 cm and 4.5 cm from the distal end of the applicator falling to 0.5% beyond this. It is common for the last few centimetres of an applicator to be made of clear plastic, allowing accurate positioning of the applicator against visible guide marks or surface lesions.

### 10.6.1 SUPERFICIAL APPLICATORS

Typical SSDs for superficial applicators range from 10 cm to 35 cm with field sizes from 1 cm to 20 cm diameter. Applicators are open-ended, ensuring the maximum surface dose rate is available to treat superficial lesions.

### 10.6.2 ORTHOVOLTAGE APPLICATORS

The typical SSD for orthovoltage applicators is 50 cm with rectangular or circular field sizes from 4 cm to 20 cm. Applicators in this range normally have closed ends to enable compression of the patient's skin. This brings the treated tissue closer to the applicator surface and so increases the percentage depth dose at the tumour with respect to the skin dose.

Applicators also accurately define the treatment distance and the dose rate. Actual applicator SSDs should be determined at commissioning as small differences can lead to unexplained step changes in plots of in-air dose rate as a function of field size.

## 11.1 INTRODUCTION

Kilovoltage x-ray beams are useful for the treatment of skin lesions and shallow tumours, but for deep-seated tumours, the dose that can be delivered is limited by the high skin dose. Megavoltage beams are not only more penetrating, but they have the major benefit that the maximum dose is delivered below the skin surface (see [Section 22.3.1](#)). In addition, because the principal interaction with tissue is through the Compton effect, the locally absorbed dose is not dependent on the atomic number of the tissue, and the dose to bone is not enhanced.

It is not practicable to use transformer-based high voltage x-ray generators for energies above 300 kV, and another method of accelerating the electrons must be used. Higher energy beams can be produced in a number of ways. Methods of accelerating electrons to high energies include *linear accelerators*, *betatrons*, and *microtrons*. Betatrons were widely used in Europe and can produce very high energy electron beams (up to 50 MeV). However, they are bulky; the beam current is limited, and these machines are now obsolete. The *microtron* (from Scanditronix) is able to produce high energy electron beams at higher currents, but the high cost of the equipment has limited sales outside of Scandinavia. The linear accelerator is now the principal means of generating megavoltage beams in the developed world. Space constraints limit the

electron energy that can be achieved to about 22 MeV, but in practice, this energy is sufficient for satisfactory treatments. The electron beams from linear accelerators can be converted to x-rays or can alternatively be directly used for patient treatment. A useful review of the history of clinical linear accelerators has been written by Thwaites and Tuohy (2006).

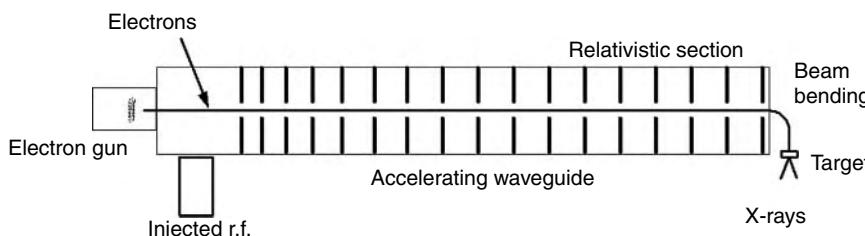

## 11.2 PRINCIPLES OF LINEAR ACCELERATORS

In a linear accelerator (*linac*) designed for radiotherapy, electrons gain energy by interacting with a synchronised radio-frequency electromagnetic field rather than by acceleration by direct potential. In free air, electromagnetic waves travel at the speed of light, but in a suitably designed waveguide, the speed of propagation of the waves can be substantially reduced. The *accelerating waveguide* (or accelerator structure) consists of a long cylindrical tube (see Figure 11.1), containing a series of circular baffles. These are designed so that speed of propagation of the microwaves increases in the first part of the accelerating tube until it eventually reaches velocities close to the speed of light. Bunches of electrons generated in the gun are injected into the guide in synchronism with pulsed microwave radiation and are carried down the guide in a manner analogous to riding the crest of a wave (i.e. surfing).

The high energy electron beams, typically 6 MeV or above, can be directly used for therapy and have a number of advantages compared to kilovoltage x-ray beams. Their depth dose curves are characterised by initial skin sparing followed by several centimetres of uniform dose (depending on energy) and then a rapid fall-off in dose (see Chapter 24). Electron beams from linear accelerators are useful for treatment of tumours up to about 70 mm deep, but for more deep-seated tumours, it is better to use photon beams (see Chapter 22). If the electron beam is to be used for therapy, the originally narrow beam of electrons must be broadened by scattering the electrons.

In photon mode, the electrons are focused onto a high-atomic-number thick target, and their energy loss is converted into bremsstrahlung radiation. At megavoltage energies, the principal direction of bremsstrahlung emission is in the forward direction. In the simplest accelerators, the target is fixed and the accelerating structure is coaxial with the emerging x-ray beam (i.e. it is parallel to the direction of travel of the electrons so that no bending of the electrons takes place) and is perpendicular to the crano-caudal axis of the patient. However, for energies above 6 MeV, the length of the accelerator tube is such that it makes this impracticable. In order for the radiation beam to be brought in to irradiate the patient from any angle, it becomes necessary to bend the beam. Electrons are easily deflected in a magnetic field, and it is convenient to bend them through about 90°.

The challenge for accelerator design is to produce a stable monoenergetic high current electron beam concentrated onto a small focal spot that will ensure that a sharply focussed x-ray beam can be produced. The x-ray beam must be modified to allow uniform irradiation of the intended treatment area of the patient, which can vary from a very small area up to a

**FIGURE 11.1**

Schematic diagram of a linear accelerator designed for radiotherapy and used in x-ray mode. The electrons are injected with an electron gun in a section where an electromagnetic field is obtained from a radiofrequency (r.f.) microwave power source. At the exit of the relativistic section the electron beam may be bent before reaching the x-ray target.

maximum of about 40 cm  $\times$  40 cm. It is also of considerable benefit to be able to choose the beam energy to suit the tumour being treated.

Modern accelerators are the result of a complex design process with different emphases being placed by different manufacturers. In the following pages, the issues relating to the different components will be considered.

## 11.3 THE LINAC COMPONENTS

### 11.3.1 THE MICROWAVE POWER SOURCE

In the 2 MW to 10 MW power range that is necessary for pulsed operation of medical accelerators, there are two radiofrequency (r.f.) power sources available: the magnetron and the klystron. In lower energy machines (4 MeV to 6 MeV), magnetrons providing peak outputs up to 3 MW are used, but in dual energy linacs, requiring peak r.f. powers in excess of 5 MW, some manufacturers favour klystrons.

Medical linacs normally operate in the S-band either at 2856 MHz or 2998 MHz frequencies. The corresponding wavelengths in free space are 10.5 cm and 10 cm, respectively. This represents a compromise between the high power capability of large L-band (390 MHz to 1550 MHz) wave guides and the compactness needed in therapy applications.

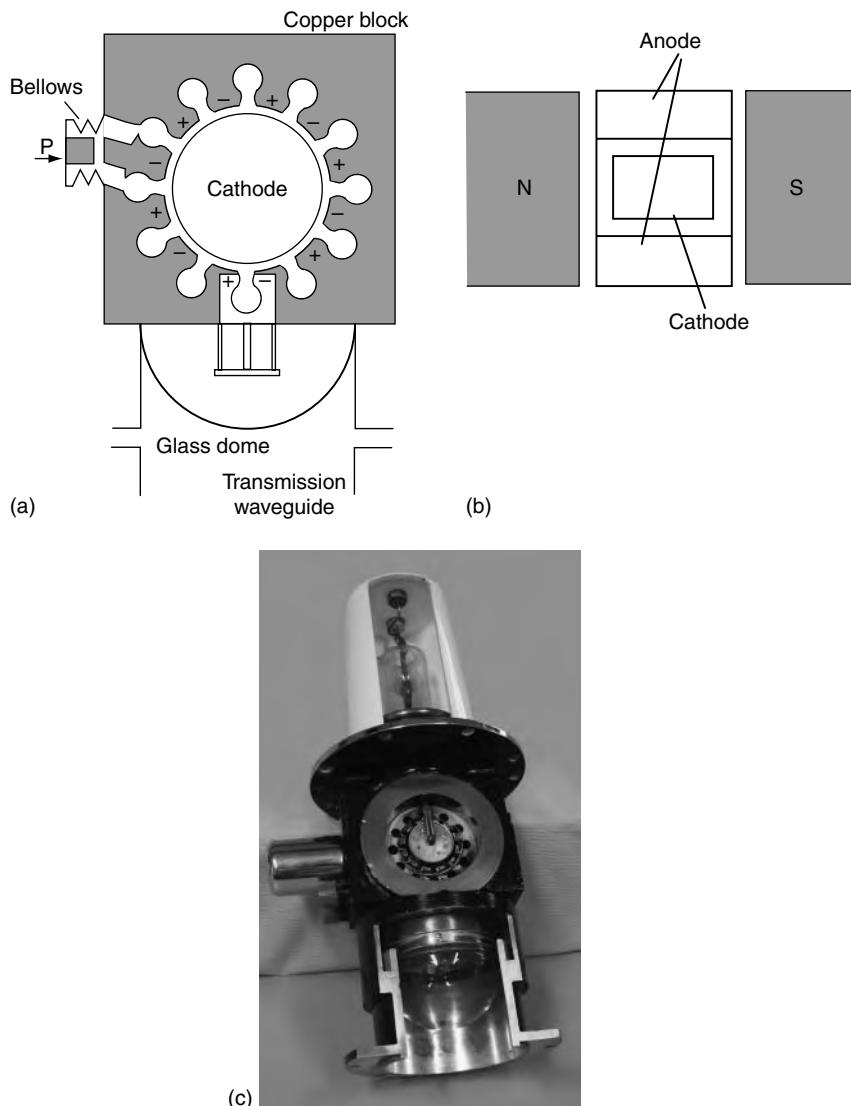

#### 11.3.1.1 *The Magnetron*

The *magnetron* (see [Figure 11.2](#) [Greene and Williams 1997]) is an r.f. oscillator that extracts microwave energy from electrons by means of a slow wave resonant structure in a strong magnetic field. Negative 50 kV voltage pulses, lasting up to 5  $\mu$ s, are applied to a heated cylindrical cathode. Thermionic electrons are then attracted toward a radially symmetric anode, comprising an array of cylindrical cavities. A magnetic field parallel to the cathode axis causes electrons to follow curved trajectories. At a critical field strength, the electrons sweep close to the anode before spiralling back to the cathode. In doing so, two things happen; first, induction currents are set up in the anode cavities, creating oscillating electric fields that will subsequently modulate later spiralling electrons; and second, the returning electrons will liberate more electrons by secondary emission at the cathode. This latter feature requires the cathode heater current to be reduced during the high-voltage pulse to avoid an avalanche situation developing. The cavity oscillations cause electrons to form bunches or spokes at each alternate cavity in a slowly rotating space charge cloud. A quasi-stable equilibrium state is reached where the rotating cloud of electrons transfer energy to the oscillating cavities. R.f. power is extracted at the output transition via wires from two adjacent cavities that are fed out beneath an evacuated glass dome to a loop antenna that directly feeds into a transverse-magnetic mode rectangular waveguide.

The dimensions of the resonant cavities determine the operating frequency of the magnetron, although an adjustable tuning probe can vary this over a small range (see discussion of automatic frequency control later—[Section 11.7.1](#)). The maximum power available is determined by the electron emission from the cathode, the magnitude of the applied high-voltage pulse, the transverse magnetic field strength, and the ability to shed heat from the water-cooled anode assembly.

As the r.f. power source essentially determines the maximum energy of an accelerator, some manufacturers of linacs offering dual x-ray operation use long anode, so-called Boot magnetrons (named after an early designer H. Boot). These have adjustable electromagnets, and when they are supplied with variable pulse voltages, they permit operation in low and high energy modes and can deliver peak outputs of 5 MW.

Magnetrons are compact devices and are usually mounted in the gantry arm. This avoids the need for expensive rotational r.f. couplers and lengthy transmission waveguide elements.

**FIGURE 11.2**

(a) Diagram of a tunable magnetron. This is placed in a magnetic field with lines of force normal to the plane of the diagram. (b) A section through the magnetron normal to that in (a), showing the poles of the magnet. (c) A photograph of a magnetron that has been opened to show the anode–cathode structure.

However, despite the high power levels present in magnetrons, they are very sensitive to magnetic field effects, and gantry mounting does require that corrections are made for different orientation within the earth's magnetic field as a function of gantry angle. For this reason, Siemens employed a fixed mounting position in their smaller Mevatron accelerators, avoiding geomagnetic variations and other causes of instability.

### 11.3.1.2 The Klystron

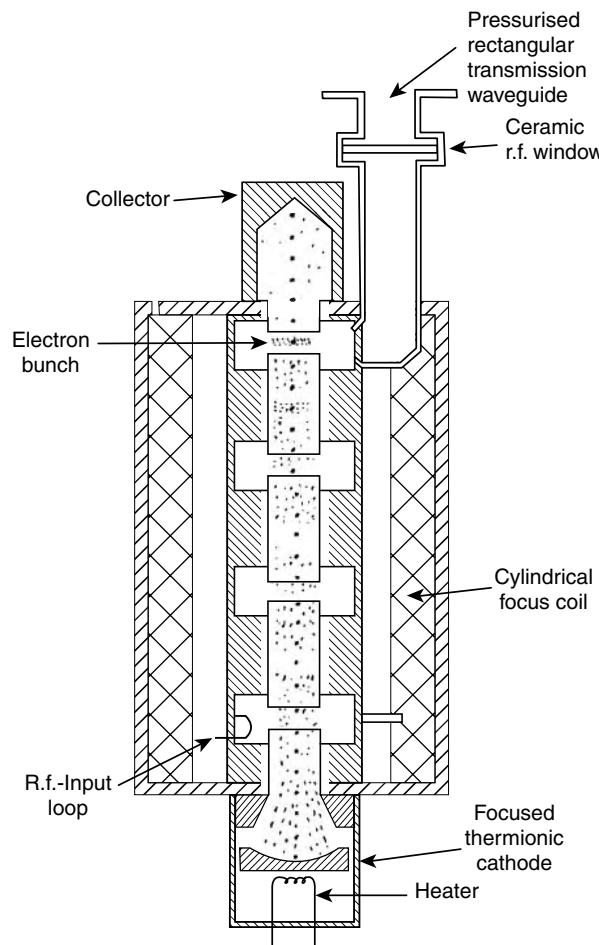

One of the earliest examples of a *klystron* was built by the Varian brothers in 1937, but since then, the design and application range has extended enormously. Unlike the magnetron, the klystron is not an r.f. oscillator, but it is an r.f. amplifier. It requires an r.f. input signal to excite it that it then amplifies from a few dB to nearly 100 dB, depending on the design. Functionally,

klystrons can be regarded as inverse accelerators in that they transfer energy from an electron beam by velocity modulation to power an intense r.f. microwave output.

Figure 11.3 schematically shows the main components of a *Pulsed Klystron Amplifier*. Mounted vertically, an *electron gun* injects thermionically emitted electrons through an aperture in the anode into the r.f. section above. At the gun end, these electrons are confined to a narrow axial beam by electrostatic or magnetic focusing and are kept on axis throughout the r.f. section by large solenoidal coils. Finally, at the top of the klystron, the electrons are captured in the walls of the *collector*.

R.f. operation begins at the input or buncher cavity. Usually, an input loop from a coaxial transmission line, fed by a low power microwave oscillator, excites this first cavity. Induced field effects result in bunching the electrons as they pass through, some being slightly accelerated and some retarded. This is known as velocity modulation. After passing through a field-free region or drift tube, the now bunched electrons will induce r.f. oscillations in a similarly designed resonator cavity. This can be repeated at successive cavities, building up r.f. power at the expense of that present in the original electron beam. Finally, at the output cavity or *catcher*, the r.f. power can be propagated through a coupling iris and fed to a transmission waveguide for subsequent use in the accelerator waveguide.

At this stage, it is worth noting some of the parameters involved in a modern high power klystron. Typical high voltage pulses lie in the range 100 kV to 150 kV, electron currents

**FIGURE 11.3**  
Schematic representation of a Klystron.

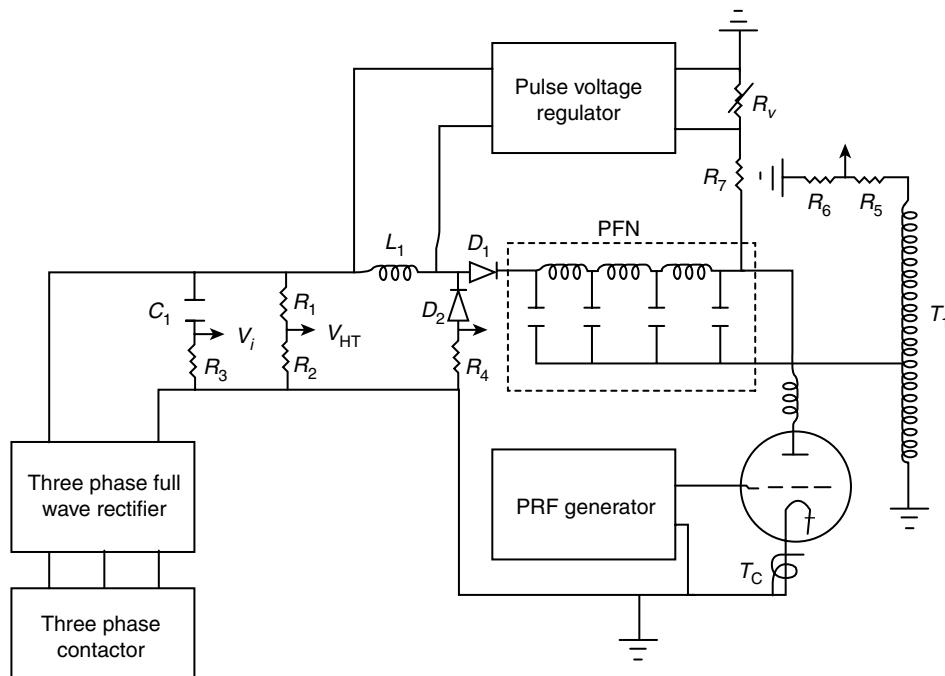

during these pulses are of the order of 100 A, and the r.f. power conversion gain is typically 50%. Three design requirements should be highlighted:

1. Electrons reaching the collector will generate bremsstrahlung x-rays (up to 100 keV) and need some significant shielding.
2. Even with a low duty cycle (1:1000), tens of kilowatts of heating will occur at the collector and need substantial cooling.
3. To reduce the risk of electrical arcing and to keep the overall dimensions small, at least part of the klystron should be oil-immersed. In practice, as the high voltage is confined to the gun end of the tube (negatively pulsed cathode) with the remainder at or close to earth potential, it is only the lower portion that is required to be mounted in an oil tank.

Linac klystrons and their associated shielding are heavy and bulky items. For this reason, they are always mounted in a fixed position in the drive stand and not in the gantry arm. As discussed in reference to the magnetron, this incurs a higher cost because of the need for more extensive r.f. plumbing.

### 11.3.2 HIGH VOLTAGE PULSED POWER SUPPLY OR MODULATOR

The *modulator* supplies high-voltage pulses lasting a few microseconds to the *microwave source* and *electron gun*. Details of the many circuit configurations employed are outside the scope of this work. The interested reader is referred to Karzmark et al. (1993) and service sheets supplied by accelerator manufacturers. Figure 11.4 shows the important components of a linac modulator in a much simplified form, following the treatment of Greene and Williams (1997). A high-voltage, three phase power supply (with two output levels in dual energy applications) typically delivers 10 kV to the smoothing capacitor  $C_1$ . This can be monitored at the voltage divider  $R_1$  and  $R_2$  where  $R_1 \gg R_2$ . The *pulse forming network*

**FIGURE 11.4**  
Simplified modulator circuit.

(PFN) is charged through inductance  $L_1$  and diode  $D_1$  while the *hydrogen thyratron*  $T_c$  is in its non-conducting state. The inductance  $L_1$  and the combined capacity of the PFN act as a series resonant circuit (the inductance of  $L_1 \gg$  PFN), and the voltage across the PFN will swing up to twice that of the power supply. Diode  $D_1$  holds the voltage at its maximum level until the high power *thyratron* is fired to discharge the PFN. The resulting current pulse is fed to the primary windings of the pulse transformer  $T_1$ . This has its low end close to earth potential, and the high voltage ends go to the microwave generator and electron gun of the accelerator. Pulse lengths of 3  $\mu\text{s}$  to 6  $\mu\text{s}$  are common, and peak currents in excess of 500 A flow through the thyratron. The PRF (pulse repetition frequency) is set by the *PRF generator* connected to the thyratron grid and is usually adjustable in the range 50 Hz to 1000 Hz.

### 11.3.3 THE ACCELERATING WAVEGUIDE

At a basic level, this core component of a linac looks like a copper pipe. Internally, *irises* or *washer-like disks* divide the structure into *cavities* throughout its length. Powerful r.f. waves enter the guide and establish intense electric and magnetic fields in each cavity. These fields that accelerate the electrons along the guide axis are set up by induction currents created in the surface of the cavity walls. To keep resistive losses low, high purity copper is the most common material used. The microwave power dissipated  $P$  in the walls of a guide for an electron energy gain  $V$  and guide length  $L$  is given by

$$P = V^2/ZL \quad (11.1)$$

where  $Z$  is the shunt impedance per unit length of the accelerator and provides a simple measure of waveguide efficiency.

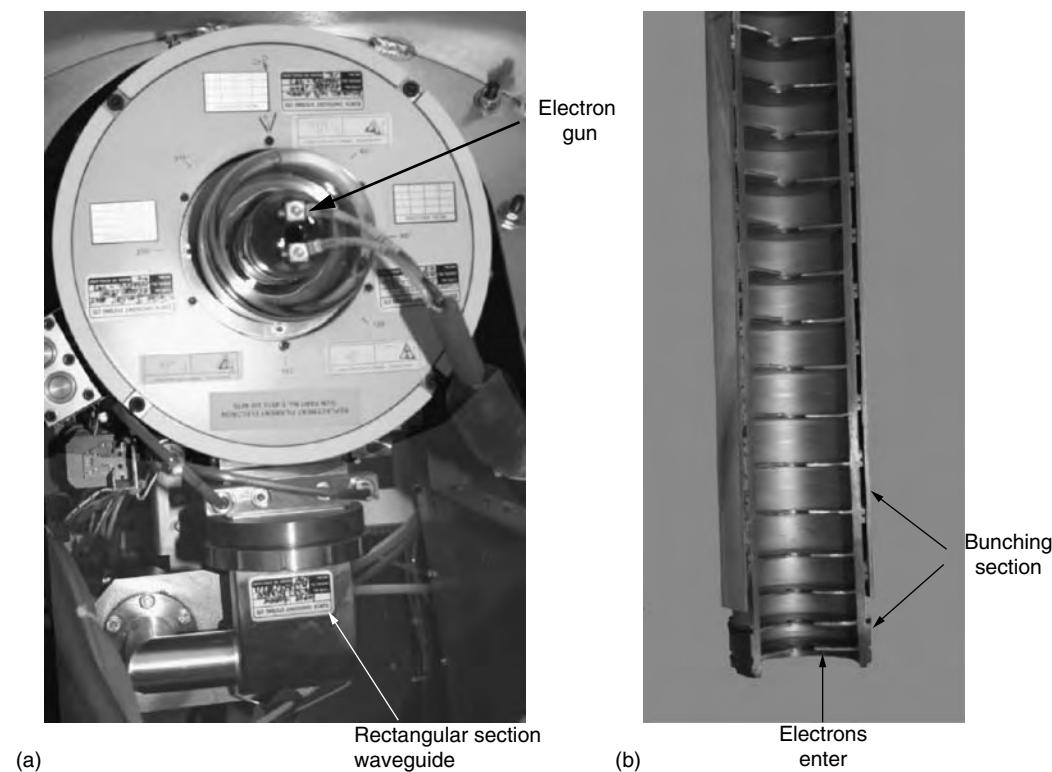

There are two distinct types of guide: the *travelling waveguide* favoured by Elekta (formerly also ABB/Dynaray and Philips) and the *standing waveguide* used by Mitsubishi, Siemens, and Varian (formerly also CGR/GE). Both systems launch electrons from an electron gun into an initial accelerating buncher section in phase with an intense r.f. waveform. In the former, the wave is propagated along the guide axis, and in the latter, it is stationary.

Detailed coverage of waveguide design is beyond the scope of this text; interested readers are referred to the references Lapostolle and Septier (1970), Karzmark et al. (1993), and Greene and Williams (1997).

#### 11.3.3.1 TW or Travelling Waveguides

These guides have relatively low shunt impedances compared to standing waveguide systems; therefore, they need to be physically longer to achieve the same output energy. However, they were the first in clinical use and their construction is much simpler. Figure 11.5b shows a section through part of a modern Elekta Travelling Waveguide. Electrons from the *gun* end enter from the bottom of the figure with a velocity of  $0.8c$  (at 80 kV) where  $c$  is the velocity of light. After the first 30 cm, they are travelling at velocities close to  $c$ . This first part of the guide is called the *buncher section* (notice the reduced spacing of the irises here and their tapering diameters). Thereafter, further energy gain results in a relativistic mass increase, and the iris separation remains constant. In the *buncher*, as the name implies, the electrons are brought together in space, phase and velocity as they acquire energy from the electromagnetic fields. These are set up by a synchronised r.f. pulse entering the guide through a mode transformer near the gun.

An overview of a typical microwave system used in the acceleration process is schematically shown in Figure 11.6. Rectangular *transmission guides*, pressurised with high dielectric gas (e.g. sulphur hexafluoride ( $\text{SF}_6$ ) or freon), are used to transport r.f. power from the magnetron to the accelerating guide. These gases not only help to reduce r.f. arcing, but they also cool the output glass dome of the magnetron. At both ends of the accelerator, *door-knob mode*

**FIGURE 11.5**

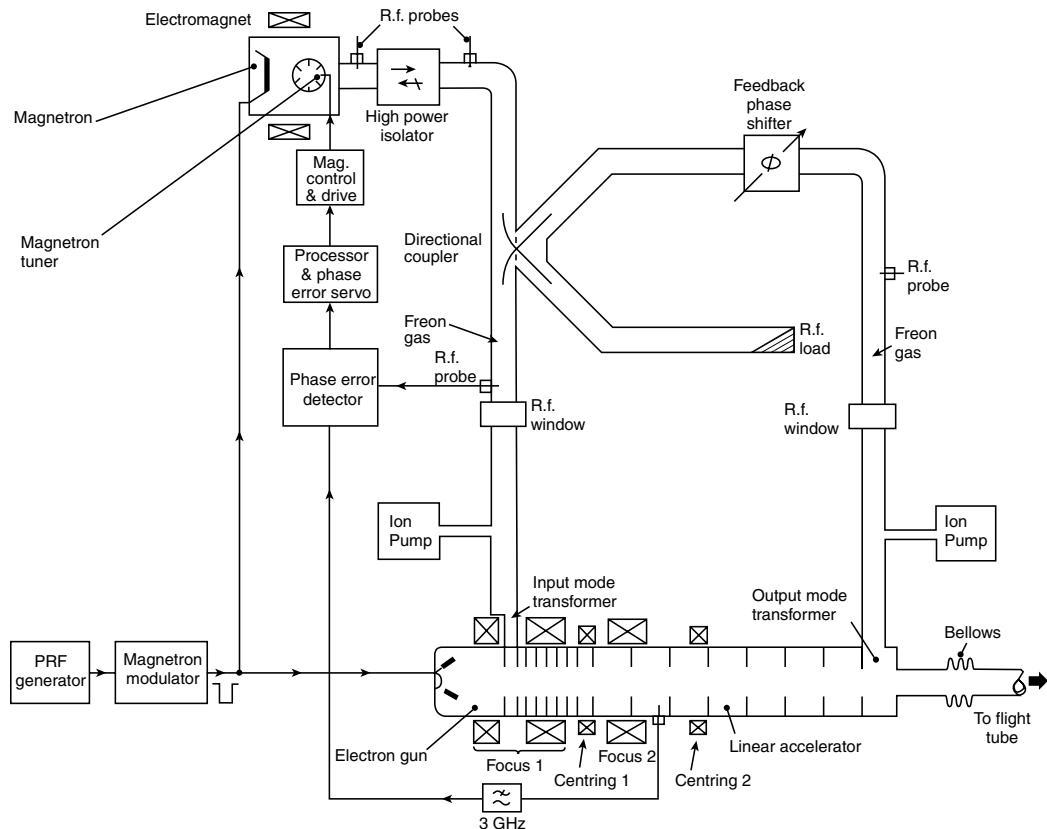

(a) View of the gun of an Elekta accelerator looking towards the accelerating waveguide from the rear. The rectangular waveguide at the bottom of the image brings the microwaves from the magnetron. They pass along this guide and upwards (in the picture) to where a junction is made with the circular accelerating waveguide involving a further turn through 90° to pass down the accelerating waveguide (located behind the glass gun assembly at the centre of the circular area). (b) Cut away section of the circular accelerating waveguide—electrons are accelerated in the direction from the bottom towards the top of the page as indicated by the arrow. Note the baffles in the waveguide are closer together at the bottom. This is the buncher section in which electrons are accelerated to relativistic velocities.

*transformers* (input and output) are used to couple the rectangular transmission sections to the accelerating guide. Sintered ceramic *r.f. windows* separate the pressurised guide regions from the highly evacuated (using *ion pumps*) *accelerating structure*. At the output end of the guide, unused r.f. power is either dumped into an absorbing water load or returned through a *recirculator circuit* to augment the available power at the input.

Also shown in the figure are external *solenoidal focus and centring (steering) coils* that are used to confine the electron beam and keep it directionally on axis. These help maximise the guide's efficiency and improve beam definition at the exit window.

### 11.3.3.2 SW or Standing Waveguides

If each end of an iris loaded waveguide is terminated with a conducting disc, microwave power will be reflected with a  $\pi/2$  phase change at the ends, allowing *standing waves* to build up. A simple account is given by Greene and Williams (1997) and will be followed here. Figure 11.7a shows a schematic *standing waveguide* with the arrows in cavities 1, 3, and 5 indicating the axial electric field at an instant. The fundamental mode (at least in this model) is shown by the solid curve in (b) with nodes at 2, 4, and 6. Clearly, electrons present at this moment in 2, 4, and 6 will receive no acceleration. One half cycle later, the situation has reversed and is shown by the dotted curve in (b). If the time required for an electron to travel from cavity 1 to cavity 3 equals half the r.f. wave period, then it will gain energy in both cavities.

**FIGURE 11.6**

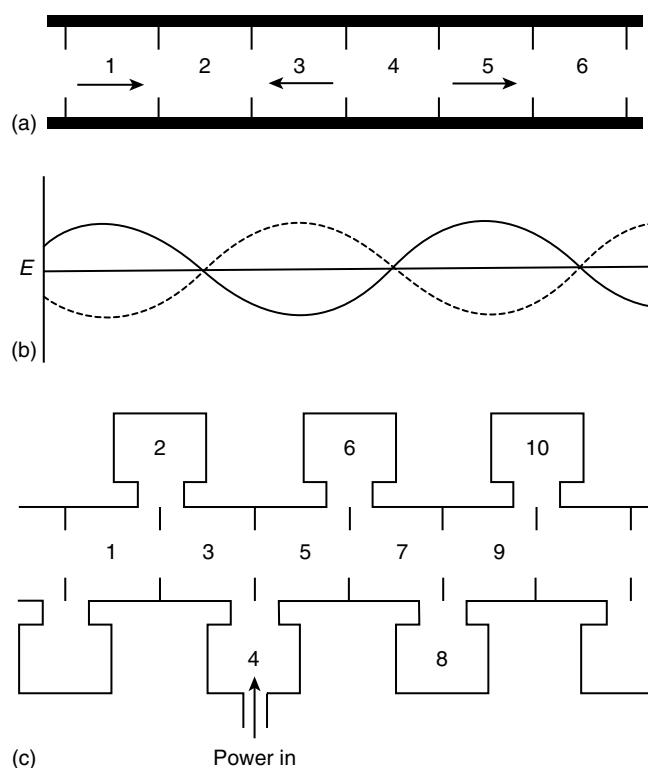

Full microwave system in a travelling wave accelerator. (Reproduced by permission of Elekta Oncology Systems.)

This is the basis of a standing waveguide. In practice, this can be implemented a number of ways, depending on the energy and particular application. For single energy x-ray applications (4 MV to 6 MV), both Siemens and Varian have adopted the *side coupled cavity* design shown in Figure 11.7c. Here, the non-accelerating cavities are taken out to the side, leaving only accelerating cavities on axis. Figure 11.8 shows a detailed sectional view of a Varian side cavity system. Such a longitudinally compact design allows these guides to be mounted *straight through* down the collimator axis and so avoid the need for a bending magnet as shown in Figure 11.9. In dual energy high powered guides, where their length would always preclude such an arrangement, the guide's transverse dimensions can become a problem.

With injection voltages of typically 50 kV, standing waveguides also require an initial *buncher section* where the electrons are gaining velocity. Here, it is necessary to shorten the first few cavities to allow transit times to be kept to one half cycle. Because the guide is soon filled with standing waves, it no longer matters where the r.f. power is fed in. This allows designers to avoid perturbing field effects at the gun end and to choose a more convenient central location.

### 11.3.3.3 Comparison of Travelling and Standing Waveguides

Shunt impedances in *standing* waveguide systems may be twice as high as in corresponding *travelling* waveguides. Inter-cavity coupling is usually magnetic rather than electric and more intense fields are set up. This does place higher demands on manufacturing tolerances, but in turn, results in a much tighter beam both in energy and spatial position. Where guide length is critical, standing wave systems, especially of the side cavity type, can offer a fourfold length

**FIGURE 11.7**

Standing wave accelerator: (a) Shows schematically the arrangement of the waveguide. (b) Illustrates the standing waves. (c) Shows a *side-coupled cavity*. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.)

reduction. However, maximum beam currents can be much higher in travelling waveguides, up to 2 A compared with 0.5 A in standing waveguides. In electron treatment modes where the required beam currents are very low compared with those for x-ray production, small changes in *frequency* in travelling waveguides can be used to change the electron energy. Standing waveguides, on the other hand, are much higher  $Q^*$  devices and must be driven very close to their design frequency. The electron energy here is determined by the *r.f. power* available and its *phase* relationship to the cavity oscillations.

#### 11.3.4 THE ELECTRON GUN

The *electron gun* is the source of the electrons that are to be accelerated. As in a conventional x-ray tube, the electrons are generated from a heated cathode by the process of thermionic emission. A pulsed electron beam is produced by the application of a voltage pulse of about 10 kV. This produces an instantaneous beam current of the order of millamps. Details of electron gun construction differ between manufacturers.

In *travelling* waveguides with their larger iris apertures (necessary for adequate electric field coupling) and the lower field strengths present, the system is more spatially tolerant. This allows simple heated tungsten wire coils to be used. Not only does this reduce the

\* The Quality Factor  $Q$  in this context refers to the narrow performance window for electron acceleration in a waveguide. In a resonant circuit, it is usual to measure  $Q$  as the ratio of the resonant frequency to that of the difference between the upper and lower half power frequencies.

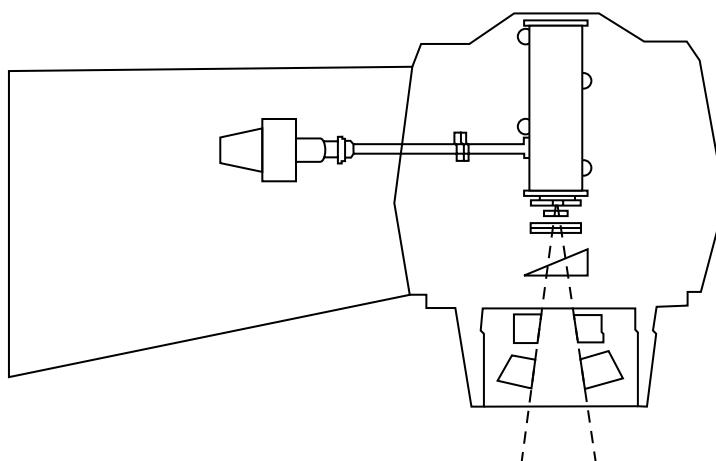

**FIGURE 11.8**

(See colour insert following page 590.) A Varian 4 MV side cavity standing waveguide.

complexity and the cost of the gun assembly, but it also has the additional benefit of providing a simple method of dose-rate control. As later demonstrated, this is a crucial requirement of any clinical accelerator and can be performed in these guides by controlling the gun current provided that it responds rapidly enough. The thermal capacities of these guns are very small, and they meet this requirement. A picture of the cathode for such a gun can be seen in [Figure 11.10](#).

Standing waveguides are much more critical structures and cannot accept the possible spatial fluctuations of a gun filament as it ages or distorts with gantry rotation. Instead, indirectly heated guns are used that comprise a heating element embedded in a solid matrix supporting a high thermionic emissive cathode front surface. The whole forms part of an electrostatic focusing assembly precisely aligned with the anode aperture. For even

**FIGURE 11.9**

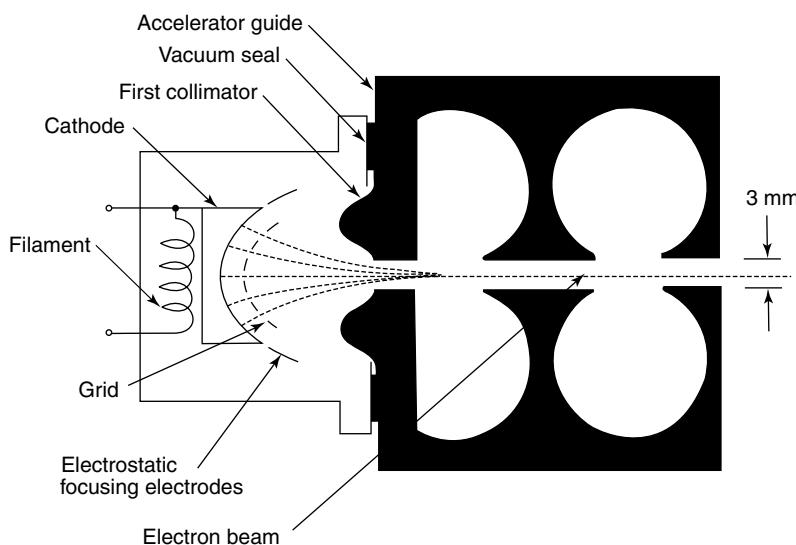

Magnetron-driven straight-through accelerator head. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.)

**FIGURE 11.10**

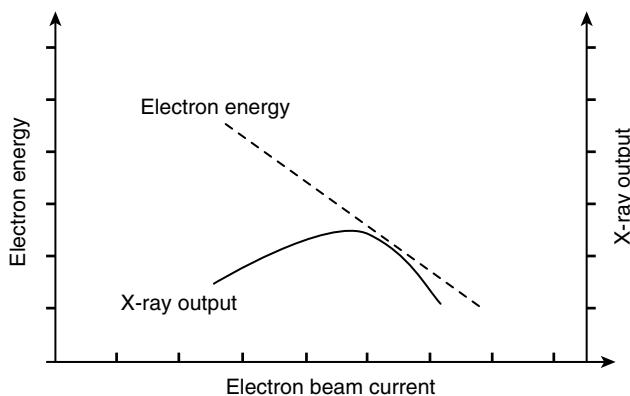

Cathode assembly from an Elekta SL series linac. Note the spiral cathode at the centre.

better control, a gridded element can be added in front of the cathode surface, creating a triode gun assembly and is schematically shown in Figure 11.11. The precise and constant geometry of these indirectly heated guns is favoured in standing wave machines, but because of their relatively high thermal capacities, they necessitate alternative methods of dose-rate control.

For normal operation, the peak beam current drawn from the gun is fixed at a precise level. This, together with the design of waveguide, the phase relationship, and r.f. power level

**FIGURE 11.11**

Triode electron gun assembly. (Reproduced by permission of Varian Medical Systems.)

**FIGURE 11.12**

The relationship between electron beam current, electron energy, and x-ray output in a linear accelerator. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.)

available, will determine the output energy. In both travelling and standing wave systems, it is important to realise that small variations in gun current alone will affect the energy of the accelerated beam. Figure 11.12 shows how the electron energy falls as beam current rises in an exactly analogous way to a transformer load line. Clearly, any departure in beam current from its intended level will give rise to a consequential energy change and this indicates how important a parameter it is to control.

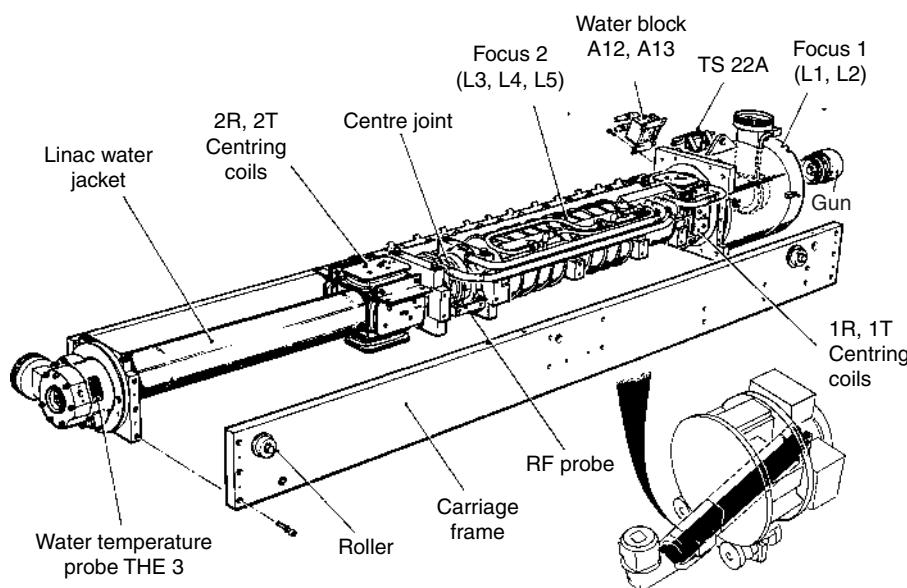

### 11.3.5 BEAM STEERING AND FOCUSING

In both travelling and standing waveguides, it is necessary to constrain (focus) the accelerating electron bunches close to the central axis of the guide. Throughout the guide, but especially in the buncher section, mutual repulsion would otherwise cause the electron beam to diverge. These losses would not only result in a reduced beam current, but they could also seriously damage the guide structure. Again, the standing-wave tolerances are tighter, and as the waveguides tend to be wider (especially those using side cavities), more powerful and correspondingly larger solenoidal focus coils are necessary.

Because a narrow beam of electrons travelling parallel to the axis of the waveguide is required, it should not be surprising that all systems employ some beam steering elements in their design. So-called steering coils, usually a pair of Helmholtz coils\*, are mounted at critical points along the guide to steer the beam *radially* R (i.e. along the treatment couch) or *transversely* T (i.e. across the couch). Adjustment of currents through coil pairs mounted near the gun end of the accelerating guide (commonly referred to as 1R or 1T for their radial or transverse effects, respectively)<sup>†</sup> are made during installation or following a major repair. Coils mounted at or near the bending chamber (2R and 2T) are used to adjust beam centring either manually during servicing or automatically via feedback circuitry from any unflatness signals monitored by the transmission ion chamber (see Section 11.7.3.2). This latter dynamic aspect of accelerator control is critical for safe operation. Any beam

\* Helmholtz coil pairs are commonly used to obtain a region of uniform magnetic field between them. The arrangement comprises two equal coaxial circular coils set parallel to one another with their centres at a distance apart equal to the radius of either coil. With the same current passing through each coil and wound in the same direction, a uniform magnetic field is established between them. For steering or deflection purposes, it is sufficient to vary the current in either coil.

<sup>†</sup> The 'R' and 'T' designations are manufacturer dependent and other conventions may be used for the same purpose.

**FIGURE 11.13**

Focus and centring coil positions for a travelling waveguide. The insert at the bottom of the figure shows how this waveguide is mounted on the accelerator gantry. (Reproduced by permission of Elekta Oncology Systems.)

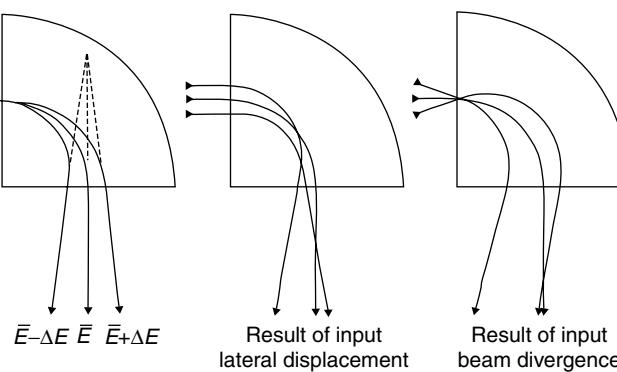

misalignment would result in the beam striking the target at the wrong angle, leading to a non-uniform x-ray beam with possible effects on beam energy. Figure 11.13 shows the focus and centring coil positions on a travelling waveguide (notice that it has not been necessary to have solenoidal focus coils around the second half of the waveguide).

### 11.3.6 THE BENDING SYSTEM

Ideally, the accelerating tube would be mounted with its axis parallel to the central axis of the radiation beam. However, except for low energy linacs with standing waveguides, the resulting height of the linac would be prohibitive. It is necessary to mount the accelerating waveguide approximately at right angles to the direction of the radiation beam. This requires that the electron beam is bent through an angle of approximately 90°.

Electrons moving in a magnetic field will be bent in a trajectory dependent on the energy of the individual electron. The requirement for the generation of satisfactory clinical beams is that all the electrons shall exit from the accelerating tube within a small focal spot and at the correct angle. Ideally, the electron beam at the input to the bending chamber will have a very narrow energy spread so that all the electrons will automatically follow the same trajectory. Such precise control of beam energy is difficult to achieve and a more stable solution is to design a so-called *achromatic* bending system where electrons of different energies exit at the same point and in the same direction in spite of their having followed different trajectories. *Non-achromatic* bending systems do, however, have the advantage that the bending magnet acts as a very precise system for ensuring that the energy is correct. In achromatic systems, some other means must be found to monitor beam energy (see [Section 11.7.2.3](#)). In all systems, it is of the utmost importance to set the magnet currents at a very precise and stable value, depending on the energy, because it will have a direct influence on the electron trajectories.

Many systems have found commercial success over the years, each having their advantages and disadvantages. Five of them will be briefly discussed, but for a fuller coverage, the reader is referred to Karzmark et al. (1993).

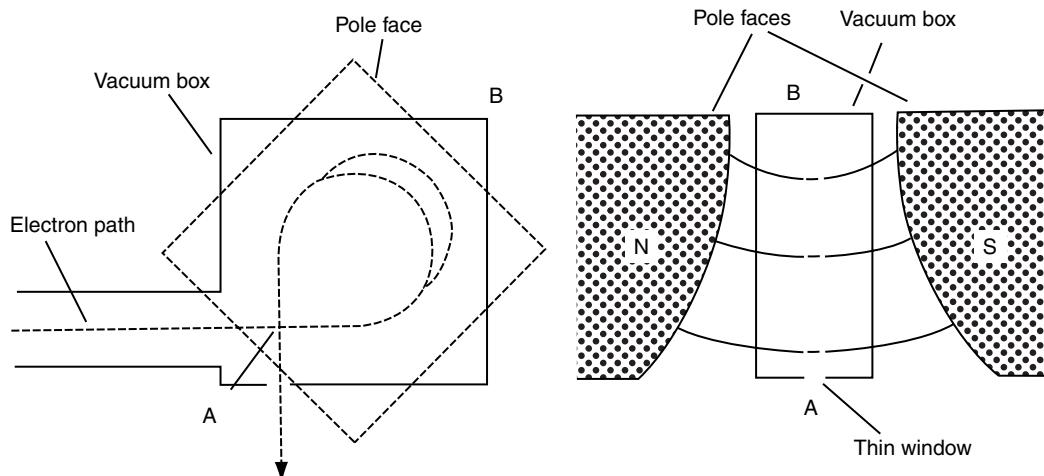

**FIGURE 11.14**  
Simple 90° non-achromatic bending system.

### 11.3.6.1 90° Bending Magnet

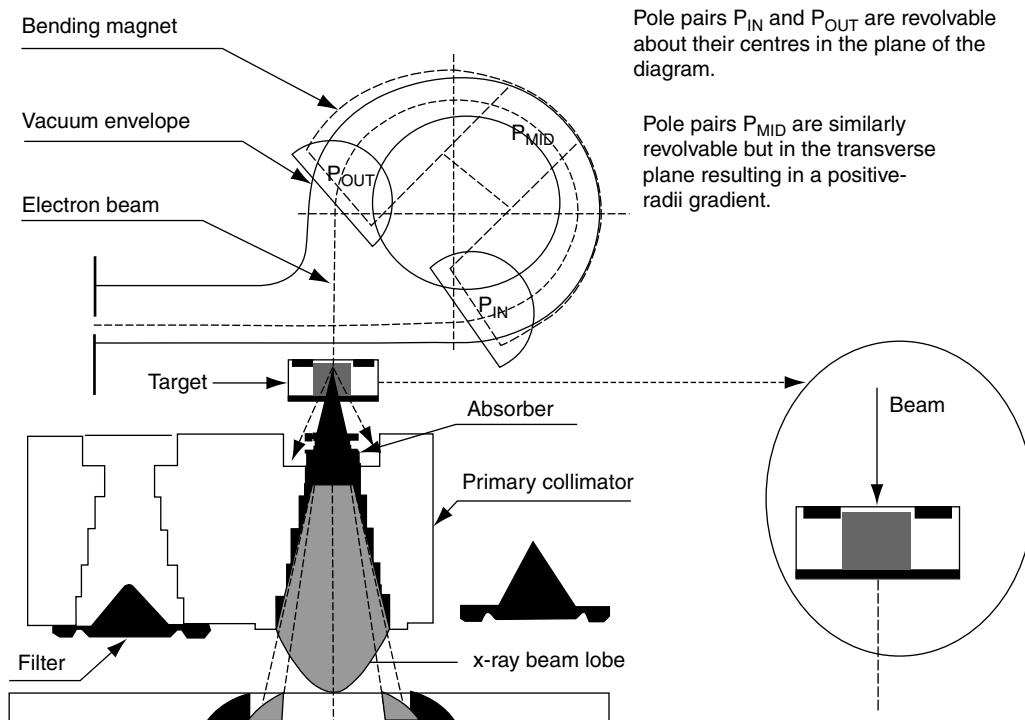

The simplest bending system provides a 90° bend using a simple dipole magnet. This was the bending system employed on many early linacs. Such a system is not achromatic. In Figure 11.14, the effect of energy spread lateral displacement, and beam divergence on electron trajectories through such a magnet can be seen. Precise control of beam energy is difficult to achieve and as a result, target diameters in excess of 2 cm were common, and even with large flattening filters, fluctuations in x-ray uniformity were considerable. Exit window slits were tried in order to trim the electron beam, but these became secondary sources of x-rays, further broadening the effective focal spot.

### 11.3.6.2 A 270° Magnet Using Hyperbolic Pole Faces

Figure 11.15 shows how, by shaping the pole faces, more energetic electrons (larger radii) enter closer spaced regions with higher bending fields, and less energetic electrons encounter lower bending fields between the wider pole spaces. In principle, all electrons that entered on

**FIGURE 11.15**  
Bending chambers with hyperbolic pole faces. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.)

**FIGURE 11.16**

axis at  $0^\circ$  should converge again at the same point at  $270^\circ$ . The deflection is without dispersion with energy (i.e. achromatic). This system was used in the ABB/Dynaray units, but it requires stringent manufacturing tolerances in the pole face shaping and is a costly component.

### 11.3.6.3 A $270^\circ$ Magnet with Locally Tilted Pole Pieces

Figure 11.16 shows the configuration of locally tilted pole pieces that are used in Siemens Mevatron and Primus accelerators. In this system, both uniform and non-uniform field regions are combined in the same magnet sector. This focuses a range of entrant momenta and a range of lateral displacements and divergences to be geometrically equivalent at its output and rotated by  $270^\circ$ . It is achieved by having two adjustable pole sections of the magnet providing an increased radial field gradient. At higher radii, more energetic electrons encounter a narrower spaced higher bending field and are focused to a single spot at the x-ray target. Entrant and exit pole faces are adjustable for optimal radial and transverse focusing.

### 11.3.6.4 A $270^\circ$ Three Sector System

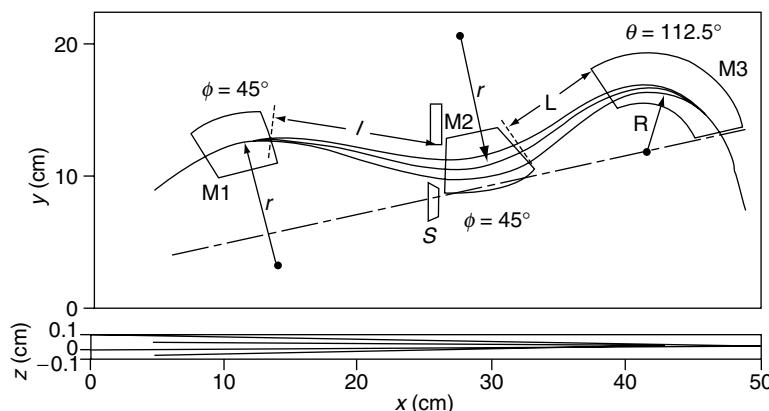

The  $270^\circ$  three sector design, favoured by Varian, is shown in Figure 11.17. It comprises three uniform dipole magnets separated by short drift spaces. A narrow pair of *slits* limits the transmitted energy to within 3% of that intended and where any bremsstrahlung is produced, it is directed away from the useful beam into the shielded head. The whole assembly is enclosed in an evacuated bending chamber which also includes the target sections and radial and transverse steering coils. Notice the target position lies above the accelerator guide axis, which allows a lower isocentre position for what would otherwise be a large magnet assembly.

**FIGURE 11.17**

Three sector bending chamber. Also shown are the guide and chamber steering coil positions. (Reproduced by courtesy of Varian Medical Systems.)

### 11.3.6.5 A 112.5° Double Focusing (Slalom Bend) System

The slalom bending system (Figure 11.18) pioneered by Philips (now Elekta) is intended to minimise the vertical height associated with other achromatic bending systems. The purpose is to reduce the isocentre height of the overall machine. Maximum energy dispersion occurs between magnets M2 and M3, but the energy slit S is located at the entrance to the second dipole magnet to minimise the x-ray shielding that would otherwise be required closer to the treatment head. In the lower figure, the transverse or Y-field is shown being weakly focused at the exit plane. This is achieved by having the entry and exit pole faces of each dipole magnet slightly rotated. With better beam control systems in the early part of the waveguide, it has proved possible to dispense with the energy slit.

**FIGURE 11.18**

Slalom bending magnet system. (From Botman, J. I. M., Bates, T., and Hagedoorn, H. L., *Nuclear Instruments and Methods in Physics Research*, B10/11, North Holland, Amsterdam, 1985, pp. 796–798. With permission.)

## 11.4 THE HEAD ASSEMBLY

The accelerating and bending structure described above will deliver a narrow focussed beam of electrons that would be of little use for patient treatment. In order to generate a beam that can be used for patient treatment, this beam must either be converted to photons or the narrow electron beam must be appropriately scattered. An example of the features contained in the head is shown in Figure 11.19.

### 11.4.1 PHOTON BEAM GENERATION

#### 11.4.1.1 *The X-Ray Target*

Just as with kilovoltage x-rays, megavoltage x-rays are generated by bremsstrahlung from a high energy electron beam striking a high atomic number metal target, usually tungsten or a copper–tungsten laminate. However, as the energy is increased, the bremsstrahlung emission becomes increasingly directed forward, so that at megavoltage energies, the target acts as a *transmission target*. The target is water cooled, but because of the higher efficiency of x-ray production, the target assembly is sufficiently compact so that it can be moved out of the beam to enable an electron beam to be delivered.

#### 11.4.1.2 *The Flattening Filter*

The bremsstrahlung generated when a high energy electron beam strikes a target is primarily directed forward as shown in Figure 11.20a. For this reason, it is necessary to

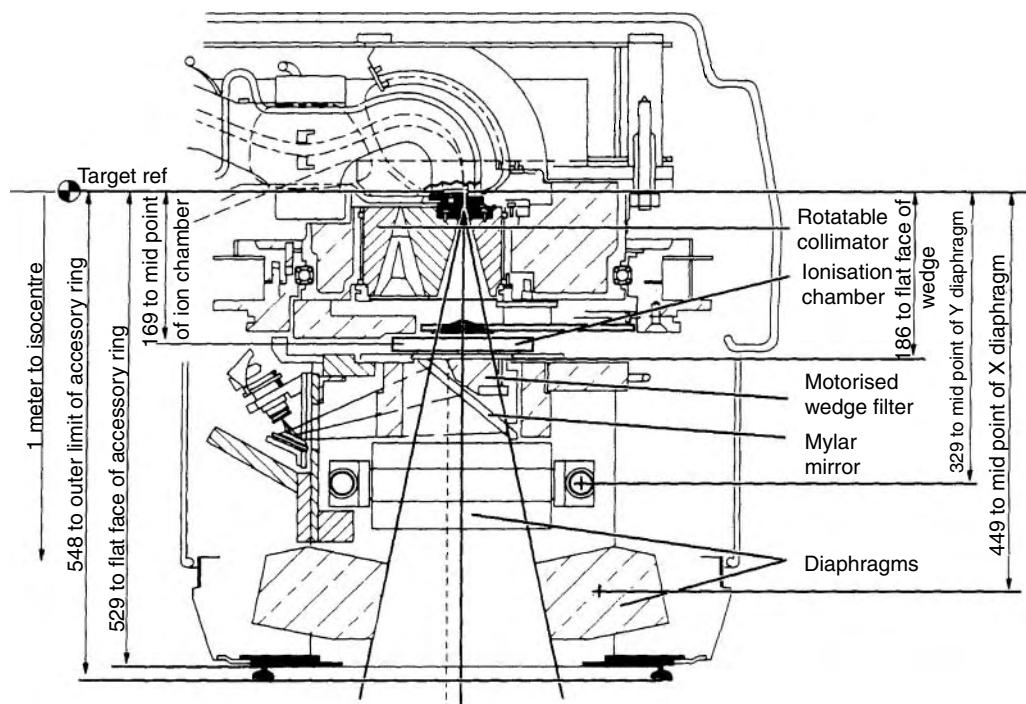

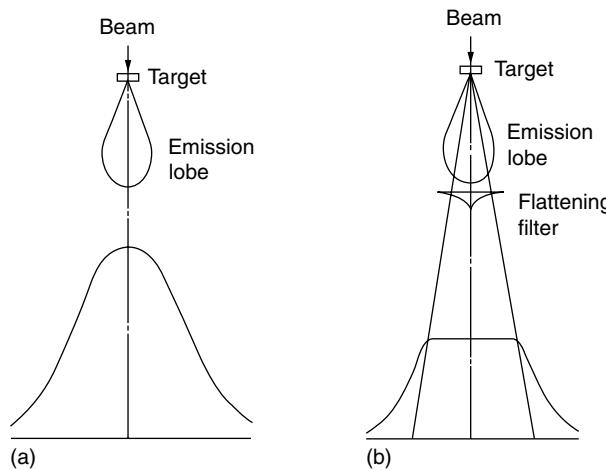

FIGURE 11.19

Diagram of the dual energy treatment head of an Elekta SL series accelerator showing the position of the primary collimator, flattening filter, wedge filter, and secondary collimators. Note that for the high energy beam, the high energy flattening filter (shown to the left of the beam axis in the diagram) is used in conjunction with the low energy flattening filter, which is the solid object just above the ionisation chamber. The numbers are distances expressed in mm. (From Elekta Oncology Systems.)

**FIGURE 11.20**  
Linear accelerator beam without (a) and with (b) flattening filter.

insert a flattening filter in the beam as indicated in [Figure 11.19](#). The effect of this is shown in Figure 11.20b. The use of a flattening filter makes it possible to compensate for the lack of scatter at the edge of the field by deliberately designing a profile that increases toward the edges. The flattening filter is generally circularly symmetric; although, additional material may be needed especially for machines with non-achromatic bending systems. The design of the flattening filter can have a considerable impact on the radiation beam, and this will be discussed further in [Section 22.3.3.2](#).

#### 11.4.1.3 Visual Beam Position Indication

In order to enable the treatment staff to see where the radiation beam will be located, a light beam is generated that coincides with the useful limits of the beam. This is obtained by a high intensity light bulb containing a small filament that must be optically coincident with the source position. It can be mounted on a *moving mechanism* or, as shown in Figure 11.19, can be placed outside the radiation field using a *mirror* to ensure that the image of the light source appears to be at the same point as the radiation source. A graticule is also included in the optical path so that the centre of the radiation beam can be indicated as a cross.

#### 11.4.2 COLLIMATION OF RECTANGULAR FIELDS

The radiation beam must be constrained in some way to ensure that only the required part of the patient is irradiated. In order to meet the requirements for very low dose rates at a large distance beyond the edge of the radiation field, accelerators have a *circular primary collimator* close to the source. This limits the field to a circular shape. On most accelerators, this circle is slightly smaller than the diagonal of the largest square field so that the corners of the field will be cut off (see, for example, Prasad and Bassano 1991). In the Elekta SL25, the maximum field size of 400 mm square at 100 cm distance from the target has a diagonal of 565 mm, but the primary collimator limits the field to a maximum circle of 500 mm. The Varian 2100C has the same maximum field size and a maximum circle of 495 mm. Other manufacturers' current equipment is similar. It is important to be aware of any particular machine's limitations in this respect.

The *secondary collimators* (sometimes also called *diaphragms*) is usually made of flat-faced blocks of lead that move in an arc in order that the face of the block shall be aligned with the field's divergent edge. Inevitably, one of the collimator jaws will be closer to the source than the other, and as a result, the sharpness of the edges of the beam will be different. Various approaches have been used to try to make the two collimators more nearly equivalent. In the

CGR head, an extra penumbra trimmer was attached around the outside of the upper jaw. This has the effect of reducing the penumbra by around 1 mm. Such methods may increase the size of the head or restrict jaw movement across the centre. However, it is more common to use a single block for each collimator jaw as this facilitates the generation of asymmetric fields and large fields while minimising the size of the collimator assembly. The thickness of the jaws and the relationship between the source size and the distance of the front face of the collimators must be such as to achieve the desired beam sharpness. This is discussed further in [Section 22.3.3](#).

The geometric basis of the penumbra (see [Section 22.3.3.1](#) and [Section 22.5.1](#)) dictates that the 50% field size is defined by the geometric edge of the field. However, optical systems may indicate a slightly larger field size than the useful radiation beam, which can be rectified using optical penumbra trimmers. These usually are thin strips of metal attached to the collimator so that they obscure the optical field while not blocking the radiation beam. It used to be common practice to use optical penumbra trimmers to make the optical field demonstrate the 80% field margins (i.e. the limits of that part of the field where the dose is greater than 80% of the dose on the central axis). Although this had the advantage of discouraging radiation oncologists from applying too narrow field margins, it does lead to difficulties when matching fields, especially using asymmetric collimation. Optical penumbra trimmers can also lead to confusion in setting up the field because it is very easy for them to become asymmetrically set, thereby masking other problems. For all these reasons, it is better to avoid their use and accept a slight mismatch in the field size. The standard specification is that the optical field must agree with the radiation field to within 2 mm, although, most centres will aim for agreement within 1 mm.

The collimation system and head shielding is required by IEC 601 (IEC 1998) to ensure that:

“In a plane circular surface of radius 2 m centred on and perpendicular to the axis of the beam at the normal treatment distance [isocentre] and outside the useful beam, the absorbed dose due to leakage radiation (excluding neutron radiation) shall not exceed a maximum of 0.2% and an average of 0.1% of the absorbed dose measured at the point of intersection of the axis of the beam and the plane surface. These values refer to measurements which have already been averaged over 100 cm<sup>2</sup>. Except in the area defined above, the absorbed dose due to leakage radiation (excluding neutron radiation) at 1 m from the path of the electrons between the electron gun and the Target or electron window [i.e. the target] shall not exceed 0.5% of the maximum absorbed dose on the axis of the beam at the normal treatment distance.”

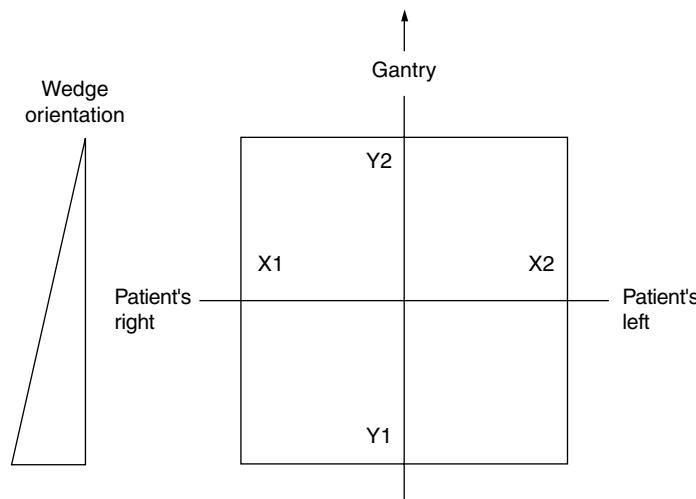

Provided that the collimation system has been correctly designed, any problems in meeting this specification are likely to be caused by poor beam steering resulting in the electron beam striking the edges of the waveguide and generating x-rays at a point other than the target.

Conventionally, jaws are labelled X1, X2 and Y1, Y2. The current IEC specification known as IEC1217 (1996) defines the orientation of these jaws as follows: With the gantry vertical and the head at 0°, Y2 is at the gantry end, and X2 is on the right side (i.e. supine patient's left) as viewed facing the gantry. Clockwise rotations as viewed from the isocentre are positive. This is illustrated in [Figure 11.21](#).

As an illustration of the conventions and limitations which can be found on current machines, on Elekta accelerators that conform to IEC1217:

1. The built-in wedge toe points towards Y1
2. The X jaws are closest to the source and have a poorer penumbra
3. The X jaws will cross the centre-line by 125 mm (asymmetric head only). (100 mm on the Varian 2100C)
4. The Y jaws will only move as far as the centre-line (asymmetric head only).

On older Philips accelerators, the X and Y jaw labelling is reversed. Older Varian machines used A and B rather than X and Y. In spite of the IEC1217 recommendations, there are still

**FIGURE 11.21**

Labelling of collimator jaws according to IEC1217 (supine patient, head towards the gantry). Wedge orientation shown is also consistent with IEC1217 and is used for the Elekta built-in automatic wedge.

differences according to the manufacturer or even to the accelerator model in the method used to name the jaws and also in the orientation of the wedges. This is further discussed in [Section 11.5.4](#) and illustrated in [Figure 11.31](#). In all cases the collimator dimensions are displayed to be representative of the field size at the distance of the isocentre (i.e. usually at 100 cm see [Section 11.5.3.1](#)).

### 11.4.3 MULTILEAF COLLIMATORS

Conventional collimators are only able to constrain the radiation to a rectangular shape. In order to provide more flexibility, multileaf collimators have been introduced. Instead of a single block of metal, these have up to 80 pairs of leaves that can move independently, allowing any beam shape to be produced subject to the width of the leaves.

There are many variants of the multileaf collimator; some are commercially available, and others are designed and built for specific applications by research groups. The principle is the same in each case. A detailed description of systems available up to 1993 can be found in [Chapter 5](#) of “The Physics of Three Dimensional Radiation Therapy” Webb (1993).

Modern multileaf collimators for use in radiotherapy started to appear in the 1980s. Early developments of multileaf collimators took place in Japan. The first European development took place in Scandinavia where specialised MLCs were designed to fit onto the Scanditronix race-track microtron. Philips (now operating as Elekta) and Varian introduced commercially available MLCs in 1990 in Europe and in the USA. Siemens and GE were, at that time, a few years behind.

There are three main types of MLC:

- *Type A* (e.g. Scanditronix and Siemens): The MLC provides all the collimation (except for the primary collimator) and completely replaces the standard collimation system
- *Type B* (e.g. Elekta): The MLC provides field shaping but additional shielding is provided by backup collimators. The MLC (including the backup collimators) replaces the standard collimation system
- *Type C* (e.g. Varian): The MLC provides field shaping in addition to the standard collimation system. Although part of the head assembly, it is externally mounted and complements the standard collimation system.

In addition to these distinctions, there are several ways of measuring and controlling the position of each leaf. This will be discussed later, but it should be noted that some type C high resolution research systems have been constructed without any form of motor control. In these, the leaves were positioned manually. One way of doing this was to produce a template of the proposed field, scaled to the position of the leaf banks. Each leaf was then pushed to be in contact with the template before its position was locked. This has been used mainly for the mini-MLC (see [Section 11.4.3.2](#)).

[Table 11.1](#) summarises the specification of the Varian, Elekta, and Siemens MLCs. As specifications are subject to change, current manufacturers' literature should be consulted for up-to-date definitive specifications.

#### *11.4.3.1 Design Features and Relationship to Performance*

The following description centres mainly on the Elekta type of system (Jordan and Williams 1994), but most of the considered points are applicable to the other configurations. More information can be found in Galvin et al. (1992) for Varian and in Boyer et al. (2001).

[Figure 11.22](#) shows the arrangement of the jaws in the Elekta head. In this example, the two banks of tungsten leaves are mounted inside the treatment head immediately below the flattening filter and the housing of the motorised wedge. In this position, the leaves are at approximately 1/3 of the distance from the x-ray source to the isocentre and are approximately 3 mm wide in order to project to a leaf width of 10 mm in the isocentric plane at 100 cm from the target. Manufacturing tolerances are very tight in this design. MLCs with the leaves nearer the patient will not require such tight tolerances. The leaves are tapered so that each of their edges can be focused toward the target. The leaf thickness of about 7 cm is sufficient to reduce the intensity of the primary beam to 1%. Additional attenuation is provided by the backup collimators, the requirements of which will become apparent after further consideration of the leaves. In this design, the leaves are mounted on rollers that allow them to be moved across the beam by lead-screw mechanisms driven by small DC motors. There has to be a mechanical clearance between the leaves to permit easy movement, and this results in leakage between adjacent leaves that is minimised by the use of stepped and overlapped leaf sections as shown in [Figure 11.23](#) and by keeping the gap as small as reasonably possible. The Varian design has two steps, forming a tongue and groove joint that has the same effect.

As long as the overlap is maintained, the maximum leakage between leaves will be approximately 10%, but in practice, lower leakage is achieved because the gap, being very small, does not subtend the full focal spot from points in the isocentric plane. The average leakage through banks of leaves designed in this way is about 2% with local maxima of up to 5%. [Figure 11.24](#) shows the leakage and transmission measured through leaves alone (i.e. without backup collimators) for the prototype of this collimator. The peaks are on a 10 mm pitch as expected.

Such levels of leakage over the full area exposed by the primary collimator are not acceptable, and the backup collimator moving in the same direction as the leaves provides attenuation by a further factor of about 10 so that areas shielded by both leaves and backup collimators receive a dose of less than 0.5% of the dose in the beam. A more difficult leakage problem arises between the opposing banks of leaves. When a pair of opposing leaves is required to be closed, the gap for mechanical clearance is exacerbated by the curved profile, shown in [Figure 11.25](#), the need for which will be explained below. The projection of this gap onto the isocentric plane can be slightly reduced by setting the closed position away from the central axis, but the leakage will approach 100%. Therefore, the backup collimator moving normal to the leaves must provide attenuation to about 1% of the open beam intensity. The intensity in the shielded areas outside a shaped beam is clearly dependent on which shielding elements are called into play. [Table 11.2](#) gives the transmission through each of the elements of the Elekta MLC. Transmission at each point can be calculated from the products corresponding to various combinations. Note that where MLCs are used in addition to normal collimators, both the X and Y collimator will have similar transmission at less than 1%.

**TABLE 11.1**

Parameters of Multileaf Collimators Available in 2006 (Manufacturers' Specifications)

	Elekta	Elekta Beam Modulator	Varian MLC-80	Varian MLC-120	Siemens 82 leaf	Siemens 160 leaf
Type	B	A <sup>a</sup>	C	C	A	A
No. of leaf pairs	40	40	40	60	41	80
Leaf pitch at isocentre <sup>b</sup>	10 mm	4 mm	10 mm	40×5 mm+20×10 mm	41×10 mm <sup>c</sup>	80×5 mm
Field size at isocentre <sup>d</sup>	40×40 cm	16×21 cm	40×40 cm	40×40 cm	40×40 cm	40×40 cm
Interdigitation possible	No	Yes	Yes	Yes	No	Yes
Maximum over-travel	12.5 cm	11 cm	20 cm <sup>e</sup>	20 cm <sup>e</sup>	10 cm	20 cm
Leaf transmission	<2%	<1%	<2.5%	<2.5%	<1%	
Inter-leaf leakage	<5%	<1.7%	<4%	<3%	<2% (typically 1.3%)	
Positional accuracy	1 mm	0.5 mm	1 mm	1 mm	1 mm	0.5 mm
Leaf speed	20 mm/s		25 mm/s	30 mm/s		40 mm/s
Head to isocentre clearance	45 cm	45 cm	41.5 cm	41.5 cm	42.8 cm (including fixed block tray)	42.8 cm (including fixed block tray)

<sup>a</sup> The Elekta Beam Modulator does not have jaws orthogonal to the MLC (Patel et al. 2005).

<sup>b</sup> Note that the length of a field need not be an integer multiple of the leaf pitch. It can be trimmed with the backup or standard collimator except in the case of the Elekta Beam Modulator.

<sup>c</sup> Siemens have developed a system called HD270 for moving the couch during treatment to produce a virtual leaf width from 10 to 2 mm. Unlike the other manufacturers, the centre of the centre leaf is on the central axis rather than the junction of two leaves.

<sup>d</sup> Elekta's MLC aperture is constrained to have rounded corners at primary field diameter of 50 cm.

<sup>e</sup> Subject to max separation of 15 cm for leaves belonging to the same bank.

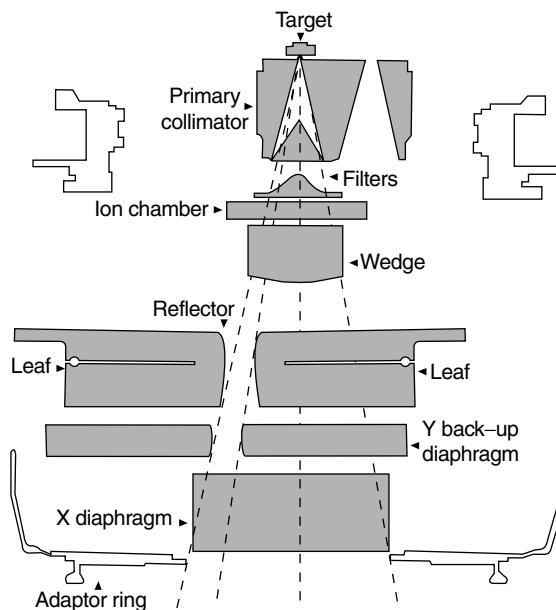

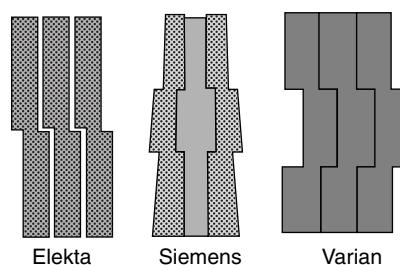

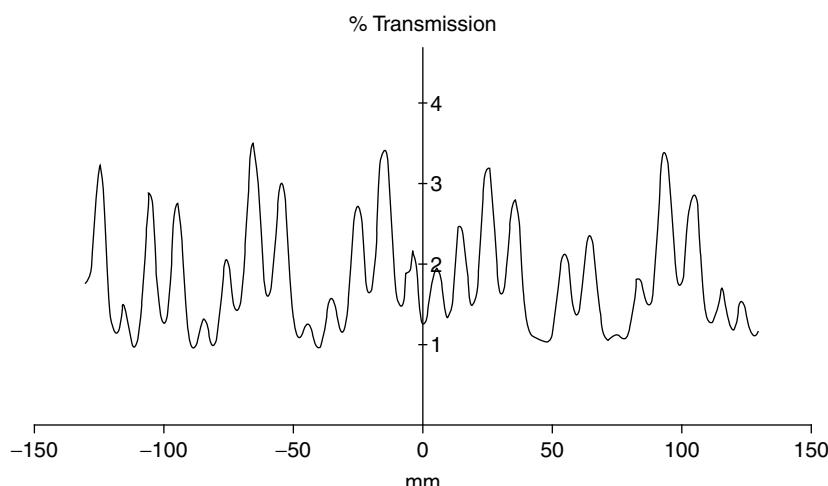

**FIGURE 11.22**

Diagram of Elekta MLC head. The tungsten leaves are mounted between the motorised wedge and the back-up diaphragm.

Of the three manufacturers, only Siemens drives the leaves along arcs centred on the focal spot and, therefore, achieves a double focussed design with each leaf having a flat leading edge. Elekta and Varian use a curved leaf profile, shown in [Figure 11.25](#), that provides a method of minimising the penumbra without the complex mechanical arrangements necessary to keep the flat edge of a conventional collimator aligned with the x-ray source. The curvature allows some penetration of the beam through the edge of each leaf, but this is the same for all field sizes. The penumbra (i.e. the distance between the points receiving 80% and 20% of the dose on the beam axis) is increased by penetration through the collimator. The primary beam intensity is attenuated to 80% along a ray passing through only approximately 7 mm of tungsten. This small depth is achieved within a fraction of a millimetre of the leading edge of the leaf. This is almost independent of the form of the leading edge. The position of the ray attenuated to 20%, having passed through 50 mm of tungsten, is more dependent on the form and can be several millimetres from the leading edge. Use of a circular form ensures that the chords along which 20% transmission occurs are at equal depths: the depth of penetration corresponding to the additional width of the geometric penumbra compared to a perfectly focused system. Because this is true for all chords, irrespective of the angle

**FIGURE 11.23**

Stepped leaves to reduce leakage showing the method employed by different manufacturers. (From Huq, M. S., Das, J. J., Steinberg, T., and Galvin, J. M., *Phys. Med. Biol.*, 47, N159–N170, 2002. With permission.)

**FIGURE 11.24**

Example of leakage between leaves of the Elekta multileaf collimator (without back-up jaws).

of incidence, the degradation of geometric penumbra is independent of the position of the leaf. The penumbra width obtained by this simple design feature is 7 mm, which is only 1 mm greater than that of the standard collimator jaw. Because the position of the beam edge is defined by a different part of the leaf, depending on where it is relative to the central axis, the field size does not change linearly with leaf movement. Therefore, it is necessary to have a look-up table to correct for this.

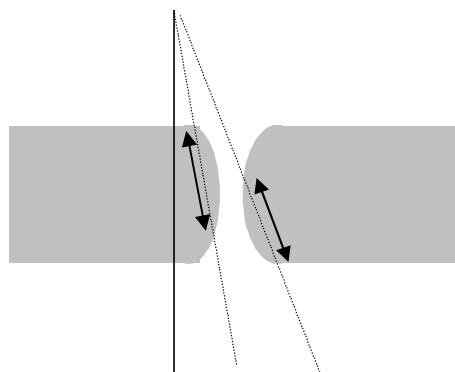

Clearly, the positional control of up to 84 moving elements of a multileaf collimator (i.e. up to 80 leaves and 4 backup collimators)\* is somewhat more complicated than for simple symmetric or independent systems. The simplest way to measure the position and to provide control signals for positional control is to use potentiometers and/or shaft encoders. Varian and Siemens use both on their MLCs. Scanditronix and Elekta use another system, the principle of which is shown in [Figure 11.26](#).

In the Elekta system, each of the leaves is fitted with a reflector that is illuminated by the main optical beam. In addition, there are four fixed reflectors mounted on the collimator frame. These are then viewed by a CCD video camera via an optical beam splitter. The video image is captured 12.5 times per second (a sub-multiple of the video frame rate) and processed within the computer to identify the four reference reflectors and each of the 80 leaves. Failure to find a reflector within predefined limits of position and brightness causes the system to interrupt and the *MLC ready* interlock to the accelerator to be opened. If any spurious reflections are detected, this also interrupts the process.

The calculation of the position of each leaf from the measured positions of each of the reflectors in the video image is based on a stored calibration table. The measurement of the position of the reference reflectors provides a continuous check that the stored calibration data and the algorithms for the calculation are valid. The measured position of each leaf is displayed on a graphic display so that the radiographer can visualise the shape of the field defined by the 80 leaves. The accuracy of leaf positioning has been shown to be well within specification with a root-mean-square positional error of between 0.1 mm and 0.2 mm.

Movement of the leaf positions is by miniature DC motors, each driving a small lead screw through a nut fixed in each leaf. Control is achieved by servo control where the actual position of each leaf is compared with the prescribed position.

\* Up to 120 or 160 leaves for the more recent designs of Varian and Siemens MLC respectively.

**FIGURE 11.25**

The penetration through curved leaves is independent of leaf position.

#### 11.4.3.2 Mini and Micro Multileaf Collimators

The reduction in treatment volume afforded by the use of standard MLCs is comparable with that of customised divergent blocks, but the precise delineation of the edge of the treatment volume is, in many cases, compromised by the projected width of the MLC leaves. The stepping of the field edge, caused by an MLC with a projected leaf width of 10 mm, has been identified as a potential limitation in the restriction of morbidity in up to 19% of cases (Galvin et al. 1992). The limitations imposed by the leaf width have been addressed by smoothing techniques, and the development of MLCs with narrower leaves that are described as *mini* or *micro* MLCs. The distinction between mini and micro is arbitrary, but it has been suggested that MLCs with leaves projecting to between 2 mm and 5 mm should be considered as mini MLCs and those below 2 mm as micro MLCs (Schlegel et al. 1992; Bortfeld et al. 2000). It should be noted that by this definition, the higher resolution integrated MLCs available from each of the linac manufacturers shown in [Table 11.1](#) are mini multileaf collimators (at least for part of the field).

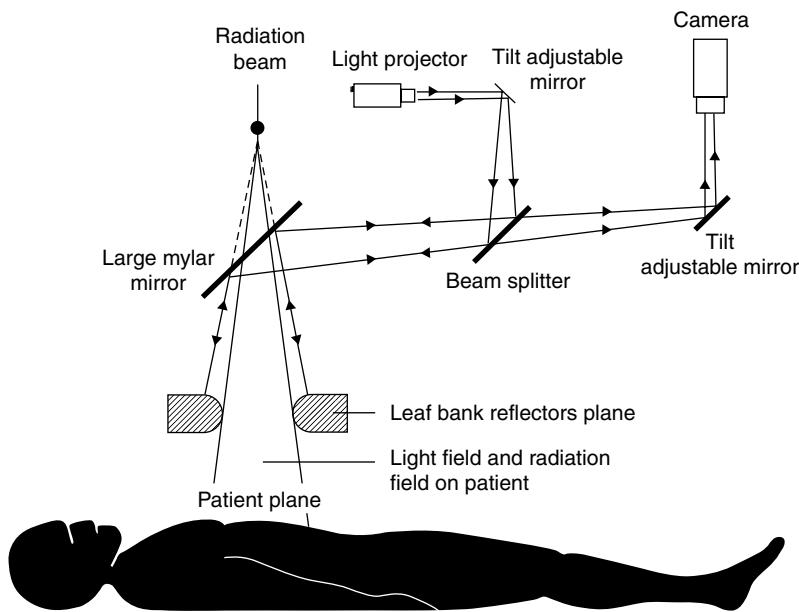

Field edge smoothing can be achieved by the superposition of multiple fields, each of whose centres are shifted slightly relative to the next (Galvin et al. 1996), and this is implemented commercially in the Siemens HD270 facility. An alternative method of smoothing is to superimpose multiple fields rotated about the collimator axis. Superposition techniques provide smoothing, but not increased resolution; they are severely limited in cases where it is necessary to shape a field with features smaller than 1 cm in the direction normal to that of leaf movement. A further disadvantage is that movement of the patient between fields increases the complexity of verification compared to that required for treatment with a single field.

Improved resolution can be achieved by the use of MLCs with narrower leaves. These are generally tertiary collimators mounted as accessories below standard collimators

**TABLE 11.2**

Elekta MLC Transmission at 20 MV (X and Y as defined in [Figure 11.21](#))

Collimator Section	Transmission
Leaves (X direction)	2% (mean)
Gaps between leaves	4.3% (max)
Y jaw	0.5%
X jaw (back-up)	12%

**FIGURE 11.26**

The optical system for measurement of leaf position for the Elekta MLC.

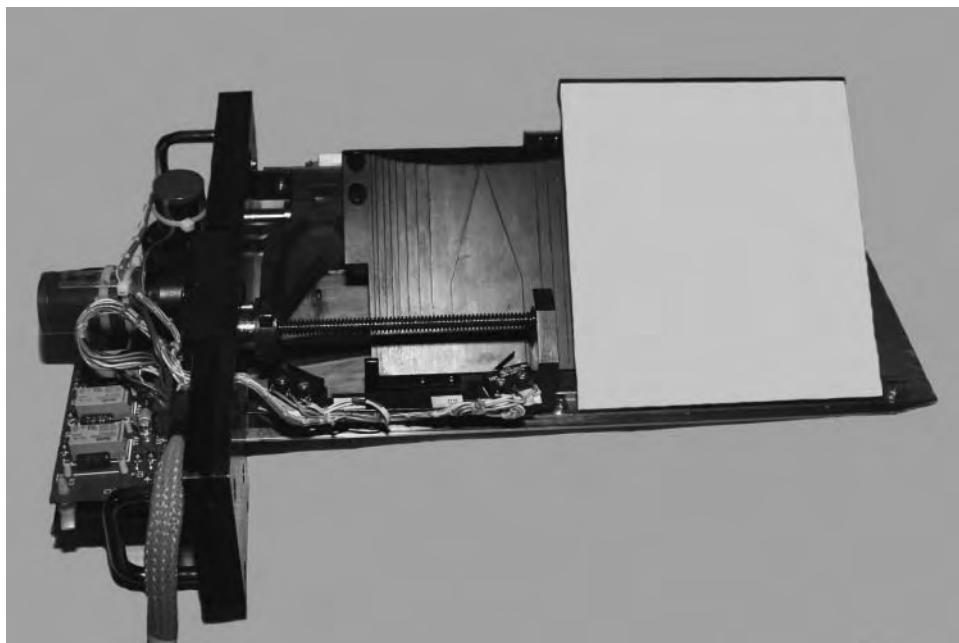

(or below conventional MLCs that replace the standard collimator). The geometric features of four such MLCs are listed in Table 11.3.

The number of leaves and leaf width determine the maximum field size, which in all cases is much smaller than for a conventional MLC. This has been justified if the main application is in stereotactic radiosurgery where it has been estimated that 95% of cases can be treated within the range of field size from 1 to 6 cm (Schlegel et al. 1997). In other applications, if precise shielding of a critical structure adjacent to the periphery of a large field or to a field that is significantly offset relative to the central axis is desired, these devices will have limitations. If they are to be used to provide precisely defined boosts to fields larger than the maximum covered by the mMLC, it would be necessary to attach the mMLC to the treatment machine between delivery of the main and boost fields to the patient. This would not be practicable in day-to-day use.

**TABLE 11.3**

Parameters of Mini and Micro MLCs not Integrated into the Treatment Head

	MRC (now Siemens)	MRC (now Siemens)	BrainLAB m3	Radionics	3D Line (IBA- Wellhöfer)

#### 11.4.4 BEAM MODIFIERS

##### 11.4.4.1 *Mechanical Fixed or Motorized Wedge Filters*

As discussed in [Section 33.3.3](#), there are frequent occasions when, instead of a uniform intensity across the beam profile, a wedge-shaped intensity profile is required. *Traditional wedge filters* are simply wedge-shaped pieces of brass, aluminium, or lead that are placed in front of the collimators. This simple design is still an option offered with Varian and Siemens accelerators. Filters of different maximum thickness are used to provide different wedge angles; commonly, angles of 15°, 30°, 45°, and 60° are provided. These wedges are mounted below the collimator assembly. Philips (now Elekta) and CGR/GE have introduced the concept of the *automatic* (or *motorized*) wedge. This is mounted inside the head ([Figure 11.19](#)) and is automatically moved into the beam for part of the treatment. Figure 11.27 shows a picture of an automatic wedge. By adjusting the proportion of the treatment for which the wedge is inserted into the beam, the effective wedge angle can be adjusted. Some authors have published formulae for calculating the wedge angle (Petti and Siddon 1985; Zwicker et al. 1985), but it is probably not necessary to precisely know the angle. Design and dosimetry considerations for mechanical wedge filters are discussed in [Section 22.6.1](#).

##### 11.4.4.2 *Dynamic Wedges*

The *automatic* wedge has the potential disadvantage that it increases the distance between the source and the front face of the accelerator head. This is a particular disadvantage for machines that use either an in-line accelerator tube or a 270° bending system. Because of the inconvenience of having to enter the treatment room to insert a manual wedge, there was a need to provide some form of automation without decreasing the clearance between the machine and the patient. Varian was the first to solve this problem by developing the *dynamic* or *flying* wedge

(Leavitt et al. 1990) that is now available from other manufacturers as well. To achieve a wedged beam profile, one of the jaws is kept stationary, and the other is moved during the treatment. This technique is potentially more flexible than fixed wedges because, in principle, it is possible to design any shape of beam profile that is required, but it is most often limited to one jaw pair because of the requirement for the jaw (or leaf) to cross the central axis of the beam.

#### 11.4.4.3 Accessory Holders

Also mounted beneath the treatment head is an accessory holder. This can be used to add a *shielding tray* where lead or low melting point alloy blocks or a tissue compensating filter can be placed. The accessories should be linked to the treatment machine verification system so that confirmation is provided that the correct accessory is being used (see [Chapter 41](#)).

### 11.4.5 ELECTRON BEAM GENERATION

#### 11.4.5.1 The Initial Beam

For clinical electron beam production, the x-ray target and flattening filter are withdrawn, under interlock control, and the accelerated electron beam emerges from the vacuum system through a thin metal vacuum window. This is typically chosen to be a lower atomic number material and is designed to produce minimal scatter and bremsstrahlung. The exiting beam is narrow, typically a few mm in diameter, and is essentially Gaussian in profile.

The narrow pencil electron beam is not suitable for clinical use as reasonably uniform distributions are required over fields of up to 25 cm×25 cm. Two methods are used to produce this, either *scattering foils* or *scanned beams*.

#### 11.4.5.2 Scattering Foil Systems

Most linear accelerator designs use *scattering foils* to widen the beam. In this case, thin foils of higher atomic number metals are placed in the beam, usually positioned on the same interlocked slide or carousel system that also carries the x-ray beam flattening filter. The foil thicknesses are chosen to be a compromise between being thick enough to produce acceptable levels of electron scattering while being thin enough to ensure that energy loss and additional bremsstrahlung contamination of the beam are not too high. As this balance of electron interactions is energy-dependent, each electron energy requires its own foil, although, in practice, this is not always the case. The electron distribution produced across the field from a single foil is generally not flat; rather, it is a significantly-widened Gaussian distribution. The clinical beam flatness is then improved towards the beam edges by making use of in-scattered electrons from the sides of applicators to increase the electron fluence. This can be adjusted by changing the x-ray collimator positions, and the optimum settings can be selected and pre-programmed in for each electron-energy/applicator size combination. Most scattering foil designs are based on a *dual-foil system* with two sets of foils a few cm apart. The first is a uniform thickness higher atomic number foil as in the single foil design. It is followed by the secondary foil that is a roughly cone-shaped stack of lower atomic number foils. This produces a better balance of effects and can give a flatter beam across the required width. The in-scatter required from the applicator is then less. Scattering foil systems have the advantage that they are simpler and safer in use than the alternative. However, they produce more energy loss for a given spectrum beam and larger bremsstrahlung contamination of the beam.

#### 11.4.5.3 Scanned Beam Systems

The alternative to produce the clinically required beam is to scan the pencil electron beam across the field in a *raster* pattern using a magnet system controllable in two orthogonal

directions. Various patterns are used to produce uniform coverage. The spatial resolution requirement does not need to be too demanding as the pencil beam widens in travelling through intervening material such as the dose-monitoring chamber and the air. To produce a uniform distribution along the raster path and, therefore, across the field, the raster line frequencies should be low (typically around a few Hz) compared to the pulse repetition rate of the accelerator (typically tens to hundreds of Hz). Scanned beam systems produce cleaner beams with less bremsstrahlung contamination and narrower spectra. This results in rather deeper therapeutic ranges and steeper gradient depth-dose curves. However, they do not provide as much flexibility to get optimal field flatness, especially for lower energies, because at low energies the scanning system under-doses the outer part of the beam and this is more difficult to compensate than with a shaped scattering foil. Furthermore, the system is significantly more complex than scattering foils, and it has the potential for malfunction, posing a safety concern. In addition, the high local beam intensities over short periods while the pencil scans near any particular point mean that ionisation chamber dosimetry requires significantly higher recombination corrections. Scanning systems are not favoured on recent linacs.

#### 11.4.5.4 Applicators

As electron scatter is so significant, applicators are necessary to delineate the field sharply close to the patient. In addition, the applicator is designed to help to achieve a flat beam over the required widths as discussed above. Single scattering foil designs required applicators with an upper section of solid wall to provide in-scatter. However, this requirement is less stringent in modern designs, typically resulting in lighter more open applicators and an example of which is shown in [Figure 11.28](#).

The lower sections are made up of successive collimation layers that absorb electrons that would scatter out of the field. The final layer that defines the field size typically lies at between 0 and 5 cm from the patient surface. *Applicators* are constructed of low Z materials (e.g. aluminium, plastic, etc.) to minimise x-ray contamination. They are generally supplied as a set of squares, circles, and rectangles that attach and are interlocked to the accelerator via the accessory plate. As noted above, each applicator for each specific energy will have pre-set x-ray collimator positions assigned to it that should be automatically safety checked as part of the modality verification. A frame is generally provided near to or at the final section, into which irregular or non-standard size *cut-outs* can be positioned for tertiary field shaping.

Some manufacturers offer *continuously variable electron trimmers* that attach to the head and provide more flexibility in varying field shape with a reduced need for cut-outs.

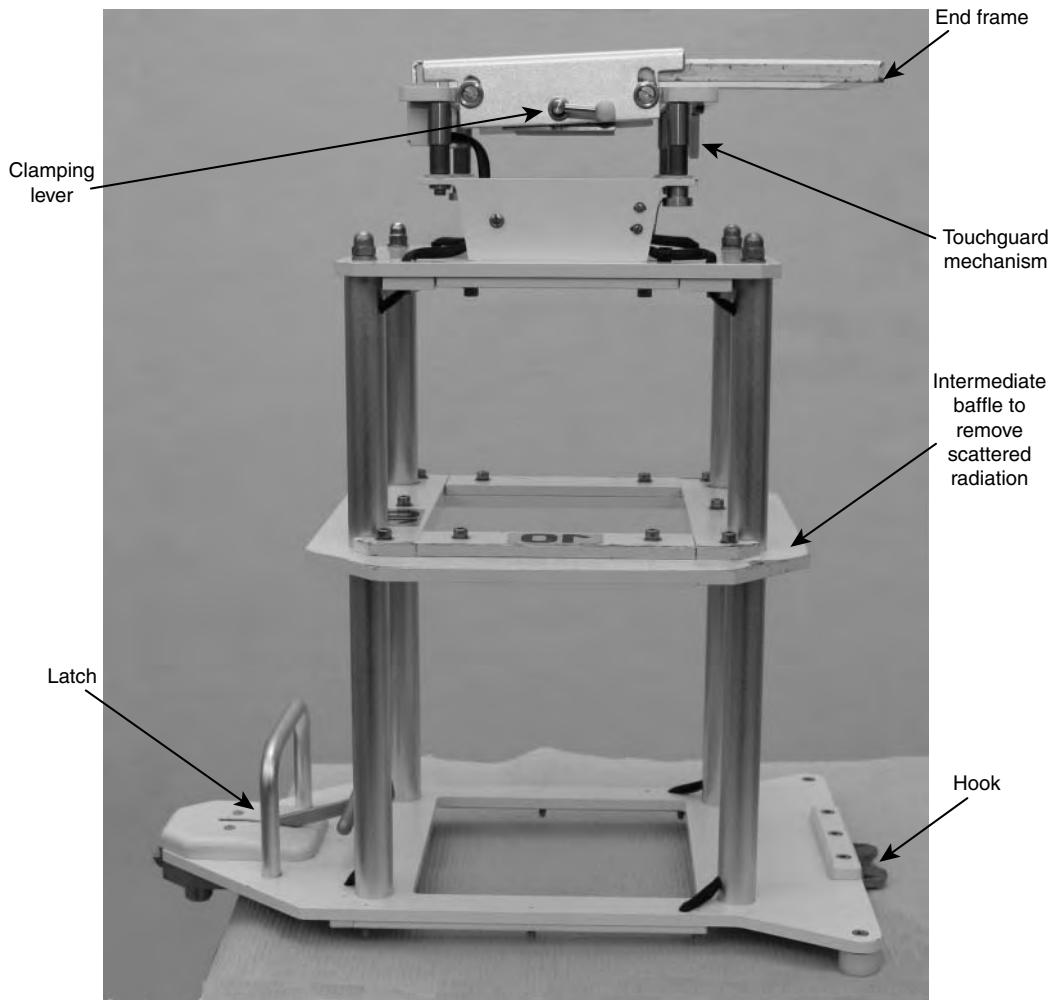

---

## 11.5 THE GANTRY

To allow patients to be treated with beams from different directions, there is a need to be able to rotate the treatment head through 360° about the patient. The accelerator waveguide and the head assembly must be mounted on a *gantry* that enables the beam to be rotated around the patient. There are two distinct mechanisms for supporting linear accelerators now being used: the *drive stand* and the *drum gantry* supports.

#### 11.5.1 DRIVE STAND GANTRY SUPPORT

The *drive stand* ([Figure 11.29](#)) is popular with all manufacturers for low energy machines and at high energy for those using standing-wave accelerator guides. Here, an upright stand is bolted to a base frame embedded in the floor to which is attached an “L” shaped support via a

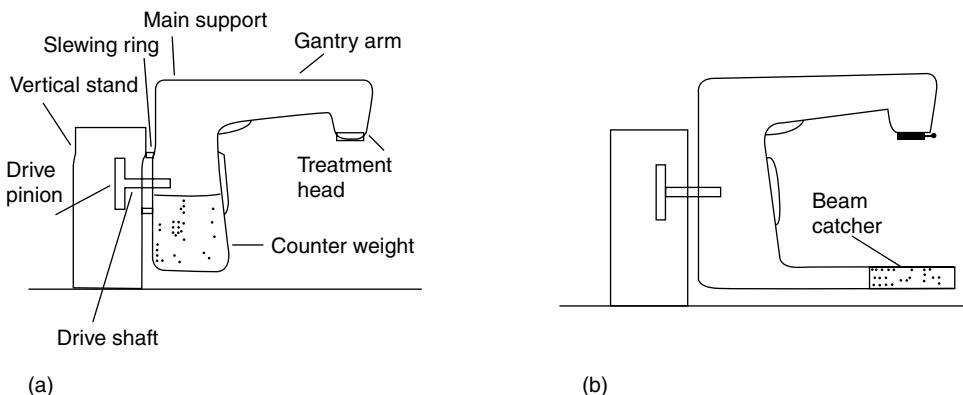

**FIGURE 11.28**  
Open applicator (Elekta) suitable for a dual scattering foil system.

massive thrust bearing. It is usual to add weights to this support to counterbalance the mass of the waveguide and treatment head about the rotation axis. In some cases, this can be extended forward to act as a primary beam stop for use in rooms where there is a radiation shielding problem. The main attraction of the drive stand support is its compactness, and in recent years, much design effort has gone toward space reduction, enabling some manufacturers to avoid the need to have a separate modulator enclosure.

### 11.5.2 DRUM GANTRY SUPPORT

Manufacturers using high-energy travelling wave guides favour the *drum gantry mounting* (Figure 11.30). The guide length would otherwise require an excessively long gantry arm and place unacceptable out-of-plane loads on the central thrust bearings. With a drum mounting, the gantry arm can extend through on both sides of the support structure, allowing only enough overhang on the patient's side to cover at least half the length of the longest patient. Further, the counterbalancing load can be placed towards the rear of the drum and reduce the tipping out-of-plane moment as well. It is common with drum systems to have only the gantry

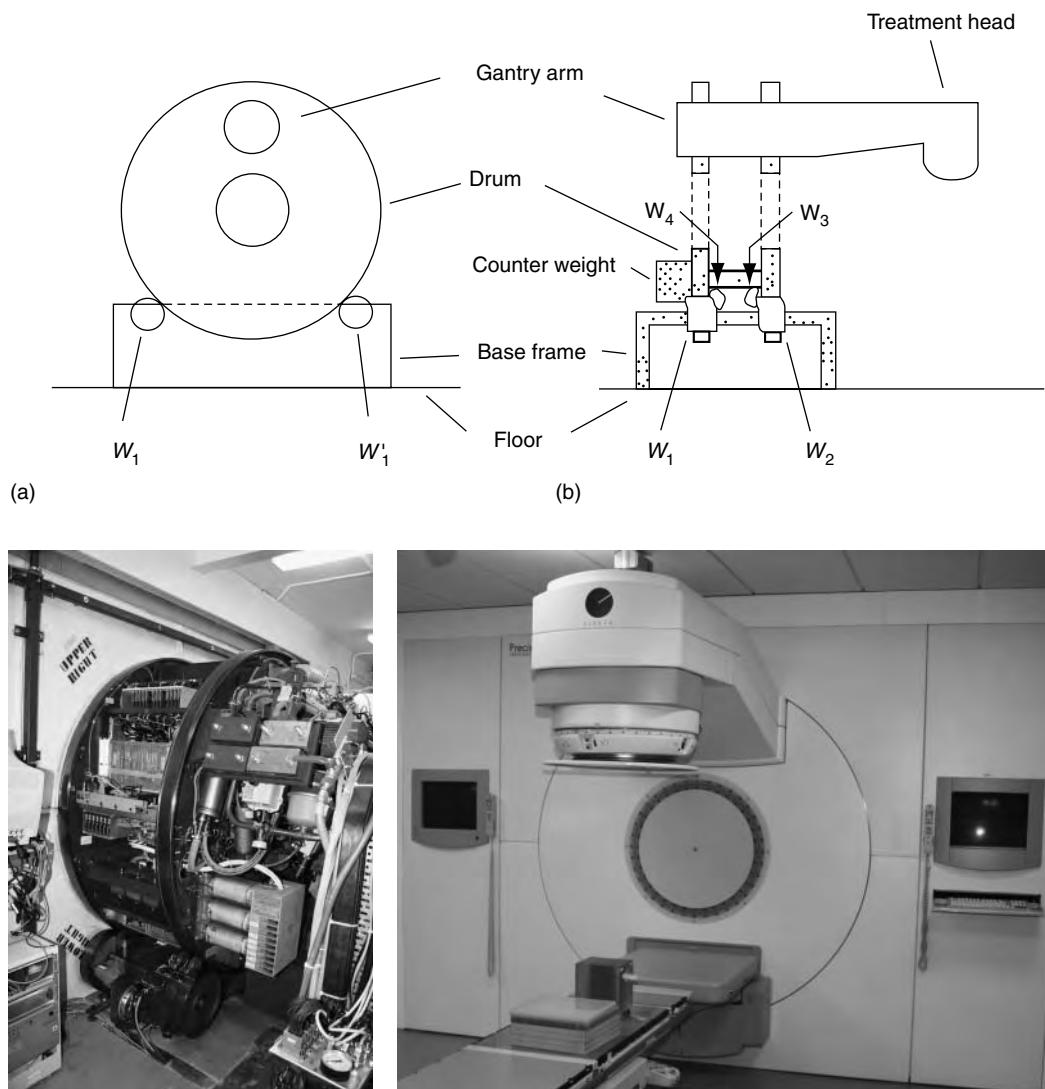

**FIGURE 11.29**

Drive stand gantry. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.) The counterweight can either be built into the base of the gantry as in (a), or a beam catcher can be used. The picture shows a Varian 2100C (without beam catcher) without its covers. The klystron can be seen at the extreme left of the picture.

arm on view protruding out of the surface of a wall panel. This allows the working components to be left exposed (behind safety interlocked doors in the panel) that greatly facilitates access for servicing.

### 11.5.3 THE ISOCENTRE

The intercept between the beam central axis and the gantry rotation axis (also the collimator and couch rotation axes) defines the isocentre of a linac, which should ideally be a fixed point in space. A typical dual energy accelerator weighs nearly ten tons with more than one ton in the gantry arm. In addition, to allow treatments to any part of an adult's anatomy, longitudinal access space between the isocentre and the vertical gantry structure needs to be in excess of 110 cm. This results in a large out-of-plane torque that is exaggerated further by the mass of the bending chamber, head shielding, and collimator. The engineering problems are therefore considerable. In general, the centre of rotation will not be a single point, but the locus of the centre of rotation will be contained within a sphere whose diameter defines the size of the isocentre. For geometrically accurate treatments, there is a need to obtain tight isocentre

**FIGURE 11.30**

Drum gantry. Diagram (a) shows a section normal to the rotation axis, and (b) shows a section through the axis and the beam arm. The picture on the left shows the drum mounting from the rear. The picture on the right shows the accelerator as seen from the treatment room. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.)

tolerances. Some manufacturers have recently relaxed their specifications in machines for general use, but most can be set up with isocentric error surfaces having radii less than 1 mm.

#### 11.5.3.1 Isocentre Distance, Isocentre Clearance and Isocentre Height

All current linac manufacturers employ 100 cm for their *isocentre distance* (i.e. the distance from the isocentre to the x-ray target). The *isocentre clearance* is the actual space available for the patient (i.e. the distance between the isocentre and the treatment head covers or accessory tray position). The *isocentre height* is simply the height of the isocentre above the floor. It is this last item that features rather large in accelerator sales information. Here it is argued (albeit correctly) that a high isocentre will force the treatment staff to use ladders or stools in order to carefully set the patient up (unless the staff are tall), costing time and fatigue.

To see what options are available to the designer, three combinations of accelerator and bending system will be considered:

- (i) *A Low Energy Straight-Through Guide.* The benefits of the compact side cavity standing waveguide, requiring no bending or beam steering elements, have already been described. Below the target, as with all machines, there must be a flattening filter, a dose-monitoring ion chamber, and collimation jaws. In practice, the only significant compaction available here is in the choice of wedge system: choosing dynamic jaw closure over mechanical wedges will save 5 cm height. However, at a gantry angle of 180° (undercouch), the balance of the overall guide length must be accounted for. Varian offers a retractable floor pit option that automatically operates when the gantry is within  $\pm 30^\circ$  of 180°. This enables the isocentre to be kept moderately low for such a system: 133 cm for a 6 MV guide.
- (ii) *A High Energy Standing Waveguide with a 270° Bend Magnet.* Above 6 MeV, it is no longer practical to use a straight-through guide mounting. Here, it is the vertical bulk of the various *Pretzel*\* bending magnets and the larger transverse dimensions of the standing waveguide and solenoid focus coils that the designers must contend with. In an earlier design, AECL chose to employ in-line cavities in their larger standing waveguides, and these, though longer, were correspondingly narrower than side cavity guides and had their isocentre heights reduced down to 131 cm. Other improvements can be made in the balance between isocentre height and clearance by careful positioning of the target in relation to the bending chamber. Varian mounts its x-ray targets within their large evacuated bending chamber at a position above the waveguide axis and achieves a 129 cm isocentre height as a result.
- (iii) *A Travelling Waveguide Using 112.5° Slalom Magnets.* Characteristic of the travelling waveguide is the reduced demand on beam focussing and narrower guide dimensions. If coupled with a vertically compact bending system, this combination should result in the lowest isocentre machines. At present, only Elekta produces high-energy machines of this type and can offer 125 cm isocentre heights. In principle, this could be further reduced if dynamic jaw closure was used instead of mechanical wedging.

#### 11.5.4 STANDARD COORDINATE SYSTEMS

The IEC has defined the way in which the machine coordinates should be specified (IEC 1996). The details of this coordinate system are shown in [Figure 11.31](#).

Not all machines (or even planning equipment) conform to this standard which can be problematic for networked departments (see [Chapter 41](#) and [Chapter 42](#)). A common variant is the previous standard (IEC 601) where the couch rotation is reversed, and the X and Y jaws are differently labelled.

---

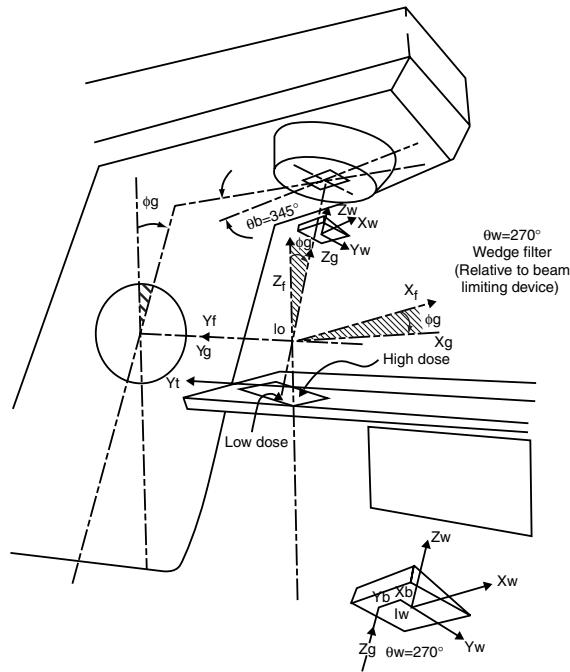

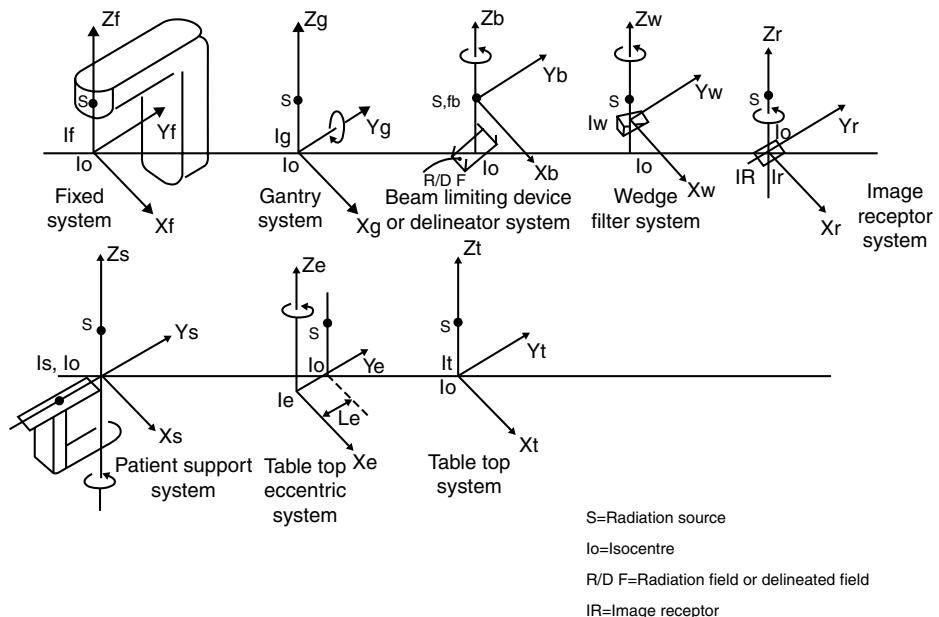

## 11.6 ANCILLARY EQUIPMENT

### 11.6.1 VACUUM SYSTEM

For clinical use, modern accelerators are expected to have a high up-time (i.e. they must rarely fail). Manufacturers now quote up-time figures as high as 98% on their new machines. One of the most important reasons for this is the systems' ability to provide a good vacuum. Typical vacuum levels of  $10^{-7}$  torr are used (1 torr = 1 mm Hg = 133.3 Pa, 1 atm = 760 torr). This is to avoid arc discharges in any residual gas when exposed to high transient electric fields. This is particularly important in the accelerating waveguide where the phenomena of

---

\* The electron trajectory, through typical 270° bend chambers, resembles that of the savoury Pretzel; hence, the name is often taken in describing such systems.

**FIGURE 11.31**

Coordinate system specified by IEC 1217. (From International Electrotechnical Commission, *IEC Publication 1217*, IEC, Geneva, 1996.)

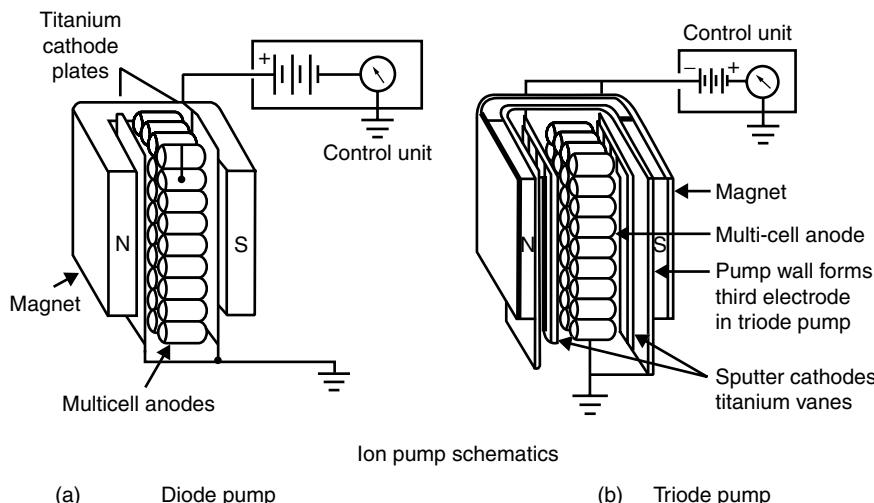

multipacting may occur. This is where collisions of electrons with the guide wall are multiplied in intense field regions. When a scattered electron impacts the guide wall or iris, secondary emission electrons are liberated. These may then be swept up in localised field vortices and continue to impact the guide wall. An avalanche situation soon occurs and can lead to serious damage if ignored.

The minimum requirement of a vacuum system for a linac is that the accelerated electrons should not be deflected by collisions with gas molecules. Alternatively, the mean-free path between collisions needs to be long compared to the overall flight path. This distance is typically between 1 m and 3 m. The corresponding vacuum to satisfy this condition is roughly  $10^{-5}$  torr. Early accelerators operated at these levels with the vacuum being provided by *oil diffusion pumps*.

### 11.6.1.1 Ion Pumps

The development of improved *ion pumps* was necessary to allow accelerators to be operated at higher r.f. field strengths and to increase gun (cathode) life. Figure 11.32 shows both *diode* and *triode* type ion pumps. Strong external permanent magnets (0.1 tesla to 0.3 tesla) and a cathode voltage of 5 kV are applied. Electrons caught in perpendicular electric and magnetic fields spiral toward the anode, increasing their path and chance of ionising gas atoms. This makes it possible to run a self-sustaining discharge at low pressures. Ionised atoms reaching the cathode liberate further electrons and keep the discharge going. Titanium is used for the cathode which sputters readily when bombarded by ions. Sputtered titanium atoms are deposited on the pump walls. Gas atoms striking the sputtered layer are adsorbed onto its surface and are subsequently buried in the next layer. The anode in the triode pump is held at the same potential as the wall, allowing the wall to collect low energy ions unable to sputter at the cathode. Clearly, an ion pump's life is determined by the consumption of the cathode material, typically 5000 h at  $10^{-5}$  torr and 50 000 h at  $10^{-6}$  torr.

Modern dual energy accelerators often employ three separate ion pumps: a large capacity (20 L/s) triode pump for the body of the waveguide and a smaller (2 L/s to 5 L/s) diode pump for the gun region. A third, usually a diode pump, is used to provide the vacuum for the klystron.

**FIGURE 11.32**

Ion pump schematics (a) shows a diode pump and (b) a triode pump. (Reproduced by permission of Varian Medical Systems.)

## 11.6.2 CIRCULATING WATER SUPPLIES

As already discussed, many accelerator components need cooling to shed heat, including the solenoidal focus coils, the waveguide, and the x-ray target. In addition, many of these components need the temperature to be maintained at a steady level. Linac *chiller* supplies circulate cooling water in a closed circuit through all the main components and return it to the secondary coils of a large *heat exchanger*. Flow rates at different points need to be carefully regulated to ensure a stable working system and can usually maintain temperatures to within 5°C.

# 11.7 THE LINAC CONTROL SYSTEMS

In order to deliver a stable radiation beam, *control circuits* are required. Beam characteristics are affected, among other things, by gantry angle, cooling water temperature, and ambient temperature as well as by long term changes such as component aging. Consequently, systems must exist both to correct for changes and to monitor errors. For multienergy machines, there are the safety issues of ensuring that the desired energy and modality is being delivered.

## 11.7.1 AUTOMATIC FREQUENCY CONTROL

*Automatic frequency control* (AFC) is employed in all linacs to keep them operating at their intended frequencies. In magnetron-powered systems, frequency changes may be necessary to correct for expansion effects at the anode where large amounts of heat are produced. Also, in gantry-mounted versions, different orientations in the earth's magnetic field will give rise to small frequency perturbing effects. Stability to a few MHz is needed, and this is provided via the AFC. In its simplest form, a *phase comparator* monitors the forward and reflected r.f. power and drives the *magnetron tuning plunger* to compensate. Traditionally, the tuning plunger has been driven by a rotary drive. A recent innovation is the so-called fast tuning magnetron where the tuning plunger is driven by a solenoid, allowing very rapid changes of frequency with consequent improvements in beam startup characteristics.

Frequency variations in klystron machines are more likely to result from guide temperature changes, and here, it is the frequency of the r.f. driver output that is adjusted to compensate.

## 11.7.2 ENERGY SELECTION AND CONTROL

The energy of the accelerated electrons is determined by the *r.f. power and phase* and by the *electron beam current*. How the energy is changed will depend on the accelerator system in use.

### 11.7.2.1 Magnetron Driven Travelling Wave Systems

For dual-x-ray use where the beam current needs to be high, energy selection is achieved by varying the *microwave power* supplied to the accelerating guide. Long cathode magnetrons with electromagnets allow both the magnetic field and the size of the HT pulse to be changed. As a result, outputs at 2.5 MW and 5.0 MW peak power are achievable. Low- or high-power operation is selected at the console, and different tappings are made on a high voltage transformer that feeds the *pulse forming network* discussed earlier.

High energy machines often provide the option to employ electron beams directly for treatment. Here, the beam currents are at least two orders of magnitude lower than for x-ray modes, and small *frequency adjustments* of the magnetron are sufficient to change the electron energy. A phase shifter, together with the AFC (see [Section 11.7.1](#)), maintains the frequency precision necessary.

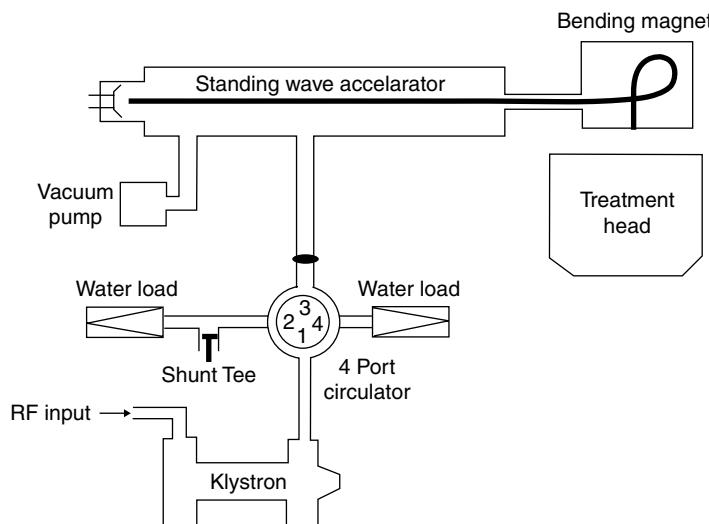

### 11.7.2.2 Klystron Driven Standing Wave Systems

In klystron-driven systems, energy selection is also initiated by selecting high- or low-power modes in the modulator. This applies either 100 kV or 130 kV pulses to the klystron (compared to 40 kV or 50 kV pulses to a magnetron). These smaller pulse differences reflect the standing waveguide's inability to cope with the possible doubling of peak power levels that travelling waveguides can tolerate. Instead, extra measures must be taken to allow dual-x-ray operation. Figure 11.33 shows the main microwave power components of a standing wave machine. The output power pulse from the klystron is fed via a *directional coupler* (this prevents serious reflections getting back that could damage the klystron) to a *four port circulator*. This, in turn, directs r.f. power to the *shunt Tee assembly* that dumps a preset portion into a *water load* (port 2) where it is absorbed. The remaining r.f. then passes through a *rotary joint* that links the fixed klystron to the moveable gantry that houses the accelerating guide. The circulator also directs any reflected r.f. power from the accelerator to another water load (port 4).

Additionally (not shown), an *energy switch*, mounted in the accelerating guide, is inserted when the low energy mode is activated. This introduces a dielectric strip that changes the phase of the r.f. beam in the downstream portion of the guide, rendering it non-accelerating. In essence, for lower energy applications, these measures collectively allow the system to run at less than the optimum power levels for which the machine had been designed.

### 11.7.2.3 Energy Monitoring

As mentioned in [Section 11.3.6](#), the path travelled by electrons within the bending system is precisely dependent on their energy. In 90° bending systems, the bending magnet current is an accurate measure of the energy, but in achromatic systems, it is necessary to insert *energy detecting slits* into the bending chamber. These offer the possibility to monitor the energy and to improve the electron spectrum because the electrons that do not have the proper energy are removed from the useful beam. However, there is the risk that large intensities would strike the slits and cause damage. An alternative method is to use the fact that the ratio between the dose at the centre and the periphery of a photon beam is energy dependent. This ratio can be measured by the transmission dose monitoring ionisation chamber. This so-called *hump detector* is then used to control the energy.

**FIGURE 11.33**

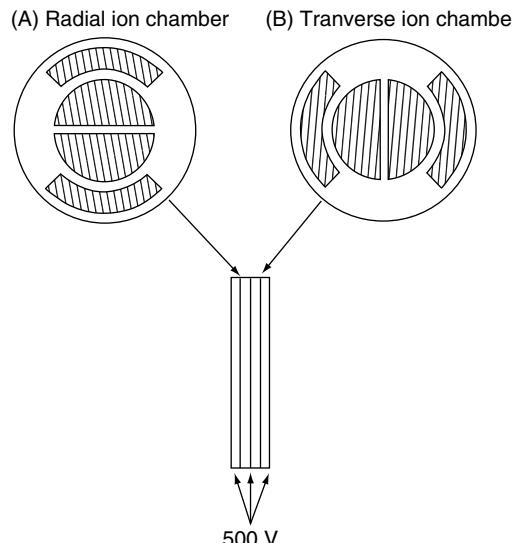

Microwave circuit for a high-energy klystron powered machine. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.)

### 11.7.3 CONTROL OF TOTAL DOSE, DOSE RATE, BEAM POSITION AND UNIFORMITY

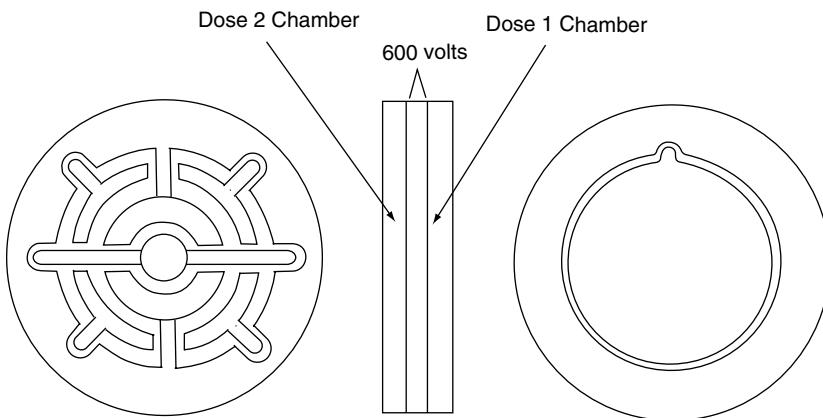

As explained briefly in [Section 11.4](#) and shown on [Figure 11.19](#) and [Figure 11.22](#), a *transmission ionisation chamber* (also called *dose-monitoring chamber* or simply *monitor*) is always present in the head of a linear accelerator. It is placed as close to the patient as possible but for practical reasons it is fixed and therefore located just above the rotating collimator assembly. It is designed to perform a number of different functions, aiming at delivering a precise, uniform radiation dose and at the correct energy. In use, the following are required:

- Monitoring and control of dose delivery whether in x-ray or electron beam mode
- Dose rate monitoring with rapid servo compensation
- Beam uniformity or symmetry and flatness monitoring also with dynamic correction
- Automatic treatment termination control if any of the above should lie outside acceptable tolerances.

[Figure 11.34](#) shows the internal structure of a typical parallel plate linac monitor chamber. It consists of two *collector plates*, each divided into zones sandwiched between three uniform *field plates*. Notice that this creates two separate ion chambers mounted back to back, and it ensures that there is dual dosimetry operation for safety reasons. The lateral view that shows the plate stack has been expanded for clarity. To avoid sensitivity changes resulting from fluctuations in temperature and pressure, these chambers may be sealed. If they are not sealed, it is necessary to monitor the temperature and pressure of the chamber and to make appropriate corrections. Because of the pulsed nature of linac beams, high field strengths must be used to ensure operation under saturation conditions. Plate gaps of the order of 1 mm with polarising voltages of 500 V are sufficient and nearly a factor of two below dielectric breakdown levels. The chambers need to be wide enough to straddle the entire beam and are usually positioned immediately below the x-ray flattening filter. This is to reduce the diameter necessary and to be beyond the last beam perturbing element. As these devices are in-line monitors, they need to attenuate the beam as little as possible; therefore, a further requirement is that they should be thin and use low atomic number materials for their entry and exit windows.

**FIGURE 11.34**  
Typical multiplate ion chamber.

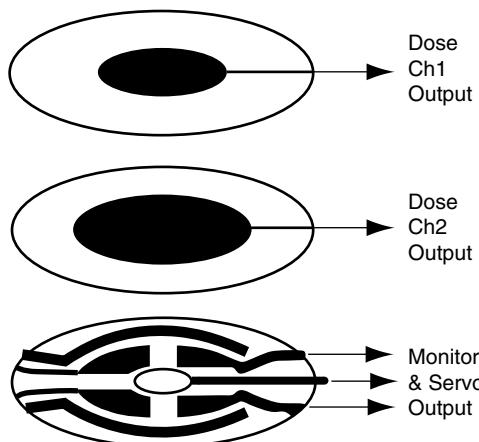

**FIGURE 11.35**

Alternative ion chamber plate configuration. (Reproduced by permission of Siemens Medical Engineering.)

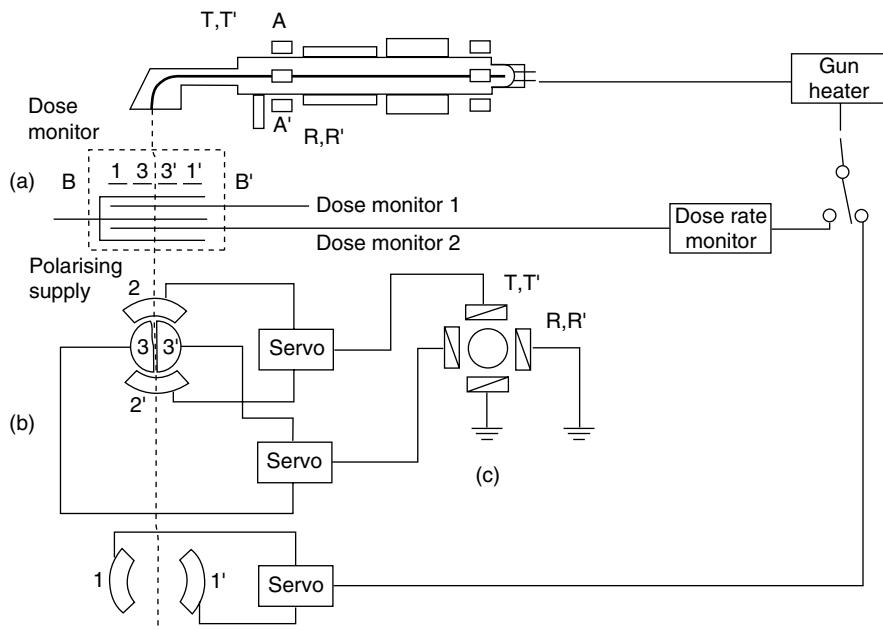

Different manufacturers employ different collector plate configurations as shown in Figure 11.35 and Figure 11.36 which are examples of designs employed by Siemens and Elekta respectively. Clearly, the more structured or zoned the design, the more possibilities there are for monitoring beam flatness, etc. Two functionally distinct areas are important and are considered in the next two sections.

### 11.7.3.1 Dose Monitoring

With the beam on, the collector current in both chambers should be related to the actual dose rate being delivered to the patient. However, it is only possible to calibrate the chamber for one particular set of circumstances at a given position in the treatment beam (typically that at 100 cm for an unwedged 10 cm × 10 cm field at the depth of maximum depth-dose). The integrated current will, in principle, give a *measure of actual dose* delivered under these standard conditions. The integrated current associated with 1 cGy in the standard conditions is defined as one Monitor Unit (MU), (see [Section 20.1.2](#)) At the operating console, the number of monitor units required to deliver a treatment dose is set and the integrated current signal from the primary dosimetry channel is used to terminate

**FIGURE 11.36**

Design of ion chamber used by Elekta. Note the different size of the plates for the two dose channels. (Reproduced by permission of Elekta Oncolgy Systems.)

**FIGURE 11.37**

Dose monitoring and control system showing the dose-rate, beam-uniformity and beam-symmetry feedback controls achieved from the different zones of the monitor chambers. (From Greene, D. and Williams, P. C., *Linear Accelerators for Radiation Therapy*, Institute of Physics, Bristol, 1997. With permission.)

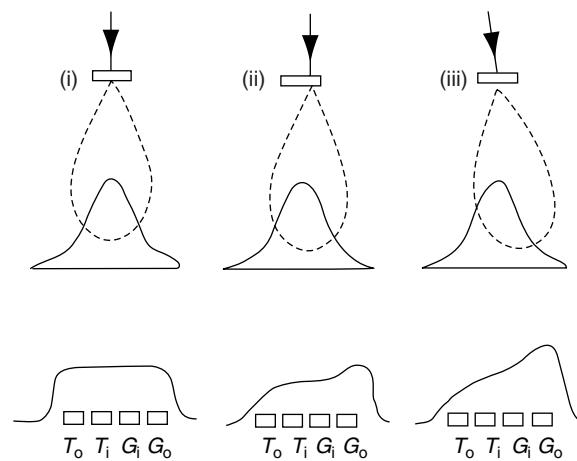

the beam delivery. The second dosimetry channel is typically allowed to over-run by a small percentage before it too would terminate the beam in the event that the primary channel should fail. With the design of Figure 11.36, the two dosimetry plates are sampling different parts of the beam so that a dose channel difference may be related to a change in beam energy rather than to a change in the calibration of the monitor ion chamber. Figure 11.37, shows how the signal from the dose monitor can be used to ensure a *constant dose rate* through feedback control of the gun heater.

### 11.7.3.2 Beam Uniformity and Beam Position Monitoring

Figure 11.37 also shows the links from the zoned collector plate structure to beam position and angle control circuit elements. Figure 11.38 illustrates how the plate positions can monitor changes in electron beam centring and angulation from variations in x-ray field uniformity. A simple two dimensional arrangement of four plate zones for monitoring the radial beam direction is shown. The two inner zones are labelled  $G_i$  and  $T_i$  for the Gun and Target directions, and the two outer zones are labelled  $G_o$  and  $T_o$ .

- (i) Ideal conditions with the electron beam both centrally and vertically incident over the target. Here signals from  $G_i = T_i$  and  $G_o = T_o$
- (ii) The situation where, because of a steering error, the beam is no longer central. Here signals  $G_i = T_i$  but  $G_o > T_o$
- (iii) The case of an inclined beam most commonly found in the radial plane. Here  $G_i > T_i$  and  $G_o > T_o$ .

Imbalance in signals from any paired zones is a strong indicator of beam unflatness or asymmetry. Modern accelerator designs only allow very small excursions before interrupting a beam to ensure tight tolerances. Feedback signals can be sent to beam control elements, adjusting the currents in the radial (R) or transverse (T) steering coils to compensate

**FIGURE 11.38**

Segmented ion chamber response to 3 different beam conditions in the gun-target (i.e. *radial*) plane.

(Figure 11.37). Depending on the machine and operating conditions (i.e. energy, x-ray or electron mode) the feedback loop may be close or open. In the latter situation, any measurement out of the tolerance would immediately stop irradiation.

### 11.7.3.3 Dosimetry Interlocks

It is of fundamental importance that the correct dose is delivered to the patient, and a number of *interlocks* are used to ensure that this is the case. As previously mentioned, ionisation chambers are required to have two channels so that if one fails, the second will terminate treatment. The *accelerator control system* also monitors the difference between the two channels during treatment. It will interrupt treatment if the values exceed preset limits. Additionally, a *backup timer* is required that will terminate the beam after an elapsed time if the ionisation chambers have both failed. (The setting of this timer is usually transparent to the operator.) Ionisation chambers require a bias voltage to be applied, and an interlock circuit checks to ensure that this voltage is present with independent systems for both chambers.

## 12.1 INTRODUCTION

Teletherapy cobalt-60 units were first used for patient treatment in 1951 in Canada (Green and Errington 1952; Johns et al. 1952). Although megavoltage x-ray units had been available for some years prior to this date, they were not in widespread use, whereas, cobalt units became the mainstay of external beam therapy for the next 30 years or so world-wide.

Cobalt-60 is manufactured by irradiating cobalt-59 in a high neutron flux nuclear reactor. The main reasons for its suitability for teletherapy are the availability of relatively small, high specific activity, sources that minimise the beam penumbra (see [Section 22.3.3.1](#)); its relatively long half-life (5.27 years); and the almost monochromatic high-energy photon emission (photons of 1.173 MeV and 1.333 MeV in equal quantity).

Compared to modern linear accelerators, cobalt units offer poorer geometrical precision in treatment because of a larger penumbra and greater mechanical inaccuracy. Coupled with the fact that cobalt beams are less penetrating than those from linacs and that cobalt units lack the flexibility in the control of the radiation output offered by linacs, cobalt can no longer provide the basis for contemporary sophisticated radiation therapy. However, commercially available cobalt units may be quite adequate for many non-radical treatments, and there are even some applications where cobalt sources have been used in specially designed equipment to give a performance that could be argued to be superior to that obtainable from a conventional linac, for example stereotactic radiosurgery with the Elekta Gamma Knife (Leksell 1971; Walton et al. 1987; Lindquist 1995) and total body irradiation with custom-designed extended source skin distance (SSD) units (Leung et al. 1981 and see [Section 47.4.1](#)).

In countries where facilities for the maintenance of linear accelerators are lacking, cobalt-60 therapy may be the most appropriate choice for radiotherapy (IAEA 1998b). Many of the major techniques and advances in the physics of external beam therapy were developed on cobalt units including arc therapy (Jones et al. 1956); conformal therapy (Davy et al. 1975); transmission dosimetry (Fedoruk and Johns 1957); the development and measurement of tissue air ratios and the subsequent derivation of scatter air ratios (Gupta and Cunningham 1966); and differential SARs and the associated algorithms for treatment planning based on the separation of primary and secondary radiation. More recently, Poffenbarger and Podgorsak (1998) have investigated the possibility of using an isocentric unit for stereotactic radiosurgery, and Warrington and Adams (2001) have shown that conformal therapy, and even IMRT, could be adequately delivered with a cobalt-60 unit except for the most deep-seated tumours.

---

## 12.2 BASIC CONSTRUCTION AND FEATURES

A major advantage of cobalt units is the basic simplicity of their design and construction that generally makes them inherently reliable. Nevertheless, care must be taken to ensure that they are robustly built and carefully maintained to minimise the potential hazards from the high activity source and the associated heavy shielding. A sectional drawing of a modern cobalt unit treatment head is shown in [Figure 12.1](#).

As with any item of radiotherapy equipment, it is essential that the physicists responsible for its performance understand the way that the unit is constructed and operates so that they will be aware of its capabilities and limitations. This knowledge will also help them to appreciate what routine safety measures should be put in place and also the possible causes when there are malfunctions or the performance deteriorates.

### 12.2.1 THE SOURCE

The cobalt source usually consists of a series of either millimetre-size cylindrical pellets (Jaffray et al. 1991) or thin, metallic discs sealed within a double capsule of stainless steel and manufactured to meet certain standards regarding protection from impact, corrosion, and heat (BSI 1976; ISO 1999). Active source diameters are generally in the region of 15 mm to 20 mm, being a compromise between achieving a high enough activity to obtain a reasonable output and keeping the source small enough to minimise the beam penumbra. The source length may be longer than the diameter, but this is not such a critical dimension because the photons from the rear of the source contribute relatively less to the clinical beam than those from the front. In a typical source, about 25% of the primary photons are lost due to self-attenuation. The space

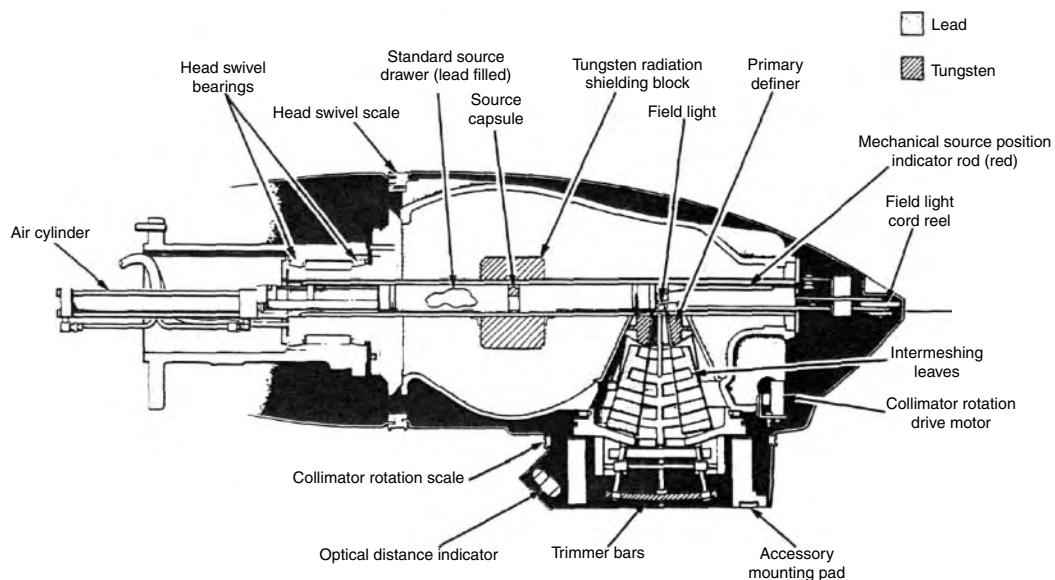

**FIGURE 12.1**

Diagram of the head of a Theratron 780 treatment unit showing the source drawer mechanism, collimator and shielding.

behind the active cobalt material in the capsule must be tightly packed with blank discs to eliminate movement. The low-energy  $\beta$ -ray emission from the source is filtered out by the capsule walls.

### 12.2.2 THE HEAD

The head of a cobalt unit has three basic functions: to shield the source, to expose the source as required, and to collimate the beam to the correct size. Shielding is achieved by surrounding the source and exposure mechanism with lead and, in many designs, with alloys of a higher density metal such as tungsten in order to reduce the volume. In some earlier designs, depleted uranium alloy (with a high percentage of U-238, density approximately  $19.0 \times 10^3 \text{ kg m}^{-3}$ ) was used, but this has been discontinued because of the problems with stability of the alloy as some of it became powdery and also because of the difficulties associated with eventual disposal.

The *source exposure mechanism* is usually one of two types where either the source is moved between a safe and exposed position (as shown in Figure 12.1) or where the source remains stationary, and a moving shutter opens or closes the beam. The latter solution, implemented on earlier machines is now obsolete. In the former solution, the source movement is either a translation (as in Figure 12.1) or a rotation. Various beam collimator designs exist to give variable rectangular fields with sides ranging in length, typically, from 4 cm to 30 cm or even up to 40 cm on isocentric units with a source axis distance (SAD) of 100 cm. Each of the four collimator leaves is usually focused on the edge of the source proximal to it so as to avoid cut-off of the primary beam and minimise penumbra. Distances from the source to the far edge of the collimators are typically between 40 cm and 50 cm for machines designed for 80 cm SSD, but this distance may be increased by *penumbra trimmers* that are particularly desirable when the machine is to be used for 100 cm SSD treatment.

With careful design of the collimation system and a 15 mm diameter source, a penumbra of no more than 10 mm (distance between the 20% and 80% decrement lines) may be achieved at 5 cm depth for field sizes with an area of less than  $400 \text{ cm}^2$ .

### 12.2.3 GANTRY

Modern cobalt units are manufactured in a standard *isocentric* configuration, with a source axis distance of 80 cm being the most common, to obtain a reasonable compromise between output, depth dose, and clearance around the patient. Units with an SAD of 100 cm are also practical if high activity sources can be afforded and offer the advantages of greater depth dose, larger field sizes, greater clearance around the patient, and geometrical compatibility with linacs. To increase their versatility, isocentric units have often been made with the ability to *swivel* the head about a horizontal axis through the source. This swivel motion keeps the beam axis in a vertical plane, and when used with an appropriate gantry angle, may be useful for extended SSD treatments or for treating immobile patients in a bed or chair. Some non-isocentric cobalt units have been manufactured with the head held by a *yoke on a vertical stand*, and these are particularly useful for giving single field palliative treatments. Where an isocentric unit has the swivel facility, great care must be taken to ensure that its position is accurately reset before the equipment is used for normal isocentric use since the slightest angulation of the head swivel will create a large deviation of the beam axis from the mechanical isocentre (see [Section 38.2.1](#)). Some isocentric units use slip rings for the supply of all power and control signals to the gantry and this allows continuous gantry rotation. Coupled with the guaranteed constant output from the source as the unit rotates, such a versatile and simple rotation mechanism provides an ideal unit for arc or full rotation therapy when this technique is required.

### 12.2.4 BEAM MODIFIERS

Although beam flattening filters can, in principle, be successfully used on cobalt units, they are rarely employed in practice because of the consequent reduction in output. Without a flattening filter, the beam homogeneity is relatively poor across a large area beam, especially at greater depths, because of scattering in the tissue and the greater distance from the source to the field edges compared to the centre for a constant depth. Users should be aware of this fact when using such fields, even for palliative applications, as the 90% decrement level will be much farther inside the beam than for a similar field on a linac.

*Fixed wedge filters* may be inserted into the beam below the end of the collimator to give a range of wedge angles, typically between 15° and 60°. These wedges will usually incorporate a certain amount of beam flattening, giving a somewhat straighter isodose curve within the central portion of the beam than for an open field. Wedge filters inevitably reduce the dose rate at the centre of the beam and this is more of a problem with a cobalt machine than with a linear accelerator. The reduction in output may be minimised by making the wedge shape always begin at the field edge by linking the toe end of the wedge to the collimator so that wedging always begins at the edge of the beam. With this system, the wedge factor will be different for each field size, so modern units usually have a fixed relationship between the centre of the wedge and the centre of the field with perhaps different wedges for different ranges of field size. In principle, there is no reason why a virtual wedge could not be created by dynamically moving one collimator during treatment in a similar fashion to that employed on linacs. Such a system has not yet been commercially produced and would probably require a different design for the collimators to allow them to travel across the beam axis, but it would have the advantage of minimising the increase in treatment time associated with the use of a wedge.

Other beam modifiers and accessories such as the *beam-defining light, range finder, accessory tray, laser positioning system, front and back pointers*, etc., will be very similar to those employed on linacs. However, on a cobalt-60 unit the beam-defining light may physically exchange places with the source as in [Figure 12.1](#).

## 12.3 SAFETY

Many of the safety features and requirements for cobalt units will be identical to those for other megavoltage machines, so only those items where cobalt requires special attention will be dealt with here.

The IEC have published specific requirements for the safety of  $\gamma$  beam units (IEC 1997). The control of the source and its exposure is paramount. Since the output of the beam is accurately predictable, a dose monitoring system is not required, and dose to the patient can be controlled simply by the exposure time alone. *Dual independent timers* are required to cover the possibility of one timer failing, and it is also required that the pre-selected time for irradiation remains on display for the duration of the exposure. Units in which the timer is set are normally min (and 1/100 min) rather than seconds. This must be clearly recognised since mixing-up minutes and seconds may be the origin of severe accidents (IAEA 1998b). It is also necessary to have a system that enables the operator to obtain the true exposure time, following a complete system failure, for example, after a mains power supply interruption, so that the dose received by the patient may be calculated. The source exposure system must be designed so that under all appropriate fault conditions, including mains power failure or any other major control system failure, the source exposure mechanism returns it to a safe state by an independent means (e.g. spring, compressed air, battery, etc.). In addition, a *manual system* must be provided to allow the unit to be restored to a safe state should the automatic system fail.

It is usual for one of the two timers to be arranged as the primary timer and for it to be activated by switches that sense when the source is in the fully exposed position and for the other, secondary timer to be activated by switches that sense when the source moves from or returns to the fully safe position. The difference between the two timers gives an accurate measure of the source or shutter transit time. This transit time should be regularly monitored to verify that the exposure mechanism is operating satisfactorily. Because of the finite transit time (typically 0.5 s to 2.0 s depending on the unit's design), it is necessary to measure a timer correction that must be applied to each treatment irradiation time to allow for the extra or, depending on the equipment type, occasionally reduced dose that would be given to the patient compared to what would be expected from the known dose rate and set time. The timer correction is most easily measured with a dose meter in the main beam using the dual exposure method (see [Section 38.8.4](#)). It is also a requirement that the total transition time from beam off, to on, and off again must not exceed a total of 5 s.

A *door interlock* mechanism must be provided and connected to the machine in such a way that (i) it is impossible to turn the beam on as long as the door is open, and (ii) if the beam is on, the source returns to the safe position as soon as the door opens.

The IEC standard requires that a *manual beam control system* is provided that directly operates on the source exposure mechanism that may be used in an emergency to return it to the beam-off condition. The status of the beam must be clearly indicated by *lights* on the head of the unit and by a mechanical system directly coupled to the exposure mechanism. An *audible warning* must also indicate when the source is not in the fully safe state.

It is essential that a robust interlock arrangement for wedge filters and, if used, flattening filters is provided. Once a filter has been chosen in the treatment room and inserted into the head, the type of filter must be re-confirmed at the external treatment control panel without the selected item's identity having been previously displayed. The orientation of any filter must also be clearly visible.

### 12.3.1 LEAKAGE

The IEC standard places limits on leakage radiation from the head both for *beam-on* and *beam-off* conditions. In the *beam-off condition*, the absorbed dose rate at one metre from the source must not exceed  $0.02 \text{ mGy h}^{-1}$ , and at a distance of 5 cm from the protective surface of

the head, must not exceed  $0.2 \text{ mGy h}^{-1}$ . These measurements may be averaged over areas of up to  $100 \text{ cm}^2$  and  $10 \text{ cm}^2$ , respectively and apply to a source of the maximum-rated activity. In some countries the  $0.02 \text{ mGy h}^{-1}$  figure is reduced to  $0.01 \text{ mGy h}^{-1}$ .

Leakage radiation *during irradiation* is measured with the collimator closed and any residual open area blocked by an attenuator thick enough to reduce penetration to below 1%. Leakage dose rates are measured at the standard treating distance and expressed as percentages of the dose rate at 5 mm depth for a  $10 \text{ cm} \times 10 \text{ cm}$  field at this distance. Within the area enclosed by the limits of the maximum field size, whose area is  $A \text{ cm}^2$ , the leakage dose rate for square fields (averaged over 8 points shielded by only one collimator and 4 points shielded by both) must be less than  $1000/A \%$  (e.g. 1% for a  $32 \text{ cm} \times 32 \text{ cm}$  maximum field) and individual collimators must not allow more than 2% transmission. Leakage outside the limits defined by the maximum field size in the plane of the patient (within a circle of radius 2 m) is limited to a maximum of 0.2% (average 0.1%) of the dose on the beam axis. Elsewhere, the leakage dose rate, measured at one metre from the source must not exceed 0.5% of the maximum dose rate measured at one metre. The latter figure also applies for all positions outside of the maximum field size during source or shutter transit.

### 12.3.2 AREA RADIATION MONITORS

The International Basic Safety Standards (IAEA 1996) recommend that an *independently operated radiation monitor* should be installed in the treatment room to give a clear indication that the source is in a safe position. A suitable monitor would normally have an adjustable threshold alarm level so that an audible and visual warning is given when the beam is on. Some centres will choose to install the monitor in such a way that when the barrier interlock is closed, the audible warning will be suppressed. Such a monitor should be powered from a separate mains supply from that used for the treatment unit plus a battery back-up. It is also advisable to keep in the vicinity of the treatment room, but not in it, a *portable radiation monitor* with ranges extending from approximately  $1 \text{ mSv h}^{-1}$  to at least  $1 \text{ Sv h}^{-1}$ \*.

*Personal electronic radiation monitors* that emit an audible indication of dose rate may be worn as an alternative (or preferably, in addition) to fixed monitors (IPEM 2001). It is desirable that such monitors should also record the cumulative dose received by the wearer so that a good estimate of any dose received in an emergency procedure can be quickly evaluated.

### 12.3.3 WIPE TESTS

It is also necessary to perform *wipe tests* on the equipment at least every two years to verify that there is no risk of contamination from a leaking source capsule. This test is most easily accomplished during a regular service of the unit when the covers are removed, and access to components such as the source mechanism and primary collimator may be achievable in order to wipe surfaces as close as possible to the source. If an activity of greater than 200 Bq is detected on the swab (IPEM 2001), the source should be considered as leaking, and steps should be taken to confirm the result followed by removal of the source and subsequent decontamination of the equipment.

### 12.3.4 LOCAL RULES

Local radiation safety rules must be written, and these must take into account the circumstances relating to each specific installation (see also Part L). For cobalt teletherapy units,

---

\* Sv stands for sievert. It represents the unit of *Equivalent Dose* used for radiation protection purposes (see Section 59.1.2). In practice, for  $\gamma$ -radiation,  $1 \text{ Sv} = 1 \text{ Gy}$ .

a clearly documented *procedure* must be produced for implementation in the event of an emergency arising from a failure of the source exposure mechanism to return the source to a safe state. If a patient is in the beam at the time, this will probably make it necessary for staff to enter the room to remove the patient without being exposed to unnecessary radiation. Prior to entering the room, any remotely controlled emergency beam-off mechanisms should be tried, and if possible, the collimator should be closed down to a minimum using controls that should be available outside the room for such an emergency. These procedures must be routinely rehearsed so that the staff know exactly what to do when required. It is usually not advisable to attempt to make the source safe manually in these circumstances as this can result in further delay with the resultant additional unplanned dose to the patient. Such action should be performed only by authorised persons after the patient has been removed from the room.

### 12.3.5 MECHANICAL SAFETY

Because of the emphasis placed on the hazard from radiation, it could be easy to overlook the importance of insuring adequate mechanical robustness. The considerable weight of the source shield and the collimation system requires that all of the supporting components in the head and gantry are carefully designed, manufactured, and maintained to avoid mechanical weakness that could result in inaccurate treatment delivery and possible injury from mechanical failure.

A mechanical lock should also be provided on the head to make sure that the source cannot be exposed when the unit is not under proper supervision. There is also a requirement that the room shall be physically secure when unattended to prevent potential terrorist activity (see [Appendix L.1.5](#)).

---

## 12.4 INSTALLATION OF COBALT SOURCES

Because of the huge activities involved, the installation of a cobalt-60 source is a potentially dangerous procedure that requires considerable care. It is usually necessary to bring a container with the new source into close contact with the head assembly, sometimes after having dismounted the collimator. The container is normally fitted with two *drawers* which can be activated from a distance, an empty one to collect the old source and the other one containing the new source. Proper mechanisms and interlocks ensure that after source exchange, the container can be safely decoupled from the treatment head and transported according to the current regulations. On the Alcyon cobalt machine, the whole head assembly is exchanged and used as the transportation container. In any case the operation must be performed by licensed source handlers under the control of the supplier. However, some of the particular issues that arise and that must be considered by the local staff are covered in the following paragraphs.

### 12.4.1 SOURCE SPECIFICATION

The two main characteristics that the user must decide upon before ordering a source are the *diameter* and the *output* at the treatment distance. The smaller the diameter, the better will be the penumbra, but this will also limit the maximum activity that can be obtained and will limit the output. Typically, sources with a diameter of 15 mm will be available with an output at depth of maximum dose for a  $100 \text{ cm}^2$  field area of up to  $220 \text{ cGy min}^{-1}$  at 80 cm SSD or  $140 \text{ cGy min}^{-1}$  at 100 cm SSD and will have an activity in the order of 300 TBq. For sources with a diameter of 20 mm, these maximum output figures will increase to  $360 \text{ cGy min}^{-1}$  and  $230 \text{ cGy min}^{-1}$ , respectively, with an activity in the order of 500 TBq. Before ordering the source, checks must be made with the supplier that the head of the unit is designed to accommodate the type of source being considered and that the room shielding will also be adequate. The user should also ensure that he has the necessary authorisation from the

Regulatory Authority\*. This must permit the user to have, at the hospital site, the total activity of both the new and old sources combined even though this may be only for a short period. Commercial suppliers of sources can usually give details of the approximate activity for a given source diameter to achieve a specified output. Although it is now recommended to express the output of a cobalt machine in air-kerma at a reference distance (in  $\text{Gy h}^{-1}$ ). Suppliers may still express the output of a source in terms of the old *Röntgen* (*R*) unit of exposure per minute at one metre from its front face, commonly abbreviated to *RMM* (or *Röntgen* per hour at one metre abbreviated to *RHM*) (ICRU 1970). Purchasers should also be careful to note if the output measurement conditions stated by the source supplier refer to a scatter-free measurement or to a measurement with the source in the head of the machine. The added scattering from the collimator and phantom for a large field size could appear to enhance the figure by 10% to 20%. The *R* unit will, in any case, give a numerically larger value than the equivalent absorbed dose rate in cGy.

#### 12.4.2 PREPARATION

It is essential that a detailed *quality plan* is prepared well in advance of the installation or source change by the radiotherapy physicist and that this is agreed to by all of the relevant parties. This plan will need to cover the transport arrangements, including local unloading and loading of the source container, local hospital security precautions, liaison with the radiotherapy department staff, and a clear definition of the responsibilities of the supplier and the local staff. It will also be necessary to clarify the arrangements for handing over the responsibility for the treatment room to the supplier's representative during the installation or source change. These should include any restrictions the hospital may wish to impose during this time. Similarly, it is better to agree well in advance to the arrangements for handing back the equipment to the hospital's control and to specify the tests the user requires to be successfully performed before accepting it back. If not involved directly, the person locally responsible for radiation protection must be consulted at all stages of the planning procedure. The hospital should also request the supplier to provide a *risk assessment* of the operations involving the sources and a corresponding contingency plan to deal with any reasonably foreseeable accident. Likewise, the hospital should also develop a *contingency plan* to cope with possible mishaps such as a source becoming stuck and irradiating an area of the room that is not fully protected. It should be noted that the IEC standard (IEC 1997) requires the equipment to be designed in such a way that the staff performing a source change receive no more than a dose of 1 mSv.

The quality plan should include taking the opportunity for local staff to become acquainted with the source exposure mechanism while there is no radioactivity present. If a source change is being made, a thorough inspection and service of the mechanism should be scheduled along with a wipe test as any maintenance of this part of the unit will, subsequently, be very expensive if it requires the source to be temporarily transferred to a separate container.

#### 12.4.3 INSTALLATION

An experienced radiotherapy physicist must be nominated to co-ordinate and oversee all operations apart from those that have been clearly designated as the supplier's responsibility. Even then, the physicist must be available in the case of an unexpected event that may need intervention by hospital staff. Clear warning signs and barriers should be placed around the treatment room during source manipulation procedures to restrict access and indicate who is in control. The physicist must be informed of when the actual source transfer is to take place so that he can monitor dose rates in the vicinity. He should also be informed of when the first exposures are made with the new source for the same reason.

\* The Environment Agency in the U.K.

Before accepting a new source, the supplier should demonstrate the following items as a recommended minimum set to satisfy the user that the specified performance has been met. It is also desirable that these checks are made before the old source leaves the site in case the wrong source has been delivered in error.

- Dose rate at  $d_{\max}$  for specified field size and treatment distance
- Radiation leakage levels around the head
- Source/shutter transit time
- Radiation field size versus indicators across full range
- Radiation beam penumbra for specified field size and depth
- Correspondence between radiation field and light field edges across full range
- Symmetry of radiation field edges about collimator axis
- Isocentric accuracy of radiation beam axis
- No contamination from source
- Optical distance indicator

It is much preferable if the method of measurement and the acceptable tolerance levels for each item are agreed in writing beforehand by including them in the quality plan if not specified elsewhere. In the case of new equipment being installed, other acceptance tests will be necessary, but these will be similar to those for a linac except specific attention may need to be given to

- Timers—method of operation, accuracy, and linearity
- Operation of exposure control system
- Arc/rotational therapy control system
- Head swivel (if fitted) and precision of zero degree position

Quality control procedures for the new cobalt unit should be established prior to clinical operation (IPEM 1999).

#### 12.4.4 DEFINITIVE CALIBRATION

A definitive calibration must be performed whenever a new source is installed (IPEM 1999, Appendix A). This should be performed according to the *codes of practice* described in Chapter 18. Once the output has been measured an attempt should be made to reconcile the measured output with that stated on the source certificate provided by the supplier after making allowances as far as possible for the inevitable differing measurement conditions. *The source certificate must never be directly used to derive the reference dose rate for clinical use.*

From the definitive calibration, it will be possible to derive the output figures required for daily treatments. Some centres may work with a single output (e.g. that for a  $10 \text{ cm} \times 10 \text{ cm}$  field, 0.5 cm depth in water at the isocentre) from which the output for all other field sizes and depths is derived by tables of factors. This has the advantage of having to change only one figure to allow for source decay. Alternatively, other users may calculate the output for a range of field sizes at a particular reference depth each time. The usual interval for re-calculating a new output to allow for decay is normally one month, and this requires a correction of almost exactly one percent. The output is usually calculated to be correct for the middle of the month.

As part of the definitive calibration procedure, the timer correction to account for the time for the source to become fully exposed must be determined. In fact, if a calibration method is used where the absorbed dose is measured for a set time on the unit's timer, it will be necessary to allow for this timer correction in order to obtain the true absorbed dose rate (see [Section 38.8.4](#)).

## 13.1 INTRODUCTION

The simulator was introduced in the late 1960s as an additional device to assist with the preparation of external radiation therapy (Green et al. 1964; Karzmark and Rust 1972). The original concept came from the necessity to check prior to treatment both that the plan can be delivered in practice and that the relationship of the beam set-up to the patient's anatomical features is correct. This could be done with the therapy machine using film or electronic imaging devices (see [Chapter 14](#) and [Section 40.1](#)), but there are then two major drawbacks:

1. The image quality of films performed with high energy x-rays is poor compared to the quality in the radiodiagnostic range
2. Using the treatment machine to simulate the actual treatment is not very efficient in terms of patient throughput.

From these considerations came the idea of designing a specific piece of equipment, mimicking the geometry of the therapy machine, located in a different room and fitted with a radio-diagnostic-type x-ray tube. It has been called a *simulator*.

Ideally, a simulator should have exactly the same mechanical and geometrical characteristics as the simulated treatment machine. This includes the patient couch and the external dimensions of the housing including any accessory equipment. It also means that the same movements, scales, and geometric accuracy should be available. There would then be one simulator for each treatment machine, and that would not be economically efficient. For this reason, the simulators presently available are designed to be universal and to match, as closely as possible, the characteristics of most existing therapy machines. For example, to cover the standard cobalt machines as well as the standard linear accelerators, the focus-isocentre distance can be changed from 80 cm to 100 cm; although as accelerators become more universal, with 100 cm as the standard distance, this facility is no longer universally provided (see Figure 13.1). This range can be even larger to cover special needs. However, it must be fully realised that significant differences exist between simulator and treatment machine. The most important issues are inconsistency of scales, inability to predict collisions or beam interception by the table structure, inconsistency of accessories or of their attachment, and differences in rigidity. In general, it must be ensured that the accuracy of the simulator is at least as good as the best treatment machine available on the site.

Simulators have the ideal characteristics to perform x-ray images in geometrically controlled conditions. Therefore, they are frequently used not only as a simulation device but also as a patient data acquisition device in conjunction with a mechanical pantograph for external contour measurements. These two practices are often combined, resulting in different schemes that will be discussed in Part F. Since the requirements for patient data acquisition and treatment simulation or verification are similar, a single treatment of the issues will suffice.

**FIGURE 13.1**  
(See colour insert following page 590.) Photograph of a fixed SAD simulator showing a digital imaging system. A slot located behind the detector allows insertion of conventional film cassettes. The imager arm has considerable freedom of movement (focus-film distance in the Z direction and X-Y translation).

---

## 13.2 DESCRIPTION OF THE STANDARD SIMULATOR

The various components of a modern simulator can be seen in [Figure 13.1](#).

### 13.2.1 X-RAY TUBE AND GENERATOR

The x-ray tube must be designed to perform high quality radiographs and to be used in fluoroscopic mode. Therefore, the requirements are not different from those for a basic diagnostic apparatus with a modest workload, although the tube and generator rating must be large enough to accommodate large distances between focus and detector (up to 170 cm) and long exposure times in fluoroscopic mode (McCullough and Earl 1979). The *focus* must be small enough to give sharp images of the anatomical structures and of radio-opaque markers that are used, for instance, to define the field limits. A typical recommended diameter is in the range 0.4 mm to 0.6 mm for the fine focus.

Unlike a diagnostic machine, the knowledge and stability of the geometrical position of the focus are of crucial importance. If two foci are available (large and small), it must be ensured that they are at the same position (even switching from radiographic to fluoroscopic mode) or preferably, provided that it doesn't limit the practical use of the equipment for thicker patients, access should be restricted to the small focus with an appropriate interlock. This focus must be aligned on the mechanical axis of diaphragm assembly. As for treatment machines, a light source must be placed at the same position. For practical reasons, this is always done through mirror reflection with adjustments for angle and distance.

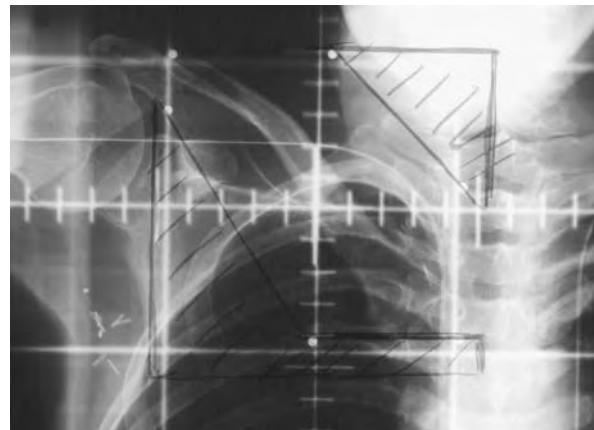

### 13.2.2 DIAPHRAGM ASSEMBLY

It is not necessary to mount a heavy collimator on the tube housing; instead, *metal wires* are used to represent the collimator edges on the radiological images as well as on the light projected onto the skin. One advantage of using wires is the possibility to see the radiological structures inside and outside of the field limits. There should be one X pair and one Y pair covering the whole possible range of field sizes, preferably with provision for asymmetry.

A *variable x-ray diaphragm* is not strictly essential, but it is recommended in order to improve radiation protection of the patient. Minimising the x-ray aperture will also improve image quality by reducing the amount of scattered radiation. The diaphragms may be used to allow exposures with different openings to be added together to enhance the contrast for thicker parts of the body (i.e. lateral pelvis). The diaphragm opening must always be larger than the field delimited by the wires. It is, therefore, advisable to have access to rectangular shapes with independent control of each blade if asymmetric fields are simulated. On sophisticated equipment, there could be a servo mechanism to keep a constant margin between the field wire and the corresponding diaphragm limit, but it is important that this mechanism can be deactivated.

The central axis of the beam must be made visible on the skin and on radiological images. This is usually done by engraving a *cross-hair* on a polymethylmethacrylate (PMMA, also known as Perspex or Lucite) sheet that slides in at the base of the diaphragm assembly. By filling the grooves with some lead material, they become radio-opaque. In addition, radio-opaque scales are often engraved along the cross-hairs in order to be able to measure distances directly on the films (as shown in [Figure 13.2](#)). Distances measured using this scale will indicate lengths in a single plane orthogonal to the beam axis at a fixed distance from the focus (usually 100 cm). If measurements are to be valid at another distance instead (e.g. 80 cm) exchangeable perspex graticules will be needed together with a system to ensure that it is clear which graticule was used.

In order to provide a full simulation of a treatment machine collimator, the whole assembly must be able to rotate around the beam axis. A visual display of the current angular rotation of the collimator must be provided.

**FIGURE 13.2**

Example of a simulation film of the supra-clavicular region. The graticule is clearly seen with its centimetric scale (at SAD) on both axes. The small white circles correspond to lead beads used as skin markers. Additional shielding blocks are manually drawn on the same field through the skin markers.

### 13.2.3 GANTRY

As for a treatment machine, the source must rotate around the patient, keeping the beam axis in a vertical plane but passing through a fixed point called the *isocentre*. As discussed above, the source-isocentre or source-axis distance (SAD) is often variable and is implemented by allowing the tube mounting to slide along the rotating arm parallel to the beam axis. The SAD value must be recorded and displayed, and it is recommended that the field size indicators are automatically adjusted according to the SAD in order to display the field dimensions as recalculated at the SAD. For mechanical and practical reasons, additional movements such as head tilt or head swivel that were sometimes found on the previous generations of cobalt machines are not available on standard simulators.

The relatively light weight of the tube and diaphragm assembly should allow an overall rigidity, giving a high accuracy of the isocentric movement. However, the existence of a variable SAD, combined with the wish to reduce the cost as much as possible, could lead to a degradation of this accuracy as compared to a treatment machine. This should not be accepted.

### 13.2.4 IMAGE DETECTION

On the gantry, opposite to the x-ray tube, an image detection system must be installed. Although not strictly needed for true simulations, an *image intensifier* is useful when the field definition is radiologically performed, on the spot, without a predefined plan (see [Section 32.2](#)). The intensifier should be large enough to analyse a large portion of the field. On the other hand, if it is too bulky, the risk of collision is increased, and movements may be severely restricted. A reasonable compromise is found with image intensifiers of diameters in the range 30 cm to 35 cm. It is important to stress that if a field limit is too far from the centre to be projected onto the intensifier entrance screen, the practice of moving the patient after delineating the field with a radio-opaque marker placed on the skin must be strictly forbidden because it gives a wrong projection. Instead, the intensifier must be mounted on an arm with provision for X and Y translations perpendicular to the beam axis. Some of the limitations of intensifier size and image distortion will be removed by the advent of *digital imaging panels* (see [Figure 13.1](#)). (In the following text *imager* will be used to include both types of imaging device.)

An additional Z translation, parallel to the beam axis, is also important to bring the image plane as close as possible to the patient in order to cover a larger portion of the field and improve the image quality (with a sharper penumbra).

The imager housing is generally equipped with a special holder for film cassettes, incorporating an anti-scatter grid. The holder should accommodate large film sizes (more than 35 cm × 35 cm), depending on the treatment techniques in clinical use. The grid can be focused, but it should not be too sharp because it has to accommodate various distances to the focus. It is very useful to record and display the film-isocentre distance that can be calculated from the Z translation of the imager. This distance can be used to calculate the film magnification.

In order to limit the consequences of collisions that are likely to happen with the imager housing, mechanical or electronic sensors are generally installed. If the sensors detect a collision, all the movements of the simulator and table are stopped except those that are necessary to restore the minimum distance between the imager and the rest of the equipment. Some simulators now have anti-collision software programs, but do not guarantee that collisions are impossible.

### 13.2.5 TABLE

A good quality *couch* is an essential component of a modern simulator. Its general characteristics are required to be very similar to those of a treatment table.

The amplitude and scales of the linear movements (longitudinal, lateral, vertical) should be the same as for treatment tables. The rotations are less useful because the presence of the imager and the problems of image interpretation make it very difficult to simulate fields with table rotations (i.e. non-coplanar fields). However, table rotation is required to facilitate patient set-up or to easily move the patient from the simulator to a mechanical contouring device.

The table top must be radio-transparent, and its flatness and rigidity must be as good as that of the treatment couch. However, the material used could be thicker because there is no concern about preserving the skin sparing.

The table must be equipped to accept the same patient positioning accessories as for treatment. However, lateral metallic rails can be an obstacle when performing some imaging procedures such as Computerized Tomography (CT) (see [Section 13.3.3](#)).

### 13.2.6 CONTROL CONSOLE

As for a treatment machine, it should be possible to control all the movements of the simulator and of the table, while in the simulator room, using, for instance, a hand pendant. However, it is also important to be able to control these movements in fluoroscopic mode in order to perform radiological adjustment of the field limits. For this, a control console must be available in a protected area behind a radiological screen or in an adjacent room. The position of the console in relationship to the simulator must allow a clear vision of the patient (to enable collisions to be avoided). Obviously, at the same location, the operator must have full access to the x-ray control and to the monitoring of the fluoroscopic images. The possibility to freeze the fluoroscopic images is beneficial to allow detailed analysis without excessive dose to the patient.

---

## 13.3 SPECIAL FEATURES

As well as the features common to standard simulators, additional functions can be found on modern machines, especially in connection with the general trend toward better integration in the computerised environment of radiation therapy (see [Chapter 32](#) and [Chapter 41](#)).

### 13.3.1 COMPUTERIZED CONTROL, NETWORKING AND AUTO SETUP

On modern simulators, the control of the machine is handled by a computer that allows movement selection and display. Therefore, even if the encoding of the various movements is done through potentiometers, the calibration of the corresponding scales can be achieved through software correction tables that make the procedure easier. Another interesting feature is the possibility to achieve relative x, y, z translations of the treatment couch coordinates in relationship to a given reference position where a new origin could be reset.

As soon as the machine coordinates are in digital form, they can be *imported* from or *exported* to other external equipment. This feature is of special interest when the simulator is part of a network, including check and confirm functions (see [Chapter 41](#) and [Chapter 42](#)). When the simulator is used to confirm the geometry of a plan previously designed on a computerised treatment planning system (TPS), it is useful to import data into the simulator from the TPS to limit the risk of transcription errors. On the other hand, if the initial setup is decided during the simulation process, the machine parameters could advantageously be exported to the TPS or directly to the treatment machine.

On computerised simulators, an *auto setup* function is frequently provided where, as soon as the geometrical parameters are defined (by importation from external equipment, direct input from the simulator console, or by recall of a predefined position), a simple confirmation through a push button initiates and sequences the corresponding movements. For safety reasons, it is required to keep pressing a switch (known as a *dead man's switch*) while the machine is moving. The auto setup feature is also useful for loading or unloading the patient or to prepare the machine for specific imaging modalities such as CT scanning (see [Section 13.3.3](#)).

### 13.3.2 DIGITAL IMAGING

Access to simulator x-ray images in digital form is useful for a number of reasons such as storage and retrieval facilities, network data exchange and image processing. One major advantage is that it is possible to transfer a reference image to an electronic portal imaging system, and this can then be compared, either manually or automatically, to digital portal images of the same field acquired during the treatment course (see [Section 40.1](#)).

One simple approach is to use a *film scanner* to digitise conventional films. However, this process is time consuming and expensive, and there is image degradation because of a loss in resolution. In addition the dynamic range is reduced because of a combination of the limitations of film and of the film scanning device. The rapid development of *Digital Luminescent Radiography* (also known as *Computed Radiography* or CR) provides an alternative to conventional film with direct access to images in digital form.

Alternatively, it is also possible to use the video signal from the image intensifier and to convert it into a digital image. The problems with this approach are essentially the risk of image distortion (Morton et al. 1991a) and the size limitation directly linked to the entrance screen of the image intensifier. In order to reach an acceptable geometrical accuracy, it is necessary to have access to hardware and/or software solutions for distortion correction and to calibrate the whole system periodically. In addition, special software has been devised to reconstruct a single image from multiple adjacent images acquired after translation of the image intensifier over the field area.

The development of *amorphous silicon* and *amorphous selenium* allows direct digital imaging. The drawback of this technology is its high cost, but it is likely that the cost will decrease.

### 13.3.3 CT OPTION

Another additional feature, often available as an option on modern simulators, is the possibility of reconstruction of *computed tomograms* (CT). The original idea (Harrison and

Farmer 1976) comes from the fact that several major components of a CT scanner are already present on any standard simulator (i.e. x-ray tube, rotational movement, image detector). It is tempting to use the detector output signal acquired while rotating the gantry to derive an image of the patient central slice by back-projection.

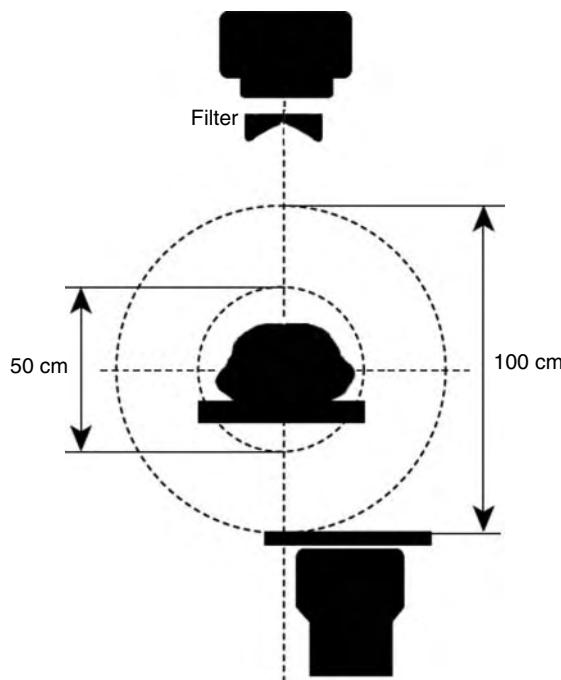

The first attempts used analogue processing of the video signal taken from the output of the image intensifier (Webb et al. 1977; Harrison and Farmer 1978). However, the image quality was very poor with many artefacts and significant background noise. A slight improvement was obtained with digital processing of the same signal, but it was only after using other detection systems that the image quality became satisfactory.

Currently, there are essentially two approaches that are implemented on commercial equipment: one of them takes advantage of the image intensifier with replacement of the standard fluoroscopic camera by a special CCD camera (line of detectors) measuring the transmission profiles as seen on the output screen of the image intensifier; the other makes use of the same detection system as a conventional CT scanner attached at the intensifier's entrance surface. Each of these methods has several advantages and drawbacks. With the first approach, there is a risk of distortion of the transmission profiles as the gantry rotates, mostly because of the influence of the earth's magnetic field on the electronic deflection within the image intensifier. This problem can be solved by the addition of a compensating coil where the current is a function of the gantry angle. Another problem is the restricted field of view that is limited by the diameter of the intensifier entrance screen. Finally, it is necessary to add a collimating slit on the image intensifier surface to block as much scatter as possible from the patient. The second approach requires the integration of a bulky device, including the anti-scatter collimator, that is not easily fixed or retracted and is also more expensive and difficult to maintain.

In both cases, a significant improvement in the image quality is obtained by adding a collimating slit at the exit of the tube assembly and by monitoring the tube output and using this as a reference for transmission measurements. It is also usual to enlarge the field of view by moving the detector laterally to the edge of the central axis in such a way that half of the image is acquired with a 180° rotation and the other half with the remaining 180° (**Figure 13.3**). For this situation, a shaped compensating filter is frequently inserted into the x-ray beam, being thicker on the external side of the body where the transmission is expected to be higher as shown in Figure 13.3. This is sometimes referred to as a *bow-tie filter*.

More recently, a new generation of devices based on digital image acquisition using *flat panels* and *cone beam reconstruction* (Cho et al. 1995; Jaffray 2002) has become commercially available. With a single rotation of the gantry, the data for a patient cross section about 15 cm long can be acquired, and from this, several adjacent CT slices of thickness 5 mm to 10 mm can be extracted. However, unless special image processing algorithms are used, the image quality is significantly deteriorated by the presence of a large amount of scattered radiation. With the advent of amorphous silicon panels (see [Section 14.3.2.2](#)), this technology is now mature, and good quality images with equal resolution in all three directions can be obtained. Such devices are also available on linacs.

Whatever technique is used, the resulting image quality is not quite as good as for a diagnostic CT scanner. Also, the acquisition time per slice is limited by the rotational speed of the gantry that is typically around 1 min for 360°. However, provided that the intention is to acquire only a limited number of slices (typically less than 10)—or for cone beam CT a limited length of the patient—and making sure that the heat capacity of the tube assembly is high enough, the CT option is very useful for 2D planning. First of all, the digital images can be directly transferred to the treatment planning systems without any need for mechanical devices for external contours. Second, the patient is truly in the treatment position as can be easily verified by a conventional simulation performed on the same machine in combination with the CT image acquisition. Also, the diameter of the virtual tunnel of this equipment can be as much as 90 cm, instead of 60 cm to 73 cm usually found on diagnostic CT machines and this allows for accessories such as arm rests or wedged boards. Finally, until it becomes more common to have CT scanners belonging to radiotherapy departments, it is very convenient to have access

**FIGURE 13.3**

To obtain a full CT reconstruction with an image detector that is not large enough, the detector can be laterally shifted in order to cover half of the body for a fixed gantry position but the totality for a 360° rotation. A filter is usually added to compensate for variable thickness of the body. In this example, the field of reconstruction is 50 cm diameter, and the aperture is 100 cm diameter (redrawn with permission from Mecaserto documentation.)

to CT imaging on the spot directly managed by the technologists who specialise in radiation therapy.

In spite of these advantages, it must be clearly understood that the CT option of simulators cannot be used for conformal radiotherapy where a series of many thin adjacent slices is required for volume reconstruction (Dahl 1996; Rosenwald 1999).

### 13.3.4 VIRTUAL SIMULATION AND IMAGE GUIDED RADIOTHERAPY

The term *virtual simulation* is used to characterise an approach where the simulation process takes place without it being necessary for the patient to be present (Sherouse et al. 1990). Instead, starting from a volume acquisition on a CT scanner, perhaps complemented by other imaging modalities, the simulation is performed on a computer console offering advanced imaging capabilities (Kessler et al. 1995). The beams are interactively generated and handled on the console until considered satisfactory on the basis of geometrical, anatomical, and/or dosimetric criteria. More details on this approach can be found in [Section 32.4](#).

Virtual simulators are becoming more widely used (Aird and Conway 2002; Mutic et al. 2003). They do not allow direct interaction with the patient, which means, for instance, that skin marking or accounting for patient internal movements is difficult. This is ideally done with a CT scanner dedicated to radiotherapy that is equipped with movable lasers to mark the isocentre position on the patient at the time of CT scanning based on a rapid definition of the target volume. It is still questionable if virtual simulation will completely replace, or just complement, conventional simulators (Webb 1990). A CT scanner suitable for virtual simulation should ideally have a wide bore and a radiotherapy-type couch as shown in [Figure 13.4](#). *Wide-bore scanners* are now available from all the major CT manufacturers,

**FIGURE 13.4**

(See colour insert following page 590.) Photograph of a wide-bore CT scanner designed especially for virtual simulation. Note the standard flat-top couch and the lateral lasers.

and there is a steady trend toward CT simulation rather than the use of conventional simulators.

A more recent development is the so-called *image guided radiotherapy*. This approach consists of having access to imaging capabilities directly on the treatment machine and is briefly referred to in [Section 40.1.5](#) and in the Introduction to [Part I](#). Alternatively, the imaging system can be part of a treatment machine specifically designed to combine imaging and treatment as in tomotherapy (Mackie et al. 1993) (see also [Section 43.3.4](#) and [Section 44.3.6](#)).

## 14.1 INTRODUCTION

When a patient is treated, it is just as important that the radiation should be delivered to the correct anatomical site as it is that the correct dose should be delivered. With the advent of conformal radiotherapy, the requirements for positional accuracy are increased. Traditionally, quality assurance of patient positioning has been achieved using industrial x-ray film, but film needs to be processed, and the information is only available some time after the treatment fraction has been delivered. In order to provide an instantaneous verification of the patient setup, *electronic portal imaging devices* (EPIDs) have been developed that are attached to the gantry of the linear accelerator.

A major difficulty of portal imaging in megavoltage photon beams is the lack of tissue contrast inherent to the energy range because the photoelectric interactions responsible for high quality images at diagnostic energies are almost non-existent.

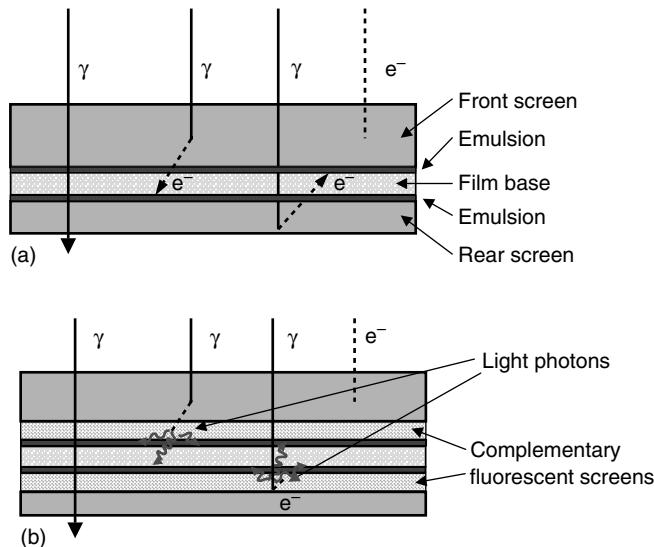

## 14.2 FILM-BASED METHODS

Until quite recently, film has been the traditional way of verifying patient position. In this section, the physical aspects of film used for patient setup verification are reviewed (see [Section 17.2](#) for a description of the detailed physical properties of film for dose measurement). The difficulties encountered when using film are also addressed.

Radiographic films normally have light-sensitive emulsion coated on both sides. In treatment positioning verification, the film is normally sandwiched between two metal or fluorescent screens. Typical conventional metal screen combinations include two sheets of lead of thickness 0.15 mm and 0.3 mm for the front and back screen, respectively, or a 1.0 mm thick copper front screen in conjunction with a 0.25 mm lead back screen. The front screen serves a dual purpose. First, the screen absorbs the electrons from the patient and the intervening air column to reduce blurring in the image while generating recoil electrons through photon interactions that directly expose the film (see [Figure 14.1a](#)). A lead back screen is usually used to intensify the fluence of the back-scattered electrons. The back screen has been reported to reduce the dose or exposure per given density by up to 50%.

The detection efficiency of the film–cassette geometry can be increased by placing the film in contact with a fluorescent phosphor screen ([Figure 14.1b](#)). With phosphor screens, the recoil electrons from the metal front and back screens interact with the heavy metal ions to produce optical photons that expose the film. The process of light photon production is described in more detail in [Barrett and Swindell \(1981\)](#). The thickness of the phosphor has to be optimised for best results. Although thick screens will result in an increase in light output, this tends to degrade the system resolution by increasing the spread in the light photons when they reach the film. The phosphor thickness has to be minimised so that the generated photons reach the film with minimal lateral spread, but it must be thick enough to increase the light output. Calcium tungstate has long been used as a phosphor because of its excellent mechanical properties. More recently, rare-earth oxysulphides such as gadolinium, lanthanum, yttrium and other halides such as lanthanum oxybromide and barium fluorochloride have been explored.

[Haus et al. \(1997\)](#) have demonstrated a 3.5 times increase in film contrast with a combination of 1.0 mm thick front copper screen plus front and back gadolinium oxysulphide intensifying screen compared to conventional metal screen-only combinations. This cassette–film

**FIGURE 14.1**

(See colour insert following page 590.) Image formation in film with (a) metal only and (b) metal/fluorescent screens.

combination is marketed by Kodak as the Kodak EC-L (enhanced contrast for localisation) fast cassette and Kodak EC-V slow cassette for verification. The improvement in contrast in the metal–phosphor–screen–film combination was attributed to both the screen combination and film granularity.

Film granularity gives an objective and quantitative measure of the film emulsion's graininess. A developed film appears *grainy* or *mottled* as a result of discrete grain structure of the randomly distributed silver grains within the clear gelatine of the emulsion. A comparison of electron photomicrographs for different film morphologies was provided by Haus et al. (1997). In their article, they showed that the enhanced contrast film with small grain sizes and a small size variation, has granularity that is about three times smaller than conventional films. Because the film sensitivity is proportional to the grain size, a narrow grain size distribution is exposed with a narrow range of exposure. This results in higher contrast than for films with large grain size.

Film is effectively a non-real-time imaging method. Some clinics will wait for the few minutes it takes to develop and read the film; this is especially true in difficult cases. Most of the time, it is used retrospectively. It is not possible to continuously monitor the patient position throughout the treatment (i.e. study patient movement). Similarly, gross errors such as missing blocks, inverted wedges, or wrongly set collimators will not be detected until it is too late. Film cannot be used to check the dynamically-varying beam parameters such as found in rotation therapy, dynamic wedges, or moving multileaf-collimator blades. For all these reasons, films tend to be progressively replaced by electronic portal imaging.

## 14.3 ELECTRONIC PORTAL IMAGING DEVICES

EPIIDs have been developed to acquire and display portal images in as short a time as possible. The image can be analysed instantly for on-line verification, or more images can be acquired per treatment field without the need to enter the treatment room. One advantage of

the electronic devices is that the image is directly available in digital format for digital processing, archival and communication with other image handling modalities. A number of EPIDs have been developed based on different philosophies. These systems fall into three main categories: *video- or fluorescent-screen-based*; *matrix*; and *scanning diode* systems. A detailed review of such systems is provided by Antonuk (2002). The matrix devices can be subdivided into two groups: van Herk and Meertens' (1988) liquid filled ionisation chamber and the solid state systems of Antonuk et al. (1991) and Munro and Bouis (1998). The video and the matrix systems are available commercially, whereas, the scanning systems are still confined to the individual development groups. Table 14.1 gives an overview of the characteristics of some commercially available systems. The  $f_{50}$  values that provide a measure of the spatial resolution of the system will be discussed in more detail in Section 38.11.1.2.

#### 14.3.1 FLUORESCENT-SCREEN-BASED SYSTEMS

Several authors (Benner et al. 1962; Bailey et al. 1980; Leong 1986, Shalev et al. 1989; Munro et al. 1990; Visser et al. 1990) have described systems based on imaging a fluorescent screen. The systems described in the latter three articles have been commercially developed by Siemens, Infimed, Eliav and Elekta. The principle is shown in Figure 14.2. The detector is a large metal screen that is bonded to a thick fluorescent screen. The patient image is formed by high-energy x-ray photons that undergo Compton scattering within the metal screen. The recoil electrons pass into the phosphor screen where each one produces a large number of optical photons, typically ten thousand. The optical image thus produced is relayed to a video camera via a  $45^\circ$  folding mirror; this bend in the optical path keeps the camera out of the main beam and allows the camera to be located in a more convenient place at or near the gantry. The signal from the video camera is then available for processing, analysis, storage and display; there is a wide range of special-purpose and general-purpose software available.

**FIGURE 14.2**

Configuration of a video-based EPID mounted on a linac. Light photons from the phosphor screen are reflected by the  $45^\circ$  mirror to the camera via the lens.

The *metal detection screen* must be thick enough to remove the vast majority of all the electrons that are scattered within the patient and patient-support system. This eliminates the patient-scattered electrons as a source of image-contrast degradation. A thickness of  $1 \text{ g cm}^{-2}$  is typically used. There is no point in having a thicker screen to absorb more x-ray photons because, by the same token, only secondary electrons produced within a distance equal to the stopping range of an electron in the metal plate will escape and help generate the optical image. At best, these metal screens have a quantum efficiency of about 1%.

The *phosphor screen* should be thick enough to remove most of the energy of the secondary electrons produced in the metal screen, and a thickness of  $400 \text{ mg cm}^{-2}$  is typical. Phosphor screens thicker than this have also been used with the aim of increasing the absorption of the x-ray photons, using the phosphor material itself. A problem arises over the efficiency with which the optical photons are transmitted to the video camera. Although many thousands of optical photons  $P_2$  are produced on average for each detected x-ray photon, less than one in a thousand actually arrive at the photo detector because of the very small solid angle subtended by the camera lens from a position within the viewing screen. The optical coupling efficiency  $P_3$  is given by Swindell (1991):

$$P_3 = \frac{T}{[4nF(1 + 1/m)]^2} \quad (14.1)$$

where  $m$  the optical magnification is typically 0.05;  $F$  is the f-number of the lens and is usually no less than about 0.6 (the smaller the better); and  $T$  is a factor usually very close to unity that describes transmission and vignetting losses within the camera lens. The refractive index of the scintillator is denoted by  $n$ . The importance of these factors can be seen from the expression that describes the overall transmission of signal-to-noise ratio through the system (after Swindell 1991):

$$\text{SNR}_{\text{out}}^2 = \text{SNR}_{\text{in}}^2 (1 + 1/(P_2 P_3 P_4))^{-1} \quad (14.2)$$

where  $P_4$ , the quantum efficiency of the video camera, is typically 30% for a vidicon or orthicon type of device. CCD cameras have intrinsically high quantum efficiency, greater than 90%, but this is reduced to an effective value of sometimes only half of this figure because the chip has a large fraction of its surface used for non-detecting functions. The term  $P_2 P_3 P_4$  is the average number of detected optical photons per detected x-ray photon, and provided this exceeds some small number, such as five, no significant additional noise is introduced by inefficiencies in the optical system. Most systems manage to achieve this desirable state of affairs. Of course, this product should be as large as possible for the purpose of maximising the signal level, thereby improving the overall SNR with respect to noise sources that occur elsewhere in the system such as in the camera. The above expression that is often quoted is derived on the assumption that the optical-photon density distribution is Poisson distributed. This turns out to be acceptable in this context.

These systems are efficient from the viewpoint that the detector is two-dimensional in nature, allowing the entire portal aperture to be sampled at once; but with a quantum efficiency of 1%, there are insufficient x-ray photons contributing to a video image's single frame. Some form of integration is required in order to reduce photon-noise degradation to an acceptable level. This can be done in software after the image has been digitised by the frame grabber, but Munro et al. (1990) have shown the advantage of integrating on the photo cathode of the camera in order to reduce read-out noise. Most commercial systems have photon-limited images and typically need to integrate over about five seconds of beam time (at 4 Gy/min incident on the patient) before acceptable quality images are produced.

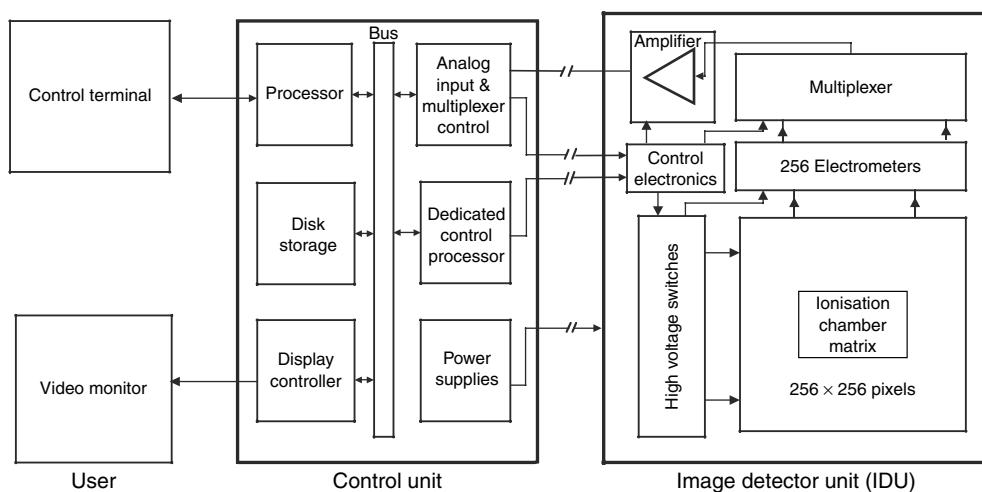

These systems are typically large and bulky, and special handling techniques have been developed to rapidly remove the imager from the treatment zone around the patient.

### 14.3.2 MATRIX DEVICES

### 14.3.2.1 The Matrix Ionisation Chamber

The *matrix ionisation chamber* system was developed at the Netherlands Cancer Institute in Amsterdam (Meertens et al. 1985; van Herk and Meertens 1987, 1988) and is shown in Figure 14.3. In the clinical prototype, the chamber was made from two fibreglass circuit boards, each etched with 128 linear electrodes on a pitch of 2.5 mm to form an array of 128 by 128 separate ionisation chambers. Therefore, the field of view at the detector was 320 mm by 320 mm. The 1 mm gap between the boards was filled with iso-octane to act as the ionising medium. The detector's spatial resolution has since been improved by increasing the number of electrodes to  $256 \times 256$  while maintaining the same detector area. As a result, the electrodes are now 0.6 mm wide with 0.6 mm gaps, giving an effective pitch of 1.27 mm  $\times$  1.27 mm pixels. The image is acquired by sequentially applying a high voltage to each of the high voltage electrodes and then measuring the signal generated in each of the 256 signal electrodes. On the first commercial detectors, a 250 V potential was applied to the switches for approximately 20 ms. This acquired an image in 5.5 s in the standard mode or 1.37 s in the reduced spatial resolution mode. The switching speed was limited by switching transients that have now been eliminated on the improved commercial version of the detector (van Herk et al. 1996). On the newer detector, the voltage was increased from 250 V to 500 V in order to increase acquisition speed. Increasing the voltage reduces the dwell or the on-time for each high voltage line, thereby reducing the acquisition time. With the more recent detector, image acquisition is possible in between 0.6 s and 2.0 s under clinical conditions. This reduces the required monitor units by up to 10 times compared to the original system.

Ideally, the detector should use all available radiation to improve image quality. As with most scanning EPIDs, the system is intrinsically inefficient because only one high voltage line is active at any one time. The physics of signal generation in the octane (2-2-4-trimethylpentane) considerably improves the quantum utilisation of this chamber. The concentration of ion pairs is stationary in the octane with a slow ion recombination rate. Calculations have shown that a latent image is formed over the entire irradiated region of the chamber after just 0.5 s of irradiation (van Herk et al. 1996). The signal measured by an electrode depends, therefore, on the electrode's previous irradiation history and the formation of new ions during the

### FIGURE 14.3

Diagrammatic layout of the matrix ionisation chamber system, showing the detector unit and layout of the control circuitry. The high-voltage switches and multiplex electronics are close to the field of view edges, so care has to be taken to reduce excess exposure.

measurement interval is negligible. The charge integration in the octane increases the measured signal. There is still, however, a large fraction of ignored radiation quanta not utilised in image acquisition. The faster timing electronics with the new detector compensate for this inefficiency so as to reduce the higher doses that would be required to generate the images. One area that still needs to be addressed is the detector's susceptibility to dose-rate-variation induced artefacts. There is no correction for the dose-rate variations during the signal collection, so a stable beam is assumed.

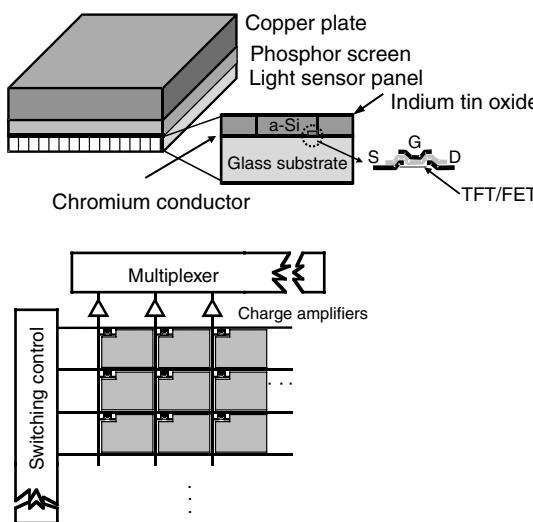

The system is relatively lightweight making it radiographer friendly. The detector unit is rigid and geometrically reliable, so there are no geometric distortions in the images, and mechanical problems are minimal.

#### 14.3.2.2 Amorphous Silicon ( $\alpha$ -Si) Devices

The most recent imaging detector to be developed is the *amorphous silicon array* detector unit (Antonuk et al. 1991, 1993, 1994, 1997; Munro and Bouius 1998). The a-Si electronic portal imaging detector consists of a scattering metal plate to produce Compton electrons and a phosphor layer to absorb the high energy electrons and emit light photons that are detected by the large-area photodiode array (as shown in Figure 14.4).

Principles of operation:

1. Compton electrons are produced in the 1.5 mm copper plate.
2. The electrons produce light photons in the phosphor material. The phosphor materials that can be used include gadolinium oxysulphide ( $Gd_2O_2S$ ) and thallium-doped caesium iodide ( $CsI:Tl$ ). The screen is either glued using transparent glue or mechanically pressed onto the light sensor system.
3. The light sensor detector pixels are comprised of photodiodes and TFT transistors that are connected to the readout and scanning electronics. The diodes initially are at 5 V bias before irradiation. During irradiation, the TFTs are non-conducting; the light photons discharge the diodes. On readout, the TFTs are made conducting to recharge the diodes. The charging is carried out row-by-row, and the charge required to re-bias the diodes is proportional to the light reaching the photodiode.

**FIGURE 14.4**

Schematic diagram of the amorphous Si detector. Photodiodes that make the individual pixels accumulate the signal generated by the light photons. When each row is switched, the TFT/FET act as switches for the individual diodes to allow current to flow along the data line to the charge amplifiers.

**TABLE 14.2**

Parameters of the Varian and Elekta Amorphous Silicon Imager Panels

Model/Supplier	Portal Vision aS500/Varian <sup>a</sup>	iViewGT/Elekta <sup>b</sup>
Detector area	40.14 cm×30.11 cm	40.96 cm×40.96 cm
Pixel format	512×384	512×512
Pixel pitch	0.784 mm	0.80 mm
Maximum image acquisition rate	15 fps	3 fps
Image display and storage rate	2 s per image	~0.3 s per image
Pixel depth	14 bits	16 bits
Metal plate thickness	1mm Cu	1mm Cu
Scintillator	Gd <sub>2</sub> O <sub>2</sub> S:Tb	Gd <sub>2</sub> O <sub>2</sub> S:Tb
f <sub>50</sub>	0.45 lp/mm	0.46 lp/mm
Software tools	Comprehensive	Comprehensive

<sup>a</sup> The Varian panel potentially has twice the resolution of the Perkin Elmer panel, but in the aS500 version, the signals are combined to reduce the resolution.

<sup>b</sup> The Elekta panel is similar to the Siemens panel; both are based on Perkin Elmer detectors.

Source: From Menon, G. V. and Sloboda, R. S., *Med. Dosim.*, 29, 11–17, 2004.

This is a self-scanning system that is very compact and flat, providing very high spatial resolution images that have been comparable to film (Antonuk 1992; Munro 1995). The spatial resolution of these detectors is governed by the size of the sensors and the focal spot size of the linear accelerator (Antonuk 2002). The size of the sensors varies from 0.4 mm to 0.78 mm for the currently available amorphous silicon panels. The read-out speeds range from 3 frames per second (fps) for RID 1640 Perkin Elmer detector that is currently supplied by Siemens and Elekta to 15 fps for the aS500 (Varian Medical systems). These panels are tiled together to provide a wide area detector. Typically, the panels are 41 cm×41 cm in dimension for the Perkin Elmer detector and 40 cm×30 cm for the aS500. These details are summarized in Table 14.2.

These devices are well-suited to *transit dosimetry* because of the linear response to dose and their compactness that make them easy to position near the patient or between heterogeneous media. For this usage their properties and acquisition parameters must be fully understood and controlled (Greer 2005; Berger et al. 2006, see also [Section 40.1.4](#)). They have gained market acceptance in spite of their significantly higher cost of ownership.

### 14.3.3 OTHER SYSTEMS

Several groups (Taborsky et al. 1982; Lam et al. 1985; Morton and Swindell 1988; Morton et al. 1991b) have developed systems that produce images by mechanically scanning a row of detectors along a path at right angles to the long dimension of the row. The Johns Hopkins group (Taborsky et al. 1982; Lam et al. 1985) used high-voltage rectifier diodes underneath a 1.1 mm plate of lead. The image is acquired by moving the scanning array across the field in 2 mm incremental steps. The Royal Marsden group (Morton and Swindell 1988) has used a double row of photo-diodes in conjunction with zinc tungstate scintillating crystals. More details of these scanning systems are provided in the review by Boyer et al. (1992).

A method based on the photo-stimulable phosphor plate, the Fuji system (Sonoda et al. 1983), has been further described by Wilenzick et al. (1987). The image receptor is a flexible plate supporting a 1 mm thick layer that contains europium-doped barium fluoro-halide. The phosphor contains electron energy traps that are filled when the plate is exposed to ionising radiation. The plate is read out in a separate reader where a red, scanning laser beam releases the stored energy in the form of visible photons that are then transmitted to a photomultiplier via a light guide. The system gives very high quality images that can be digitally stored and processed

in all the usual ways. It has gained wide acceptance in radiology as a replacement for films with the double advantage of eliminating the need for chemical processing and producing images directly in digital form. It is also more and more frequently used for radiotherapy portal imaging when EPID systems cannot be used (e.g. because of the limited size of detecting area or for special beam arrangements).

Although the lens/mirror system in video-based imagers is the most common method of coupling phosphor screens to photo-detectors such as CCD cameras, the use of fibre optic reducers has also been reported (Wong et al. 1991a and 1991b). The reducers are usually in the form of optical fibres of constant diameter that have been fused together to form a light guide. The fibre optic bundle is tapered to accomplish the required demagnification. The bundle is also bent through 90° in order to locate the photo-detector out of the radiation beam.

An excellent review of the principles of operation and some constructional details of the different types of existing EPID has been provided by Boyer et al. (1992).

# PREFACE

Radiotherapy is a comprehensive and fast-moving discipline which plays a major role in cancer care. Safe and effective radiotherapy requires close collaboration between radiation oncologists, radiation technologists and medical physicists, and all must have an understanding of each others' disciplines. Our aim has been to provide a comprehensive text providing most of the theoretical and practical knowledge that medical physicists need to know, including the essential underlying radiation biology. Although principally aimed at practising medical physicists, this book will also be useful to all other professionals involved in radiation therapy, whether they be students (master's and PhD level), university teachers, researchers, radiation oncologists, or radiation technologists.

The book is organised into 13 Parts, each dealing with a major self-contained subject area. Each part begins with an introduction by the editors and is subdivided into chapters mostly written by a single author. References are collected together at the end of each part. In order to cover in detail all aspects of radiotherapy physics and biology, a high level of expertise was required. Contributions have been brought together from eminent specialists in the field, mostly from Europe, but also some from North America. The editors have, where necessary, combined contributions from different authors in order to provide a logical flow—as far as possible details of who wrote what are shown on the title page of each chapter.

Parts A through C provide the fundamentals of the underlying physics, radiobiology and technology respectively. Parts D through H provide the practical information needed to support external-beam radiotherapy: dose measurements, properties of clinical beams, patient dose computation, treatment planning and quality assurance. An appendix to Part D gives complementary details to enable a thorough understanding of the methods and data used for absolute dose measurement. Part I seeks to capture the exciting new developments in the subject including those in particle therapy, thus providing a basis for the reader to understand the ever expanding literature in this area. Parts J and K deal with brachytherapy using sealed and unsealed sources respectively. The framework of radiation protection is covered in Part L including an appendix describing the detailed application of UK legislation. Part M contains useful tables of physical constants, and electron and photon interaction data.

In a multi-author book of this length there will inevitably be a certain unevenness of style and level of detail and also some repetition; we see this as a strength rather than a weakness although we as editors have sought to ensure consistency. We wish to thank our many authors for their high-class contributions and not least for their patience during the time it has taken to bring together this work. It is unavoidable that some chapters are even more up-to-the-minute than others which were written more promptly. We would also like to thank Don Chapman and Helen Mayles who have read and commented on some of the chapters.

Finally, we have tried to make the content as international as possible by taking into account different practices and terminology in different parts of the world. For example we have used the words *Radiation Oncologist* and *Radiation Technologist* to describe the medical staff who prescribe radiotherapy and who operate the treatment machines respectively. Colleagues who carry out computer planning are referred to as *Dosimetrists*.

It is our hope that our readers will learn as much from reading this book as we have from editing it.

**Philip Mayles  
Alan Nahum  
Jean-Claude Rosenwald**

# THE EDITORS

**Philip Mayles** Philip Mayles was born in 1947. He graduated from Gonville and Caius College, Cambridge with a BA in natural sciences in 1968. He completed a master of science degree in radiation physics at St Bartholomew's Hospital Medical School, following which he joined the staff of Guy's Hospital, where he worked until 1986. During this time he obtained a PhD from the Faculty of Medicine in London University. In 1986 he was appointed head of clinical radiotherapy physics at the Royal Marsden Hospital Surrey Branch under Professor Bill Swindell.

In 1994 he moved to Clatterbridge Centre for Oncology near Liverpool, as head of the Physics Department. During his time there he has overseen the expansion of the Radiotherapy Department from having five linear accelerators with conventional collimators to nine machines all equipped with multileaf collimators and portal imaging devices. The department uses modern imaging technology to enable 3D treatment planning for a high proportion of its patients and has been one of the pioneers of intensity modulated radiotherapy and image guided radiotherapy in the UK.

As chairman of the Radiotherapy Topic Group of the Institute of Physics and Engineering in Medicine he was instrumental in producing Report 75 on the design of radiotherapy treatment facilities and Report 81 on quality assurance in radiotherapy. He has an active interest in research especially in improving the physical basis of radiotherapy treatment and treatment planning.

In 1992 he and Alan Nahum established the Royal Marsden Course in Radiotherapy Physics which has been running successfully ever since, now under the direction of Margaret Bidmead and Jim Warrington. This course provided the inspiration for this book.

He and his wife, Helen, also a medical physicist, met at Guy's Hospital, London and have two daughters.

**Alan Nahum** was born in Manchester in 1949. He read physics at Worcester College, Oxford University. He gained his PhD in 1975 on theoretical radiation dosimetry using Monte Carlo methods at Edinburgh University under the supervision of Professor John Greening.

Alan then trained and worked as a school science teacher and worked as a gas cutter in a Volvo factory in Arvika, Sweden, before re-entering the medical physics world in 1979 as forskarassistent at the Radiofysik department, University of Umeå, where he taught and organised courses in radiation dosimetry, worked on ion-chamber response and on dosimetry codes of practice with Professor Hans Svensson, and where his two daughters Rebecka and Marie were born. He took a sabbatical (in Spring 1983) in Ottawa at the National Research Council of Canada working with Dave Rogers and Alex Bielajew on Monte Carlo simulation of ion-chamber response. He became a docent of Umeå University

Medical Faculty in 1983. He published *The Computation of Dose Distributions in Electron Beam Radiotherapy* just before leaving Umeå.

In 1985 Alan joined the Joint Department of Physics at the Institute of Cancer Research and Royal Marsden Hospital, Sutton, UK where his interests were redirected towards conformal (radio)therapy and subsequently to radioiological modelling. He co-directed (with Ralph Nelson and Dave Rogers) a course on Monte Carlo Transport of Electrons and Photons in Erice, Sicily in 1987 also co-editing a book with this title. In 1992 he and Philip Mayles started an annual  $2 \times 1$ -week course in radiotherapy physics which is still running. His PhD students at ICR were Charlie Ma, Mike Lee, Richard Knight, Paul Mobit, John Fenwick, Francesca Buffa, Mark Atthey and Margarida Fragoso. Postdoctoral scientists on his team included Beatriz Sanchez-Nieto, Frank Verhaegen, Cephas Mubata, Stefano Gianolini and João Seco, working on Monte Carlo simulation applied to dosimeter response and treatment planning, on biological modelling, and on building a database for analysis of clinical trials in conformal therapy. In 1997 he became Reader in Medical Physics of London University. He served as an associate editor for the journal *Medical Physics* between 1997 and 2004.

Alan left the ICR/Marsden in 2001 and after brief spells as a visiting scientist in Philadelphia, Reggio Emilia and Copenhagen, joined Clatterbridge Centre for Oncology, in June 2004, as head of physics research, becoming a Visiting Professor of Liverpool University in 2005. He was a member of the teaching faculty on the ESTRO course on IMRT and other conformal techniques from 1998 to 2005. His main current research is on using TCP and NTCP models in treatment plan optimisation.

Recreational interests include foreign languages, cooking, cricket and classical music.

**Jean-Claude Rosenwald** was born in 1945 in Neuilly, close to Paris. After earning an engineering degree in electronics, nuclear physics and computing sciences obtained in Nancy in 1967, he began his career as a computer scientist developing dose calculation programs in brachytherapy at the Institut Gustave Roussy in Villejuif, under the supervision of Andrée Dutreix. He obtained his PhD on this subject in 1976 from the University of Nancy.

He was appointed medical physicist at the Institut Gustave Roussy from 1971–1975 and then moved in 1976 to the Institut Curie in Paris, as head of the Physics Department. In 1996 he obtained an Habilitation à Diriger les Recherches from the Université Paul Sabatier in Toulouse in recognition of his capacity to coordinate research programmes. Altogether, more than 14 PhD and 60 master's students have undertaken research programmes under his supervision.

Dr. Rosenwald has a particular interest in the use of computers in radiation therapy, has participated in several international conferences, has been a co-author of several reports on this subject and was involved in the development of commercial solutions for treatment planning both for external-beam radiotherapy and brachytherapy. He has also promoted the use of proton beams in radiotherapy and played a major role in the development of the Centre de Protonthérapie d'Orsay. He has contributed to the expansion of the Radiotherapy Department at the Institut Curie, which is one of the leading centres in France, possessing modern equipment and practising modern radiotherapy techniques, based on advanced imaging devices and including intensity modulated radiotherapy, proton therapy and tomotherapy.

He served as president of the French Society for Medical Physics (today SFPM) from 1979–1982, as chairman of the Scientific Committee of the European Federation of Medical Physics (EFOMP) from 1990–1993 and chaired the Scientific Committee for Medical Physics at the International Conference of Bioengineering and Medical Physics held in Nice in 1997. He is a member of the editorial board of *Radiotherapy and Oncology*.

# TABLE OF CONTENTS

## Part A: Fundamentals

Chapter 1 <b>Structure of Matter</b> . . . . .	5
<i>Jean Chavaudra</i>	
Chapter 2 <b>Radioactivity</b> . . . . .	19
<i>Jean Chavaudra</i>	
Chapter 3 <b>Interactions of Charged Particles with Matter</b> . . . . .	35
<i>Alan Nahum</i>	
Chapter 4 <b>Interactions of Photons with Matter</b> . . . . .	57
<i>David Dance and Gudrun Alm Carlsson</i>	
Chapter 5 <b>The Monte Carlo Simulation of Radiation Transport</b> . . . . .	75
<i>Alex Bielajew</i>	
Chapter 6 <b>Principles and Basic Concepts in Radiation Dosimetry</b> . . . . .	89
<i>Alan Nahum</i>	
<b>References</b> . . . . .	117

## Part B: Radiobiology

Chapter 7 <b>Radiobiology of Tumours</b> . . . . .	127
<i>Gordon Steel (with Don Chapman and Alan Nahum)</i>	
Chapter 8 <b>Radiobiology of Normal Tissues</b> . . . . .	149
<i>Gordon Steel</i>	
Chapter 9 <b>Dose Fractionation in Radiotherapy</b> . . . . .	163
<i>Gordon Steel (with Alan Nahum)</i>	
<b>References</b> . . . . .	179

## Part C: Equipment

Chapter 10 <b>Kilovoltage X-Ray Units</b> . . . . .	187
<i>Tony Greener</i>	
Chapter 11 <b>Linear Accelerators</b> . . . . .	197
<i>Les Loverock (with Philip Mayles, Alan McKenzie, David Thwaites and Peter Williams)</i>	
Chapter 12 <b>Cobalt Machines</b> . . . . .	241
<i>John Saunders</i>	
Chapter 13 <b>Simulators</b> . . . . .	251
<i>Jean-Claude Rosenwald</i>	
Chapter 14 <b>Portal Imaging Devices</b> . . . . .	261
<i>Cephas Mubata</i>	
<b>References</b> . . . . .	271

## Part D: Dose Measurement

Chapter 15 <b>Ionisation Chambers</b> . . . . .	279
<i>Pedro Andreo, Alan Nahum, and David Thwaites</i>	
Chapter 16 <b>Radiothermoluminescent Dosimeters and Diodes</b> . . . . .	303
<i>Ginette Marinello</i>	
Chapter 17 <b>Radiation Sensitive Films and Gels</b> . . . . .	321
<i>Mark Oldham</i>	
Chapter 18 <b>Absolute Dose Determination under Reference Conditions</b> . . . . .	333
<i>Pedro Andreo and Alan Nahum (with David Thwaites)</i>	
Chapter 19 <b>Relative Dose Measurements and Commissioning</b> . . . . .	367
<i>Ivan Rosenberg</i>	
Appendix D <b>Supplementary Details on Codes of Practice for Absolute Dose Determination</b> . . . . .	385
<i>Pedro Andreo and Alan Nahum</i>	
<b>References</b> . . . . .	415

## Part E: Clinical Beams

Chapter 20 <b>From Measurements to Calculations</b> . . . . .	433
<i>Philip Mayles</i>	

Chapter 21	
<b>Kilovoltage X-Rays . . . . .</b>	439
<i>Philip Mayles</i>	
Chapter 22	
<b>Megavoltage Photon Beams . . . . .</b>	451
<i>Philip Mayles and Peter Williams</i>	
Chapter 23	
<b>Manual Dose Calculations in Photon Beams . . . . .</b>	483
<i>Ivan Rosenberg</i>	
Chapter 24	
<b>Electron Beams . . . . .</b>	519
<i>David Thwaites and Alan McKenzie</i>	
<b>References . . . . .</b>	539

#### **Part F: Patient Dose Computation Methods**

Chapter 25	
<b>Principles of Patient Dose Computation . . . . .</b>	549
<i>Jean-Claude Rosenwald</i>	
Chapter 26	
<b>Patient Dose Computation for Photon Beams . . . . .</b>	559
<i>Jean-Claude Rosenwald, Ivan Rosenberg, and Glyn Shentall (with David McKay)</i>	
Chapter 27	
<b>Patient Dose Computation for Electron Beams . . . . .</b>	587
<i>Alan Nahum</i>	
Chapter 28	
<b>Monte-Carlo Based Patient Dose Computation . . . . .</b>	603
<i>Alan Nahum</i>	
<b>References . . . . .</b>	621

#### **Part G: Treatment Planning**

Chapter 29	
<b>Target Definition . . . . .</b>	637
<i>Anthony Neal</i>	
Chapter 30	
<b>Patient Data Acquisition . . . . .</b>	647
<i>Anthony Neal</i>	
Chapter 31	
<b>Magnetic Resonance Imaging in Treatment Planning . . . . .</b>	657
<i>Vincent Khoo</i>	
Chapter 32	
<b>Beam Definition—Virtual Simulation . . . . .</b>	669
<i>Vibeke Nordmark Hansen</i>	

<b>Chapter 33</b>	
<b>Photon-Beam Treatment Planning Techniques</b>	681
<i>Peter Childs and Christine Lord</i>	
<b>Chapter 34</b>	
<b>Electron-Beam Treatment Planning Techniques</b>	701
<i>Alan McKenzie and David Thwaites</i>	
<b>Chapter 35</b>	
<b>Dose Evaluation of Treatment Plans</b>	719
<i>Margaret Bidmead and Jean-Claude Rosenwald</i>	
<b>Chapter 36</b>	
<b>Biological Evaluation of Treatment Plans</b>	731
<i>Alan Nahum and Gerald Kutcher</i>	
<b>References</b>	773

#### **Part H: Quality Assurance**

<b>Chapter 37</b>	
<b>Rationale and Management of the Quality System</b>	793
<i>Philip Mayles and David Thwaites (with Jean-Claude Rosenwald)</i>	
<b>Chapter 38</b>	
<b>Quality Control of Megavoltage Equipment</b>	809
<i>Edwin Aird, Philip Mayles, and Cephas Mubata</i>	
<b>Chapter 39</b>	
<b>Quality Assurance of the Treatment Planning Process</b>	841
<i>Jean-Claude Rosenwald</i>	
<b>Chapter 40</b>	
<b>Quality Control of Treatment Delivery</b>	867
<i>Philip Evans and Ginette Marinello</i>	
<b>Chapter 41</b>	
<b>Recording and Verification—Networking</b>	897
<i>Margaret Bidmead</i>	
<b>Chapter 42</b>	
<b>Data Communication with DICOM</b>	909
<i>John Sage, John Brunt, and Philip Mayles</i>	
<b>References</b>	921

#### **Part I: Special Techniques**

<b>Chapter 43</b>	
<b>Conformal and Intensity-Modulated Radiotherapy</b>	943
<i>Steve Webb</i>	
<b>Chapter 44</b>	
<b>Intensity-Modulated Radiotherapy: Practical Aspects</b>	975
<i>C.-M. Charlie Ma (with Helen Mayles and Philip Mayles)</i>	

<b>Chapter 45</b>

## 15.1 INTRODUCTION

*Ionisation* is the creation of ion pairs. This results from interactions that transfer energy from the radiation to the atomic system. For energy transfers greater than electron binding energies, electrons are ejected (see [Section 1.4.2](#)), leaving behind a positively charged *ion*. The ability of ionising radiation to *ionise* a gas was one of its first properties to be observed; and indeed, it is the defining property. The measurement of ionisation in a gas was also the basis for the first radiation detectors.

Ionisation (or ion) chambers have remained central not only to the detection of radiation but also to the precise measurement of absorbed dose. They are the reference instruments used in the radiotherapy clinic, both for absolute and relative dose measurements (see [Chapter 18](#) and [Chapter 19](#) respectively), and it is fair to say that more is known about the response of ionisation chambers than about any other radiation-detecting instrument. Because of the key role that ionisation chambers play in radiotherapy dosimetry, it is vital that practising physicists and others involved in radiation measurements in radiotherapy beams have a thorough knowledge of their characteristics. As will be made clear, though widely used and well understood, ionisation chambers are far from simple in their response or even in their mode of operation and do not possess the ideal properties of a radiation detector for *dose measurement*.

First, the sensitive medium is a gas, usually air, at atmospheric pressure that has a density around 700 times less than that of water. Hence, the signal strength from an ionisation chamber will always be relatively low compared to so-called solid-state detectors ([Chapter 16](#) and [Chapter 17](#)). Furthermore, air being a gas is not particularly close to being equivalent to water<sup>\*</sup> or to any other commonly used phantom material such as polymethyl methacrylate (PMMA, known as Perspex or Lucite) or polystyrene, and the quantity measured, charge, has first to be related to dose to the gas  $D_g$  (or  $D_{\text{air}}$ ) before cavity theory ([Section 6.7](#)) is used to derive the dose to the medium  $D_{\text{med}}$ .

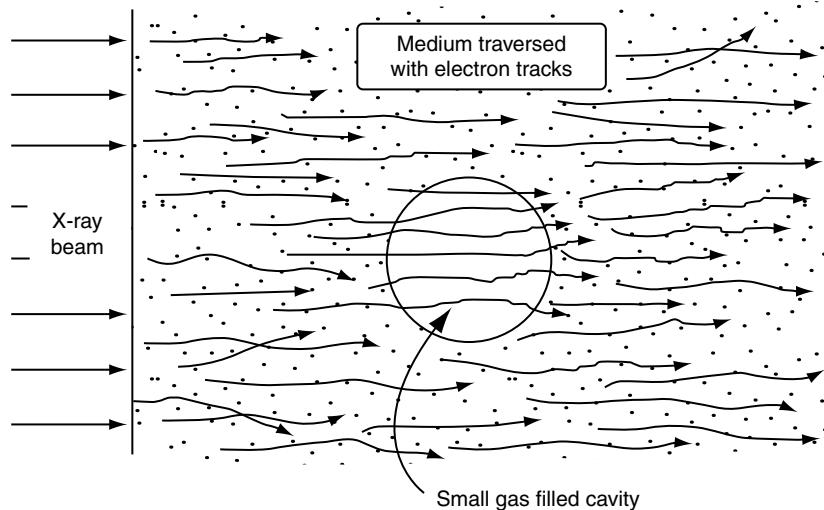

In order to be able to accurately calculate  $D_{\text{med}}$  from  $D_g$ , the ionisation chamber must behave as a Bragg–Gray cavity in a photon or electron beam that means that the range of the electrons in the gas (secondary electrons in the case of a primary photon beam) must be considerably greater than the dimensions of the cavity; in this case, it can be said that the gas cavity does not disturb the fluence of electrons present in the medium as [Figure 15.1](#) illustrates. This will generally be the case for all high-energy or megavoltage radiotherapy beams<sup>†</sup>. Consequently, the ratio  $D_{\text{med}}/D_g$  can be equated to the (mass collision) stopping-power ratio  $s_{\text{med},g}$  (see [Equation 6.48](#) and [Section 18.5.1](#)). It should be noted, however, that the Bragg–Gray principle does not apply to the so-called free air chamber that is also dealt with in this chapter (see [Section 15.3.1](#)).

If an ionisation chamber is to be used to make an absolute determination of the dose, then the charge per unit mass of gas,  $Q/m$ , also known as the mass ionisation  $J_g$ , must be determined. The gas density  $\rho$  will generally be accurately known from its pressure and temperature (see [Section 15.4.4](#)); a precise knowledge of the volume  $V$  containing the gas is also required as  $m = \rho \times V$ . Then, the dose to gas is derived by multiplying  $J_g$  by the so-called *W*-value that is the mean energy required to create an ion pair. This leads to the following equation:

---

\* It should be stressed that in spite of this large difference in density, the mass attenuation and mass absorption coefficients of air are not very different from those of water (see tables in [Part M](#)) which makes the relative response air/water approximately constant across a wide range of photon energies. Furthermore,  $(W_{\text{air}}/e)$  is constant across a wide range of photon and electron beam qualities (see [Section 18.5.4](#)).

† In practical chamber designs, there are, however, important departures from Bragg–Gray behaviour principally because of the non-medium equivalence of the chamber wall material and the finite size of the air cavity; these deviations, termed *perturbations*, are dealt with in detail in [Section 18.5.3](#) and in [Section D.2](#) of [Appendix D](#).

**FIGURE 15.1**

A Bragg–Gray cavity in a medium irradiated by an x-ray beam; the secondary electron tracks are undisturbed by the small gas-filled cavity. (Reproduced from Johns, H. E. and Cunningham, J. R., *The Physics of Radiology*, 4th Ed., Charles C. Thomas, Eds., Springfield, Illinois, 1983. With permission.)

$$D_g = \frac{Q}{\rho V} (W_g/e) \quad (15.1)$$

and for the common practical case of water as the medium and air as the gas, we have:

$$D_{\text{water}} = \frac{Q}{\rho V} (W_{\text{air}}/e) s_{\text{water, air}} \quad (15.2)$$

To make an absolute determination of the dose to water with an ionisation chamber, therefore, each of the quantities in Equation 15.2 must be known accurately: the charge  $Q$  collected during the radiation exposure; the chamber volume,  $V$ ; the ratio of the stopping power in water to that in air,  $s_{\text{water, air}}$ , which is in principle dependent on radiation quality\*; and the mean energy required to produce an ion pair, divided by the electron charge,  $(W_{\text{air}}/e)$ .  $(W_{\text{air}}/e)$  which has the precisely determined value of 33.97 eV/ion pair (or joules/coulomb) (see Section 18.5.4) and is independent of radiation quality except at photon or electron energies well below the range of interest in radiotherapy (ICRU 1979). The charge  $Q$  can usually be determined with high accuracy, including correction for any recombination losses (see Section 18.5.1), and a great deal of attention has been paid to the accurate computation of stopping-power ratios (see Section 18.5.1). In practice, the difficulty lies in determining the chamber volume with sufficient precision. This is the principal reason why ionisation chambers used for absolute dose determination in radiotherapy, where accuracy of the order of 1% is required, are provided with a calibration factor which accounts for the volume of the chamber as well as for other factors depending on the *Code of Practice* (see Chapter 18). Strictly, ionisation chambers should not be classed as absolute dose-measuring instruments in the radiotherapy context.

\* The quantity  $s_{\text{water, air}}$  has a weak dependence on the chamber properties through the size of the cutoff  $\Delta$  in the Spencer-Attix formulation of the stopping-power ratio (see Section 6.7.4) which is related to the dimensions of the air cavity.

## 15.2 PHYSICAL AND OPERATIONAL PRINCIPLES

### 15.2.1 INFLUENCE OF THE APPLIED VOLTAGE—THE IONISATION REGION

Ionisation chambers are, in principle, the simplest of all gas-filled detectors. They consist of a gas-filled receptacle with two electrodes between which a voltage is applied. As the gas is theoretically a perfect insulator, no electric current will flow between the electrodes. The radiation interactions ionise the gas, and the electric field causes the movement of the electric charges toward the electrodes of opposite sign, creating a current that can be measured with an appropriate device called an *electrometer*.

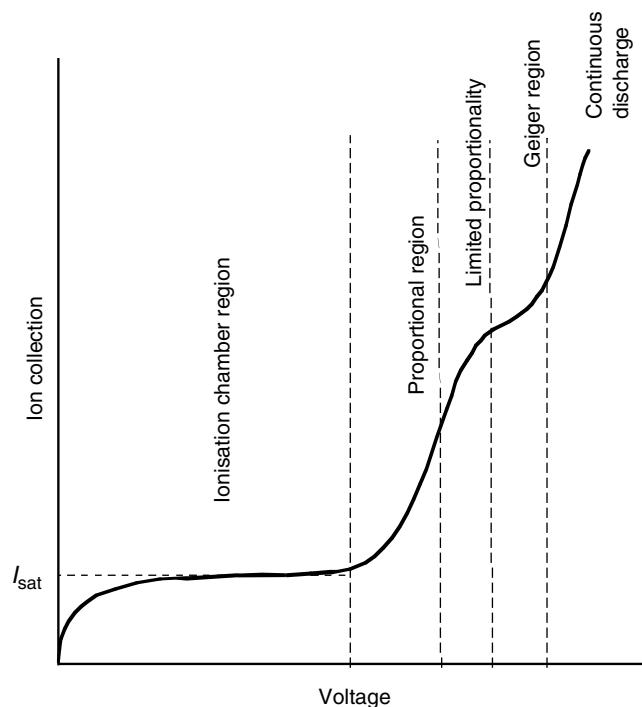

At low voltages, the charge collected from the gas is relatively small because considerable *ion recombination* occurs. Then, as the voltage is increased, the signal increases because a greater proportion of the charge is collected before it can recombine. Finally, the signal reaches a saturation value where all the ion pairs created from radiation are collected\*; the detector is then said to operate in the *ionisation chamber region*. Increasing the voltage to values beyond this region causes the electrons produced in the gas to be accelerated to such an extent that they produce additional ionisation of the gas, increasing the charge collected beyond that corresponding to  $I_{\text{sat}}$  (see Figure 15.2). Successive increases in the applied voltage cause the detector to operate successively in what are called the *proportional region*, *limited proportionality region*, *Geiger region* and *continuous discharge region* (Figure 15.2).

This typical behaviour, in addition to the possible electrical breakdown of insulators or distortion of the detector volume, gives rise to a practical limit to the voltage applied to an ionisation chamber, corresponding to the position of the first vertical dashed line in Figure 15.2. A slightly lower limit, at which the chamber can be safely used, is generally specified in the manufacturer's recommendations. Typical voltage values for ionisation chambers used in radiotherapy dosimetry are in the range 200 V to 400 V, with some parallel-plate chambers where the distance between electrodes is very small, having recommended values lower than this (see, for instance, Thwaites et al. 2003); this also applies to certain very small diameter cylindrical chambers.

Multiple designs of ionisation chambers have been developed for use in different situations. These are discussed in Section 15.3 where it is shown that the ionisation chamber is the most versatile radiation detector, capable of operating over a wide range of radiation intensities. For the determination of absorbed dose to water in radiotherapy beams, the most common types are cylindrical (thimble) and plane-parallel (parallel plate or coin) chambers; and air is the usual gas (see Section 15.3.2). The international standard IEC 60731 (1997) on dosimetry with ionisation chambers for radiotherapy provides recommended limits for the performance characteristics of these devices. The International Electrotechnical Commission (IEC) defines an ionisation chamber as “a detector consisting of a chamber filled with air, in which an electric field insufficient to produce gas multiplication is provided for the collection at the electrodes of charges associated with the ions and the electrons produced in the measuring volume of the detectors by ionising radiation”.

In general, the chamber itself consists of the measuring volume, the central collecting electrode and the outer electrode (which consists of the chamber wall and possibly a conductive coating). A build-up cap or water-proof housing may be added if needed. The collecting volume of typical cavity chambers used for radiotherapy dosimetry are in the range 0.1 cm<sup>3</sup> to 1 cm<sup>3</sup> (see Section 15.3.2). For dose rates that can vary from 0.1 Gy/min to 10 Gy/min, the typical currents created from air ionisation in the chamber cavity are in the range 6 pA to 6 nA. Such currents are very small and difficult to measure and require high quality connectors and

\* The limitations in charge collection of radiotherapy ion chambers will be discussed in Section 15.4.

**FIGURE 15.2**

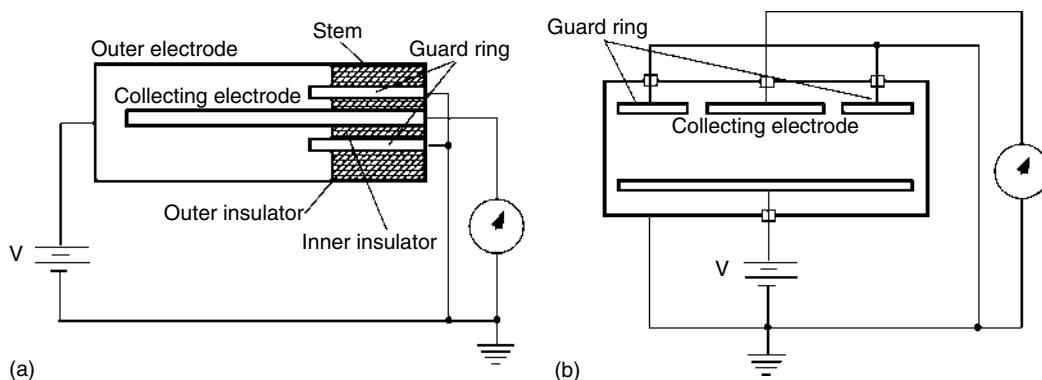

Variation of the charge collected, as a function of the applied voltage, in a gas detector. The different operating regions of the detector are indicated; the plateau corresponds to the so-called *ionisation chamber region* where a saturation current  $I_{sat}$  is achieved.

amplifiers. In radiation protection where the dose rates are much lower, the typical volume of the ionisation chambers used is several hundred cubic centimetres; even with such large volumes, only dose rates above about 10 µGy/h can be measured.

### 15.2.2 INSULATORS AND GUARD RINGS

The charge (or current) created in the air chamber is conducted to the measuring device (the electrometer) through leads connected to the electrodes. These leads pass through the chamber stem that is attached to the chamber cavity and designed to hold the whole assembly. Because the charge circulating between the electrodes should be restricted to that created within the air cavity, there must be no other conducting path between the electrodes except that of the ionised air, and an insulator must be provided between them. Although, in the past, various naturally occurring substances were used as insulators (amber, quartz and ceresin wax), today synthetic plastics can be used. These are polymethyl methacrylate (PMMA), polystyrene, polyethylene, Nylon, polytetrafluoroethylene (PTFE, Teflon), Mylar film and polytrifluoromonomochloroethylene (Kel-F) (Boag 1966). Surface leakage because of humidity is resisted well by Teflon; however, Teflon is more prone to radiation damage than polystyrene, for example.

As a result of the electric field between the electrodes, a leakage current can be created in the insulator that adds to the measured signal due to the radiation. This leakage is increased by the presence of moisture or small dirt particles; this is the reason why insulators should not be breathed upon or touched with the fingers. To minimize the voltage across the insulator, and therefore, the leakage current, the insulator is usually segmented into two parts with a conducting guard ring; one part separates the ring from the negative electrode, and another separates it from the positive electrode (see Figure 15.3a). The guard ring extends through the insulator assembly in the chamber stem and connects to the inner braid in the cable. The guard

**FIGURE 15.3**

Set-up of the guard ring in a cylindrical ionisation chamber (a) to avoid leakage current in the insulator. In a plane-parallel chamber, (b) the guard ring defines the effective collection volume between the collecting electrode where the electric field is uniform.

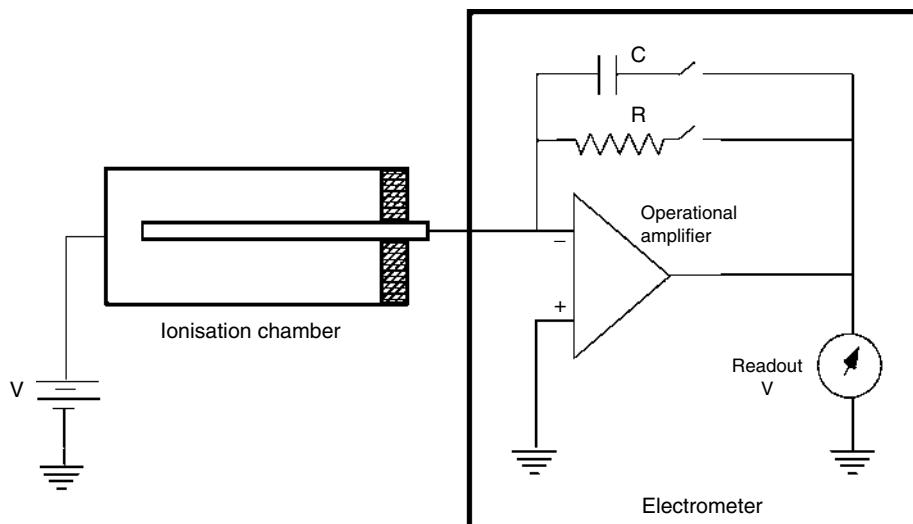

and the collector are held at the same potential, so any charge produced in the cable is collected between outer and inner braids and does not affect the measurement. Different guard ring designs are implemented in plane-parallel chambers where they are used to define the effective collection volume (See Figure 15.3b).

### 15.2.3 ELECTROMETERS

The electronics required to measure the charge (or current) is provided by the electrometer which, in most cases, includes a voltage supply and a display unit. For further details on electrometers, readers are referred to the compilation given by Attix (1986). In the early days of radiation dosimetry physicists used a gold-leaf electroscope equipped with a quantitative scale as an electrometer. Today, most electrometers are based on *negative-feedback operational amplifiers*.

An operational amplifier, represented by the triangle in Figure 15.4, has a high open-loop gain ( $>10^4$ ) and high input impedance ( $>10^{12}$  ohm) and consequently a low potential ( $<100$  mV) is maintained between its positive and negative inputs. Negative feedback means that some or all of the amplifier's output is fed back to its negative input. Total feedback results in a gain of unity. When a capacitor or a resistor is connected in the feedback loop of an operational amplifier whose negative input is connected to the chamber collection electrode and the positive input to the polarizing voltage or to the case ground, the voltage measured at the output of the amplifier is proportional to the charge collected and is equal to the voltage across the capacitor or resistor. If a capacitor  $C$  is placed in the feedback loop and the voltage measured across the capacitor is  $V$ , then the charge collected,  $Q$ , is equal to  $CV$ . This is known as capacitive feedback circuit mode, and unity gain ensures that exactly the amount of charge collected by the chamber collection electrode is deposited in the feedback capacitor. Similarly, if instead of the capacitor a resistor  $R$  is placed in the loop, the voltage  $V$  measured across the resistor allows the current  $I$  (related to the charge rate) to be determined as  $V/R$ . The reproducibility of a measurement depends almost entirely on the quality and stability of the capacitor or the resistor. Desired electrometer characteristics are the following:

- Fast warm-up (5–10 min)
- Short equilibration time after changing the high voltage across the electrodes
- Negligible ( $<10^{-13}$  A) pre- and post-irradiation leakage currents
- Sensitivity independent of ambient conditions, time, or scale position
- Ability to change the bias voltage in magnitude and polarity.

**FIGURE 15.4**

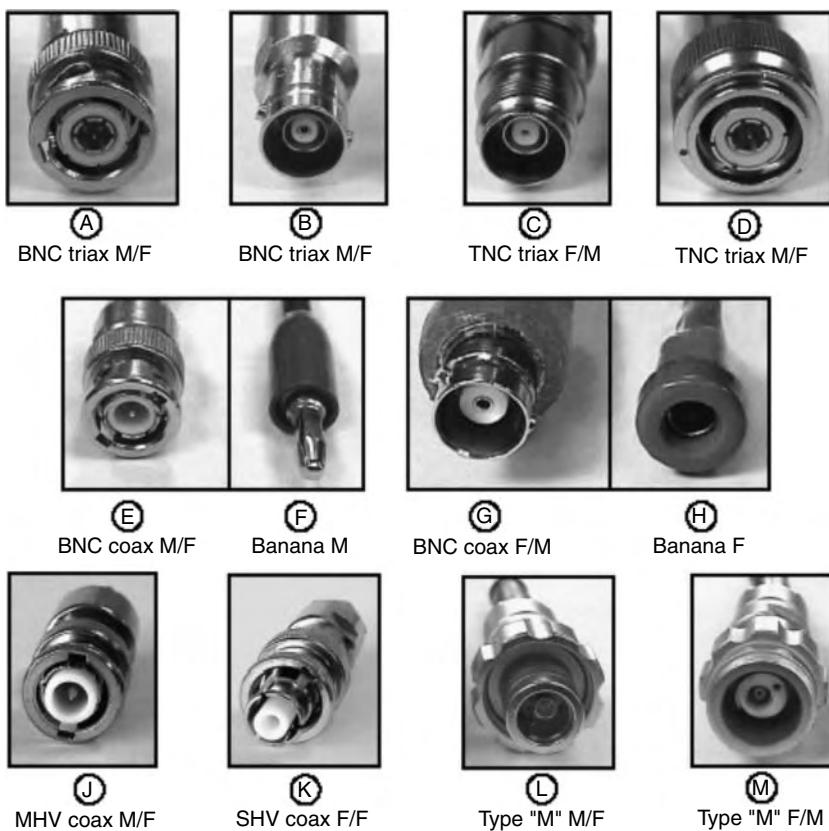

The principle of a *negative-feedback operational-amplifier electrometer*. The capacitor,  $C$ , or the resistor,  $R$ , are the feedback elements. The use of the capacitor or the resistor corresponds, respectively, to an electrometer operating in integrating or rate mode.

Most modern readout devices are digital voltmeters capable of achieving reproducibility of the reading over the entire range. They usually have maximum readings of 1999 or 19 999.

#### 15.2.4 CABLES AND CONNECTORS

The cables connecting the chamber and the electrometer are an important component of the dosimetry system (Humphries and Slowey 1986). High-quality low-noise triaxial cables having three separated conductive coatings are the obvious choice; the microphonic noise and dielectric-response time in cables provided by different manufacturers can vary significantly. These usually have a minor influence on the response of the system, but a more important aspect is the radiation-induced signal, which varies with the beam energy and, as shown by Humphries and Slowey, is often rather different between high-energy photons and electrons and from one manufacturer to another. The desired cable characteristics are the following: short equilibration time (less than one minute) when the high voltage is changed; low radiation-induced signal; low microphonic noise; low leakage (less than  $10^{-14}$  A); low capacitance; pliability; and easy and robust connector installation.

The connectors between the chamber lead and the electrometer have not been given much attention in the dosimetry literature. However they can cause numerous problems for users, e.g. the effects of dirt, moisture or small metal fragments, bad contacts, misaligned pins, breaks in connection of the cable leads to the connector contacts, mismatches of connectors, slightly different sizes of the same nominal connector, strain of the cable where it meets the connector, etc. If the two devices are from the same manufacturer they usually match each other without further problems but this is not necessarily the case when ionisation chambers and electrometers have different origins. In addition *male* and *female* connectors must be considered. There is a range of connector types used for commercially available chambers and electrometers (Nette and Czap 1994), some of which are shown in Figure 15.5.

**FIGURE 15.5**

Different types of connectors between ionisation chambers and electrometers (courtesy of Standard Imaging Inc, WI, USA). BNC coaxial (PTW, Exradin); BNC triaxial (Keithley); Miniquick coaxial (Nuclear Enterprise); TNC triaxial (Nuclear Enterprise, Capintec); PTW biaxial (PTW, type "M").

The term *dosimeter* describes the entire set-up, including chamber, electrometer and cables; although some manufacturers use this term solely to refer to the electrometer. IEC 60731 (1997) includes in the term *radiotherapy dosimeter* not only the chamber and measuring assemblies, but also stability check sources and phantoms.

## 15.3 TYPES OF CHAMBERS

In what follows, those types of ionisation chambers that are used in radiotherapy for determining the dose in the treatment field will be further discussed. The discussion will not include chambers designed for radiation protection purposes, which generally have a relatively large gas volume in order to increase their sensitivity because the measured doses are generally orders of magnitude lower than those relevant to treating tumours. In the radiotherapy clinic, essentially only one type of chamber is employed. This is known as a *cavity chamber* as its air volume is generally small (see [Section 15.3.2](#)). However, there is another type of chamber of great relevance to accurate dosimetry in radiotherapy, namely the free-air ionisation chamber that is used at Standards Dosimetry Laboratories (SDLs) in order to realise air kerma standards that are the basis for the majority of calibrations of cavity chambers.

**TABLE 15.1**

Approximate CSDA Ranges in Air of Mean Energy Secondary Electrons for Different X-Ray Qualities Ranging from 30 to 300 kV and for  $^{60}\text{Co}$   $\gamma$ -Rays

Radiation Quality (kVp)	Average Initial Secondary Electron Kinetic Energy (keV) <sup>a</sup>	CSDA Range in Air (cm) <sup>b</sup>
30	10	0.24
50	13	0.36
80	12	0.33
100	11	0.25
200	11	0.25
300	18	0.64
$^{60}\text{Co}$ $\gamma$ -rays	590	210

<sup>a</sup> The average initial secondary electron kinetic energy was estimated from Table A-3a in Johns and Cunningham (1983), on the basis of the mean x-ray energy in the spectrum approximated as 37% of the maximum energy (i.e. kVp)

<sup>b</sup> The CSDA ranges were taken from ICRU Report 37 (1984).

Sources: From Johns, H. E. and Cunningham, J. R., *The Physics of Radiology*, 4th Ed., Charles C. Thomas, Eds., Springfield, Illinois, 1983; ICRU, Report 37, ICRU, Bethesda, Maryland, 1984.

### 15.3.1 FREE-AIR CHAMBERS

The so-called *free-air ionisation chamber* is a specialist instrument usually only to be found at Primary Standard Dosimetry Laboratories (PSDLs). It is called a free-air chamber because, in principle, the walls of the chamber do not play any role in its response. The basic idea underlying the design is to produce perfect *charged particle equilibrium* (Section 6.15) in the defined collecting volume for a particular photon beam and hence to measure directly exposure (or air kerma)<sup>\*</sup>. This necessitates a consideration of the maximum range in air of the secondary electrons for various photon-beam qualities, as the dimensions of the chamber in all directions from the interaction volume must be at least as large as this for the energy of the particular beam under consideration. Table 15.1 contains estimates of this quantity. It can be seen that for megavoltage qualities (i.e. for x-ray qualities above around 300 kV) it becomes totally impractical to build such instruments.

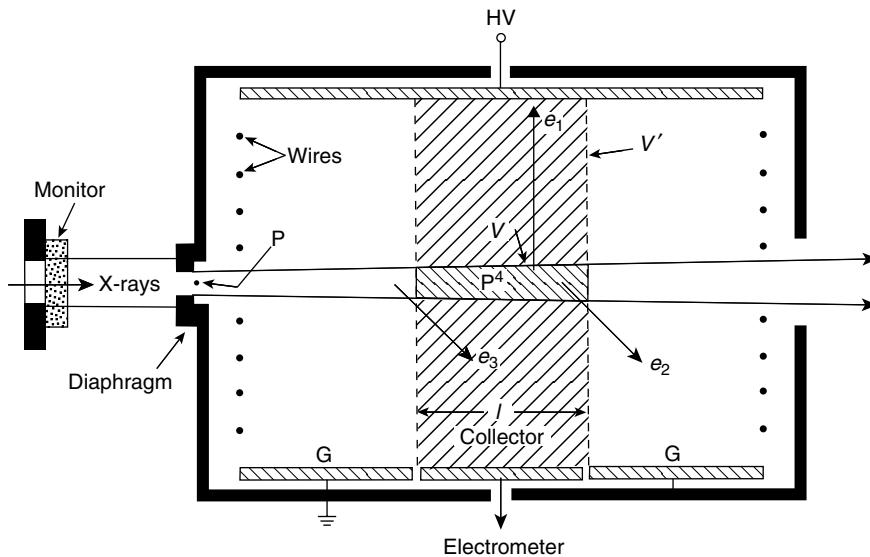

Figure 15.6 is a schematic illustration of a free-air chamber. The ionisation to be measured is that produced by secondary electrons created in the interaction volume  $V$ . Note that the collector, length  $l$ , is guarded by plates G. The two illustrative electron tracks  $e_3$  and  $e_2$  are shown balancing each other to indicate that there is *Charged Particle Equilibrium* over the complete inter-electrode collecting volume.

The mass of air irradiated is derived from the product of the cross-sectional area  $A$  of the beam aperture, and the length  $l$  of the collecting electrodes in the beam direction ( $V=Al$ ) multiplied by the density  $\rho$  of the air. The exposure rate  $\Delta X/\Delta t$  is then given by

$$\frac{\Delta X}{\Delta t} = \frac{Q}{Al\rho} \quad (15.3)$$

where  $Q$  is the charge collected in a specified time interval  $\Delta t$ . Small corrections must be made for the influence of, for example, the attenuation by the air and photons scattered in the chamber. Details of these can be found in Attix (1986).

\* *Exposure* is mostly used in this section since its original definition was closely related to the measurements that could be performed with a free-air ionisation chamber; *Air Kerma* is now preferred and can be considered as the modern replacement quantity for exposure (see Section 6.3.2).

**FIGURE 15.6**

Schematic cross-sectional view of a typical standard free-air ionisation chamber. The ionisation desired for an exposure measurement is that produced by the electrons such as  $e_1$  originating in interaction volume  $V$  (volume defined by the intersection of the beam and the collecting volume  $V'$ , in turn defined by the collector electrode). The measured ionisation is that collected from volume  $V'$ . Charged Particle Equilibrium ensures that if a particle  $e_2$  escapes from the interaction volume  $V$ , it is compensated by a particle such as  $e_3$  collected in  $V'$ . (Taken from Attix, F. H., *Introduction to Radiological Physics and Radiation Dosimetry*, Wiley, New York, 1986. With permission.)

The modern quantity required is no longer exposure but air kerma,  $K_{\text{air}}$ , which is obtained from

$$K_{\text{air}} = \frac{X}{(1-\gamma)} (W_{\text{air}}/e) \quad (15.4)$$

where  $\gamma$  is the fraction of the initial secondary electron kinetic energy re-radiated as bremsstrahlung (see [Section 6.3.2](#)) in air, and  $(W_{\text{air}}/e)$  is the mean energy required to produce an ion pair in air, divided by the electron charge (and has units of  $\text{J C}^{-1}$ ). The unit of time has been omitted from both sides of the expression for simplicity. Therefore, it is clearly seen that all determinations of air kerma rely directly on the value of  $(W/e)$  for air; this key quantity is discussed in [Section 18.5.4](#) and in ICRU (1979).

Free-air chambers of different dimensions are used at SDLs to determine air kerma in beams of x-rays between 10 kV and 300 kV. At higher energies, the secondary electron range in air becomes too large to make it practical to build such a chamber. At photon qualities of  $^{60}\text{Co}$   $\gamma$ -rays and above, air kerma is determined through the use of so-called cavity ionisation chambers.

### 15.3.2 CAVITY CHAMBERS

Cavity chambers are small chambers with walls enclosing the air volume. They are used both in SDLs and in radiotherapy clinics. The key distinction is that the design of the cavity chambers employed at SDLs must enable highly precise determinations to be made of the sensitive air volume, and that the materials used in the walls and central electrode must be as close to homogeneous as possible in order for the correction factors to be known as precisely as possible.

There are basically two types of cavity chambers: cylindrical (sometimes known as *thimble*) chambers and plane-parallel (also known as *parallel-plate*, *flat*, or *coin*) chambers. Both of these types are designed to behave as Bragg–Gray cavities in megavoltage photon and electron beams (see [Section 6.7.3](#)) and their design features can best be understood in the light of this. Some what different considerations apply to chambers used in kilovoltage x-ray beams (see [Section 18.6](#)). In all cases, the gas in the cavity is air, and the cavity should not be sealed in order for the air pressure to equilibrate with the ambient pressure (see [Section 15.4.4](#)).

### 15.3.2.1 Dosimetric Requirements for Cavity Chambers

*Requirements for fulfilling Bragg–Gray conditions:* For a chamber to behave as a good approximation to a perfect Bragg–Gray cavity, it should have the following features:

1. The air cavity should be small in order for the sensitive volume to be as well defined in space as possible, ideally being small in relation to dose gradients in any direction. In practice, the requirements that a potential difference of some 300 V be maintained between the electrodes and that the sensitivity (which is proportional to the air volume) not be too low preclude the lengths of any dimension being less than around 2 mm and the cavity volume being much less than 0.1 cm<sup>3</sup>.
2. The wall (and central electrode in the case of thimble chambers) should be made out of materials that are as homogeneous as possible and also as water- (or medium-) equivalent as possible; in practice, this is seldom possible.
3. The walls should be as thin as possible, especially in the beam direction on the upstream side of the cavity, consistent with the demands of robustness (though in principle, this would not matter if the walls were perfectly medium-equivalent and no measurements were required close to the surface of the phantom).

*Departures from Bragg–Gray behaviour:* Departure from the Bragg–Gray cavity theory (see [Section 6.7.3](#) for the theoretical derivation of this important condition) is an important issue that implies that correction factors must be used for accurate measurement of the dose to the medium. These factors will be discussed in detail in [Section 18.5.3](#) and Section 2 of [Appendix D](#). A short description of the various perturbations is, however, useful here in order to appreciate their importance in connection with the design of ionisation chambers.

Referring to conditions 2 and 3 above, the chambers wall(s) should either have negligible thickness or be continuous with or equivalent to the surrounding medium as it is only then correct to assume that the secondary electrons in the cavity all originate in the medium or in medium-equivalent material. In practice, one cannot make chamber walls from perfectly water-equivalent materials. Also, for the minimum wall thickness compatible with robustness (i.e. around 0.5 mm), some 50% of the ionisation measured with a typical cylindrical chamber in a cobalt-60 beam is due to electrons generated in the wall, falling to no lower than around 20% at the highest photon energies used in radiotherapy (Andreo et al. 1986; IAEA 1997a). Consequently, a correction for the effect of the wall will generally be necessary, and this is expressed through the wall perturbation factor  $p_{\text{wall}}$ ; generally, this is within 2% of unity for the wall materials used in practice (see [Table 15.2](#)). Note that this effect is considered to be significant only in photon beams, although, an approximate theory for wall effects in electron beams (Nahum 1988) predicts effects of the order of 0.5%.

The second important departure from Bragg–Gray behaviour is due to the finite size of the air cavity (Condition 1). This is generally<sup>\*</sup> dealt with by assigning to the chamber an effective point of measurement, denoted by  $P_{\text{eff}}$ , that, in general, lies *upstream* from the centre  $C$  of the

---

\* Another approach, presented in [Chapter 18](#) and [Appendix D](#), consists in using a multiplicative correction factor  $p_{\text{dis}}$  that accounts for the displacement of the medium by the air cavity.

cavity; the magnitude of the ( $P_{\text{eff}} - C$ ) shift is non-negligible in most practical chamber designs. More detail is given on  $P_{\text{eff}}$  in [Appendix D](#). The effect is similar in both photon and electron beams.

There is a further effect due to the non-negligible cavity size that only affects measurements in electron beams and is due to the large differences in density between the gas and the wall or medium. This results in more electrons being scattered *into* the cavity than being scattered *out*. For certain cavity shapes in relatively low-energy electron beams, this results in an appreciable increase in the electron fluence in the cavity compared to that in the (undisturbed) medium at the equivalent position (Harder 1968; ICRU 1984a; Nahum 1996; IAEA 1997b). This fluence and signal increase is corrected for, by introducing a perturbation factor less than unity usually denoted by  $p_{\text{cav}}$ . There is essentially no corresponding effect in photon beams because of the existence of (partial) charged particle equilibrium, i.e.  $p_{\text{cav}} = 1$  in Equation 15.5 (see [Appendix D, Section D.2.4](#) for an explanation).

The expression to obtain the dose to the medium,  $D_{\text{med}}$ , from the dose to the air measured by the ionisation chamber is modified for departures from Bragg–Gray behaviour (Equation 15.2) to read

$$D_{\text{med}}(P_{\text{eff}}) = D_{\text{air}} s_{\text{med,air}} p_{\text{wall}} p_{\text{cav}} p_{\text{cel}} \quad (15.5)$$

where it is to be understood that the measurement relates to position  $P_{\text{eff}}$  in the medium; a correction,  $p_{\text{cel}}$  for the effect of the central electrode material (see [Appendix D, Section D.2.3](#)) has also been added for completeness.

*Chambers designed to be air-equivalent:* Some designs of ionisation chamber for use in radiotherapy are intended to fulfill other criteria than Bragg–Gray ones. In kilovoltage x-ray beams, practical chambers do not behave as Bragg–Gray cavities because of the lower-energy secondary electrons generated with their much reduced ranges (see [Section 6.7.2](#)). Here, the primary concern is that the air kerma calibration factor,  $N_K$ , (see [Section 18.2](#)) should show as little variation as possible over a wide range of radiation quality, from say 50 kV (Half Value Layer  $\approx 1$  mm Al) up to 300 kV (Half Value Layer  $\approx 20$  mm Al) and sometimes even extending to cobalt-60 (with a build-up cap) as it was often desirable that the same chamber, e.g. a graphite-walled *Farmer* (see [Section 15.3.2.2](#)), be provided with  $N_K$  factors for the complete range of qualities existing in the radiotherapy clinic. Empirically, it was found, for example, that a graphite wall in combination with an aluminium central electrode resulted in a variation in  $N_K$  of no more than around 5% (Humphries and Slowey 1986).

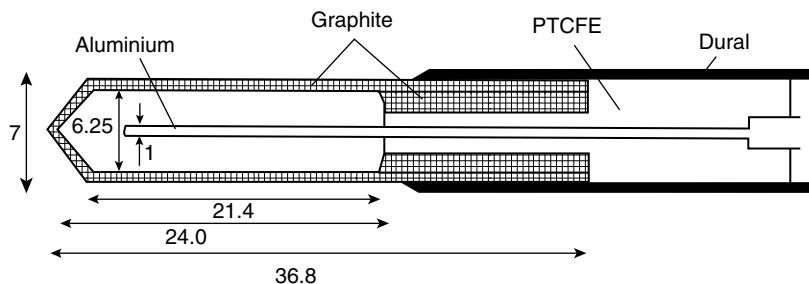

The extent to which these various requirements are fulfilled is now discussed in relation to the two main chamber types, cylindrical and plane-parallel. For completeness, the so-called monitor ionisation chambers found in accelerator treatment heads are also briefly described.

### 15.3.2.2 Cylindrical Chambers

The classic *Farmer* chamber (Farmer 1955; Aird and Farmer 1972), a very common design of cylindrical chamber for radiotherapy, is shown in [Figure 15.7](#). The cylindrical outer wall acts as one of the electrodes and is made of graphite. The other electrode is a thin aluminium central rod. The nominal cavity volume is  $0.6 \text{ cm}^3$ . The cavity length is 24 mm with an inner diameter of 6.25 mm. The graphite outer wall is 0.5 mm in thickness.

There are several other types of *Farmer* chambers commercially available with walls made variously of A-150 (muscle-tissue equivalent conducting plastic), C-552 (air equivalent conducting plastic), Delrin, Nylon 66, PMMA\*. The closest of these to water equivalence

\* When PMMA is used, it is coated on the inside with a conducting layer, usually *dag* that is basically a suspension of graphite in alcohol.

**FIGURE 15.7**

A Farmer-type ionisation chamber (redrawn from Aird and Farmer 1972), dimensions in millimetres.

in terms of atomic composition is PMMA. There are also models where the central electrode is made of A-150 instead of aluminium.

Other chamber designs may be smaller in diameter and length in order to achieve a higher spatial resolution (particularly important in situations where the dose is changing rapidly, e.g. in the penumbra region) but at the cost of a smaller signal per unit dose. [Table 15.2](#) shows a representative selection of cylindrical chamber designs.

Most cylindrical chambers are supplied with a build-up cap. This is placed around the chamber wall in order to achieve Charged Particle Equilibrium when the chamber is irradiated free-in-air in a  $^{60}\text{Co}$   $\gamma$ -ray beam as is done when providing the chamber with an air-kerma calibration factor,  $N_K$ , at a Standards Dosimetry Laboratory (see [Section 18.2](#)). The build-up cap is *not* used when the chamber is irradiated in a phantom at the Standards Dosimetry Laboratory for a direct calibration in dose to water  $N_{D,w}$  (see [Section 18.3](#)) or in a phantom in the clinic. However, if the chamber is not waterproof, it is necessary to place a thin waterproof sheath around it before using it in a water phantom.

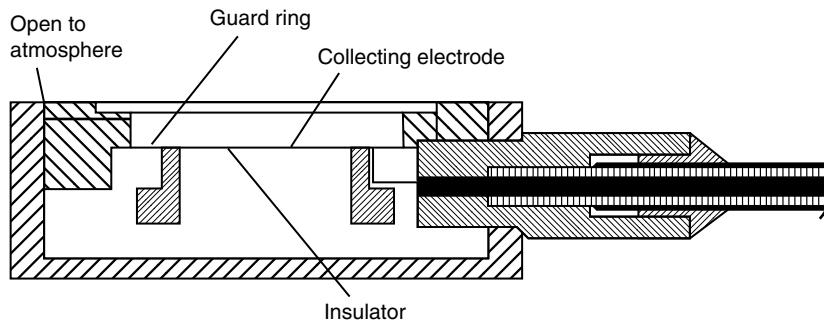

Cylindrical chambers such as those given in [Table 15.2](#) can be used for either absolute or relative dose measurements. For absolute dose measurements, they must be supplied with a calibration factor ( $N_K$  or  $N_{D,w}$ ) in order to determine the dose in absolute units (Gy) at the reference point in water by following a Code of Practice. For relative dose measurements, other types of cylindrical chambers may be used in conjunction with computer controlled beam-data acquisition systems. They are then preferably considerably smaller in order to improve the spatial resolution ([Section 19.1.4](#)). They should be waterproof or easily made waterproof. Most manufacturers make such chambers with cavities with volumes of the order of  $0.1 \text{ cm}^3$ , lengths of 10 mm or less, and inner diameters of around 4 mm (see [Table 15.2](#)).

### 15.3.2.3 Plane-Parallel Chambers

The *plane-parallel* or *parallel-plate* chamber design appears to be very different from that of the cylindrical chamber, although, both have cylindrical air volumes. The cylindrical or thimble chamber is irradiated with its central axis *perpendicular* to the beam direction, whereas, the plane-parallel chamber is irradiated with its axis *parallel* to the beam direction.

The chamber design may be different if the chamber is to be used in kilovoltage x-ray beams; the designs discussed up to this point are intended to be used in photon or electron beams from linear accelerators. For kilovoltage x-rays, it is preferable to have a very thin entrance wall, e.g. 0.004 mm of conducting mylar. It is also necessary to choose the wall and body materials with care in order to avoid significant energy dependence of the response for low-energy x-rays. For electron or megavoltage-photon beams, the entrance wall may be thicker as shown in [Figure 15.8](#).

Plane-parallel chambers are preferred to cylindrical chambers in situations where the dose gradient is steep in the direction of the beam, for example, in the build-up region in a

**FIGURE 15.8**

The NACP plane-parallel design of ionisation chamber. (From Nordic Association of Clinical Physics, *Acta Radiol. Oncol.*, 20, 401–415, 1981. With permission.)

megavoltage photon beam. Their use is recommended for absolute dose determination in electron beams of energy below 15 MeV. This is partly because of their improved spatial resolution (generally 2 mm or less cavity depth), but is mainly because the perturbation effect of *in-scattering* (see Appendix D, Section D.2.4) can be eliminated with a sufficiently wide guard ring (IAEA 1997b; Nahum 1996). Furthermore, the position of the effective point of measurement is well defined at the centre of the inside surface of the front window (see Appendix D, Section D.2.1). Table 15.3 lists desirable properties for a plane-parallel chamber in electron radiation.

The NACP chamber (Figure 15.8) is an example of a successful design of a flat chamber. It has a thin front window of 0.6 mm thickness, made of mylar foil and graphite, to enable measurements to be made at small depths. The back wall is made of graphite, and the side walls of rexolite. The collecting electrode is a very thin layer ( $>0.1$  mm) of graphited rexolite mounted on a thin insulating layer in order to give a negligible polarity effect (see Section 15.4.2). There is a 3 mm guard ring in order to exclude from the signal electrons scattered in from the side walls. The distance between the electrodes is 2 mm.

Table 15.4 lists the characteristics of plane-parallel chamber types in common use. It should be noted that relatively large values of the polarity effect have been observed with certain plane-parallel chamber types, and particular care should be taken to investigate this property when choosing a chamber. The width of the guard rings in Table 15.4 are at least 2.5 mm except for that of the Markus chamber; the latter, 0.2 mm, is insufficient to ensure a negligible perturbation from electrons scattered into the cavity through the side walls.

**TABLE 15.3**

Desirable Properties for a Plane-Parallel Chamber in Electron Beams

Chamber dimensions	
Front window thickness	$\leq 1$ mm
Collecting electrode diameter	$\leq 20$ mm
Ratio of guard ring width to cavity height	$\geq 1.5$
Cavity height	$\leq 2$ mm
In-scattering perturbation effect, $p_{\text{cav}}$	$< 1\%$
Wall and backscattering perturbation effects, $p_{\text{wall}}$	$< 1\%$
Polarity effect	$< 1\%$
Leakage current	$< 10^{-14}$ A
Long term stability	$\pm 0.5\%^a$

<sup>a</sup> Response variation per year for any radiation quality in the rated range.

The use of plane-parallel chambers for absolute dose determination in electron beams based on an air-kerma calibration (see [Section 18.2](#)) requires a knowledge of the factor  $p_{\text{wall}}$  in  $^{60}\text{Co}$   $\gamma$ -radiation. In general, it has proved difficult to determine  $p_{\text{wall},\text{Co}60}$  accurately because of the difficulty of making such chambers with homogeneous wall materials. Furthermore, it has been found that for certain chamber designs,  $p_{\text{wall},\text{Co}60}$  varies appreciably between chambers of exactly the same type ([IAEA 1997b](#)). Therefore, the use of plane-parallel chambers in photon beams for absolute dose measurements is discouraged.

Plane-parallel chambers are also used for dose determination in low-energy x-ray beams (see [Section 18.6](#)). At these qualities, the entrance window must be extremely thin in order to minimise photon attenuation. The chamber is mounted with the window flush with the surface of a phantom; in a so-called *Grenz-ray* chamber, the phantom forms part of the chamber body (*Grenz* rays are x-rays at or below 20 kVp). Commercial examples are the PTW M23342 and M23344 with cavity volumes of  $0.02 \text{ cm}^3$  and  $0.2 \text{ cm}^3$ , respectively, and the NE 2532/3A and 2536/3A of volume  $0.03 \text{ cm}^3$  and  $0.3 \text{ cm}^3$ , all with  $2.5 \text{ mg cm}^{-2}$  polyethylene entrance windows.

### **15.3.2.4 Monitoring Ionisation Chambers**

A further example of a type of ionisation chamber, usually referred to as a *monitor chamber*, can be found in the treatment heads of linear accelerators. Monitor chambers are essentially used to control the total dose, the dose rate and the beam position; they are described in [Section 11.7.3](#). Their principle and design have some similarities with plane-parallel chambers, but, since they are used as *transmission* chambers, their diameter is much larger, and their electrodes (i.e. entrance and exit windows) are very thin to prevent significant perturbation of the beam characteristics. Monitor chambers are generally sealed in order to keep the enclosed mass of air constant, independently of the pressure and (machine head) temperature. However, keeping the mass of air accurately constant is difficult to achieve in practice, and the monitor response must be checked frequently to prevent any drift. Alternatively, some monitor chambers (e.g. in *Elekta* machines) are unsealed, and their response is automatically corrected for changes in pressure and temperature (see [Section 15.4.4](#)) directly measured in the machine head. This does not, however, remove the need for frequent checks (see [Section 38.8.1](#)).

---

## **15.4 DETERMINATION OF THE CHARGE PRODUCED**

Ionisation chambers must be used in the voltage range where the collected charge reaches, or asymptotically approaches, a saturation value ([Figure 15.2](#)). However, because of the physics of ion transport and chamber electrical design, the charge collected can be different from the charge produced in the chamber gas by the passage of radiation. The most important phenomena affecting the charge collected are ion recombination, polarity effects, and leakage and stem effects. An additional important issue arises at the time of determining the charge per unit mass of air in the chamber cavity when a correction for the local pressure and temperature is usually needed.

### **15.4.1 RECOMBINATION**

#### **15.4.1.1 Initial and General Recombination**

The recombination of positive and negative ions within the air cavity reduces the amount of charge collected. Two main mechanisms for the disappearance of ions have been described (Boag 1966, 1987) that are related to the structure of radiation tracks and their distribution; these are termed *initial* and *general* recombination.

In the process of *initial* recombination, positive and negative ions in the track of a single particle recombine; this process is also called *columnar* recombination. Because only one single particle track is involved for a given field strength, this intra-track process is independent of the number of tracks formed per time interval (i.e. the dose rate). In practice, this effect is only significant for tracks with a high ionisation density, i.e. high-LET particles such as heavy ions (see Chapter 49).

*General* recombination proceeds once diffusion and ion drift have modified the initial track structure, and positive and negative ions of different tracks recombine as they drift toward the chamber electrodes. The process is also known as *volume* recombination, and it increases as the density of ions increases, being dependent on dose rate. This is the most significant process in the majority of radiotherapy beams.

Approximate empirical relationships have been proposed to describe initial and general recombination where so-called *Jaffé plots* ( $1/q$  as a function of  $1/V$  or  $1/V^2$  where  $q$  is the measured charge and  $V$  the polarizing voltage) are made to represent the complete saturation curve. *Initial recombination* is described by

$$1/q = 1/q_0 + \text{constant}/V \quad (15.6)$$

whereas *general recombination* follows the relationship

$$1/q = 1/q_0 + \text{constant}/V^2 \quad (15.7)$$

Practical limitations of these expressions have been discussed in the context of plane-parallel chambers for electron dosimetry in TRS-381 (IAEA 1997b).

#### 15.4.1.2 Collection Efficiency: Boag's Theory

For *general recombination*, Boag (1966, 1987) defined the collection efficiency  $f$  of an ionisation chamber as the ratio of the measured charge to the ideal saturation charge. It should be noted that the recombination correction factor,  $p_s$ , commonly used in dosimetry protocols, is the inverse of the collection efficiency. In his comprehensive review, Boag developed step-by-step the theory for the collection efficiency in continuous radiation, pulsed beams and pulsed scanning beams for different types of ionisation chambers. Here, a summary is given for the case of the pulsed beams commonly found in clinical accelerators; for fuller details, readers can consult Boag (1987). A more condensed, practical approach is given in ICRU (1982).

In pulsed beams, the collection efficiency is given by

$$f(u) = \frac{1}{u} \ln(1 + u) \quad (15.8)$$

where the variable  $u$  is defined as

$$u = \mu \frac{q_i}{V} A_I \quad (15.9)$$

and the coefficient  $\mu$  is a constant that depends only on properties of the ions and their mobility ( $3.02 \times 10^{10} \text{ V m C}^{-1}$ );  $q_i$  is the initial charge density,  $V$  the polarizing voltage and  $A_I$  is the solution of a double integral that, in the case of a plane-parallel chamber, is equal to the square of the distance between the electrodes. In the case of a cylindrical chamber,  $A_I$  is given by

$$A_I = (a - b)^2 \frac{(a + b)}{(a - b)} \frac{\ln(a/b)}{2} \quad (15.10)$$

where  $a$  and  $b$  are, respectively, the radii of the external and internal electrodes.

A problem with Equation 15.8 is that it depends on  $q_i$ , the initial charge density that is not known until the amount of recombination has been determined, whereas, the measured

charge density  $q_m$  is known. However,  $q_m = f q_i$ , and Boag introduced an auxiliary variable  $v = fu = \ln(1+u)$  with the result that

$$f = \frac{v}{e^v - 1} \quad (15.11)$$

This equation allows  $f$  to be determined from the measured charge as  $v = \left[ \frac{\mu A_I}{V} \right] q_m$  from Equation 15.9.

A simpler approximate equation, essentially a fit to calculated values from the complete expressions, has been given in IAEA (1997b); for plane-parallel chambers the recombination correction factor  $p_s$  is given by

$$p_s = 1 + 0.54d \frac{s^2}{V} \quad (15.12)$$

where  $d$  is the average dose per pulse in mGy,  $s$  the electrode spacing in millimetres and  $V$  the polarizing voltage in volts. The average dose per pulse refers to the absorbed dose to air. A similar equation can be written for cylindrical chambers, replacing  $s^2$  by the corresponding value  $A_I$  from Equation 15.10.

Some analyses of practical cylindrical chambers such as the NPL design standard chamber (Kemp 1972; Burns and Rosser 1990) or the Farmer chamber (Havercroft and Klevenhagen 1993) have used Boag's approach and taken into account both the cylindrical body and the end of the chamber. Expressions have been given for both these chamber designs that can be expressed as

$$p_s = 1 + n \frac{d}{V} \quad (15.13)$$

where  $d$  is again the dose per pulse in mGy, and  $V$  is the polarizing voltage in volts. The values of  $n$  are 4.6 for the NPL designed chamber and 5.75 for the Farmer chamber. Both the simpler equations given above in terms of dose per pulse (Equation 15.12 for plane-parallel chambers and Equation 15.13 for the Farmer design) are in close agreement with the illustrative values given in UK Codes of Practice for electron beams (IPEMB 1996a; Thwaites et al. 2003) and also with experimental measurements using a range of chambers recommended in those codes (Nisbet and Thwaites 1998a).

### 15.4.1.3 Collection Efficiency: The Two-Voltage Method

Situations can be encountered when an ionisation chamber does not reach saturation at the highest polarization voltage that can safely be used. However, a method based on making a second measurement at a much lower voltage has been described by Boag and Currant (1980). If the collected charges  $Q_1$  and  $Q_2$  have been obtained at the voltages  $V_1$  and  $V_2$ , and  $Q_i$  is the desired saturation value, then

$$\begin{aligned} Q_1 &= Q_i f_1 = Q_i \frac{1}{u_1} \ln(1+u_1) \\ Q_2 &= Q_i f_2 = Q_i \frac{1}{u_2} \ln(1+u_2) \end{aligned} \quad (15.14)$$

and their ratio becomes

$$\frac{Q_1}{Q_2} = \frac{u_2 \ln(1+u_1)}{u_1 \ln(1+u_2)} = \frac{V_1 \ln(1+u_1)}{V_2 \ln(1+u_2)} \quad (15.15)$$

because  $u_1/u_2 = V_2/V_1$  from Equation 15.9. Equation 15.15 can be solved for  $u_1$  numerically or graphically because both the ratios  $Q_1/Q_2$  and  $V_1/V_2$  are known. Weinhous and Meli (1984) carried out this calculation and fitted the results for the recombination correction factor  $p_s$  to the function

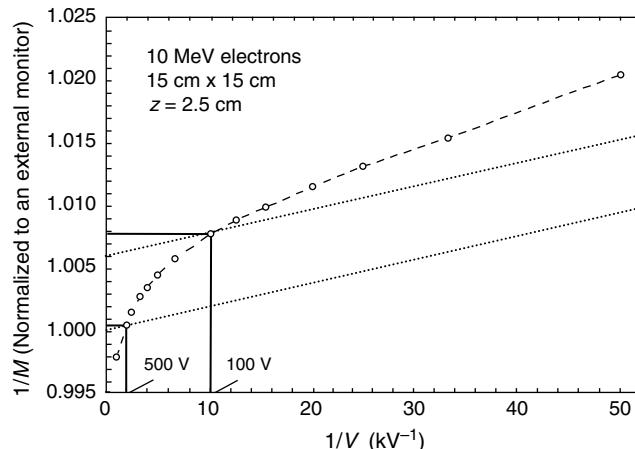

$$p_s = \alpha_0 + \alpha_1 \left( \frac{Q_1}{Q_2} \right) + \alpha_2 \left( \frac{Q_1}{Q_2} \right)^2 \quad (15.16)$$

where the coefficients  $\alpha_0$ ,  $\alpha_1$  and  $\alpha_2$  were given as a function of  $V_1/V_2$  for pulsed and for pulsed-scanned beams. These solutions have been implemented in the majority of the dosimetry protocols.

Provided that the correction required is small, the quadratic term in Equation 15.16 can be ignored, and the percentage correction reduces to the *percentage change in reading* divided by (*voltage ratio* – 1) (IPEMB 1996a). In the simplest case, if a voltage ratio of 2 is selected, the percentage recombination correction is equal to the percentage change in reading. This method does, however, rely on the linearity of the correction, and it is wise to verify this by plotting the full curve for each chamber at least once. Typical voltage values for cylindrical chambers may be  $V_1=400$  V and  $V_2=200$  V. These voltages are generally in the linear portion of the correction curve. For plane-parallel chambers, the deviation from linearity may occur at a smaller voltage value (e.g. 100 V). An example of the response of one particular plane-parallel ionisation chamber is shown in Figure 15.9.

#### 15.4.2 POLARITY EFFECT

Reversing the polarity on an ionisation chamber (e.g. making the central electrode +V with respect to the wall and then changing it to –V) may yield different readings; this phenomenon is termed the polarity effect. For most chamber types, the effect is practically negligible in high-energy photon beams, but in electron beams, notably at low energy, the effect may be significant. Several explanations have been given for this process (e.g. see Attix 1986); the effect

**FIGURE 15.9**

Response of one particular plane-parallel ionisation chamber when the bias voltage is changed.  $M$  is the chamber reading, and  $V$  the polarizing voltage in the so-called *Jaffé plot*. The deviation from linearity at the highest voltages indicates that this is not a true saturation curve but, instead, describes the overall response of the chamber. To obtain a measure of the true saturation correction using the two-voltage technique, the readings at the two voltages, corrected by Boag's theory (intercepts of the dotted lines on the ordinate) should be used instead of the uncorrected readings (solid-line intercepts). (Reproduced from International Atomic Energy Agency, *Technical Report Series no. 381*, IAEA, Vienna, 1997. With permission.)

is better understood in the case of plane-parallel chambers in electron beams (IAEA 1997b) where it is considered to be essentially a charge-balance effect on electrodes with asymmetric design. The magnitude of this effect depends on the energy and angular distribution of the incident radiation, the measurement depth in a phantom and also on the field size. By examining the pattern of charge deposition by electrons in a phantom, it can also be seen that the sign of the polarity effect may change with depth.

In situations where there is a measurable polarity effect, the true chamber reading is taken to be the mean of the absolute values of readings taken at each polarity. In the routine use of a given ionisation chamber, a single polarizing potential and polarity are normally employed. The effect on the chamber reading of using polarizing potentials of opposite polarity for each user beam quality can be accounted for by using a correction factor

$$k_{\text{pol}} = \frac{|Q_+| + |Q_-|}{2Q} \quad (15.17)$$

where  $Q_+$  and  $Q_-$  are the electrometer readings obtained at positive and negative polarity, respectively, and  $Q$  is the electrometer reading obtained with the polarity used routinely (positive or negative). The readings  $Q_+$  and  $Q_-$  should be made after ensuring that the chamber reading is stable following any change in polarity (some chambers can take up to 20 min to stabilize).

When the chamber is sent for calibration, a decision is normally made, either by the user or by the Standards Dosimetry Laboratory, on the polarizing potential and polarity to be adopted for the routine use of the chamber. The calibration should be carried out at this same polarizing potential (and polarity if only one polarity is used for the calibration). The Standards Dosimetry Laboratory may or may not correct for the polarity effect at the calibration quality. This should be stated in the calibration certificate. When the calibration laboratory has already corrected for the polarity effect, then the user must apply the correction factor  $k_{\text{pol}}$  derived using Equation 15.17 to all measurements made using the routine polarity. When the calibration laboratory has *not* corrected for the polarity effect, the subsequent treatment of the polarity effect depends on the facilities available to the user and on what beam qualities must be measured. Detailed procedures on how to perform such corrections can be found, for instance, in IAEA (2000). The polarity effect will vary in different electron beams and at different depths, but it should be less than 1% for well designed chambers (Nisbet and Thwaites 1998a).

### 15.4.3 LEAKAGE AND STEM EFFECT

Electric leakage in the ionisation chamber and electrometer may occur as a consequence of the irradiation of insulators and chamber parts, cables, and electronics of the measuring equipment. This is termed *post-irradiation* leakage, an effect that continues after the irradiation has ceased and usually decreases exponentially with time. IEC 60731 (1997) recommends that within 5 s after the end of a 10 min irradiation, the leakage current shall have decreased to  $\pm 1.0\%$  of the ionisation current produced in the measuring volume during the irradiation\*. Another kind of leakage is the so-called *stray radiation* leakage that is produced by scattered radiation in those parts of the chamber assembly and pre-amplifier that are usually outside the radiation beam (but within the radiation room). Mechanical stress on cable insulators can also cause a leakage current, and for this reason, bending or twisting cables should be avoided.

\* Similarly, the so-called *pre-irradiation* leakage, obtained with the maximum rated polarizing voltage applied to the chamber, shall not exceed  $\pm 0.5\%$  of the ionisation current produced by the minimum effective dose rate.

In the case of insulators, leakage may occur either through the volume or across the surface of insulators. The mechanisms of radiation effects on insulators are complicated and numerous (Attix 1986). The electrons produced during the ionisation of atoms in the insulators may be displaced a considerable distance from the ionised atom, requiring some time to recombine. As a result of the applied voltage, the electron-hole dipoles become aligned in a common direction, and their relaxation induces charges in the electrodes connected to the insulator forming a leakage current. Another effect in insulators that received considerable attention in the mid-eighties (Galbraith et al. 1984; Mattsson and Svensson 1984; Thwaites 1984) was charge accumulation in non-conductive plastic phantoms; this can give rise to a very large electric field around the chamber which then directs the flow of electrons toward the chamber cavity, yielding an increased signal. This is discussed further in [Section 18.8.3](#) for phantom materials, but similar effects can occur in the insulators of ionisation chambers.

The effect of irradiating the chamber stem is also a complicated phenomenon which, fortunately, has been minimized in modern ionisation chambers. Two mechanisms have been described by IEC 60731 (1997), namely *stem scatter* and *stem leakage*. The stem scatter effect arises from scattered radiation arising from interactions in the stem that may be different from those in the phantom material and that may contribute differently to the ionisation in the cavity volume. This effect can be determined using a *dummy stem*. The chamber is irradiated successively with and without the presence of the dummy stem, and the ratio of the readings allows a correction factor to be determined. The stem leakage arises as a consequence of the irradiation of the stem and the insulators and cables in it. The effect is usually determined by irradiating a chamber twice with the same narrow rectangular field, parallel and perpendicular to the long side, and a correction factor is derived as above\*.

#### 15.4.4 CORRECTION FOR THE CHANGES IN THE MASS OF AIR WITHIN THE CAVITY

The mean absorbed dose to the air in the cavity of an ionisation chamber,  $\bar{D}_{\text{air}}$ , is derived from the basic relation

$$\bar{D}_{\text{air}} = \frac{Q}{m_{\text{air}}} (W_{\text{air}}/e) \quad (15.18)$$

where  $Q$  is the charge produced in the air cavity having a mass  $m_{\text{air}}$  and  $(W_{\text{air}}/e)$  is the mean energy required to produce an ion pair in air, divided by the electron charge.

The mass of air is equal to  $V\rho_{\text{air}}$  where  $V$  is the cavity volume and  $\rho_{\text{air}}$  the air density inside the chamber. The number of interactions and consequently the charge produced is proportional to the mass of air, which in turn is proportional to its density. As most ionisation chambers are vented to the ambient atmosphere,  $\rho_{\text{air}}$  is a function of the atmospheric pressure, temperature and humidity.

It is common practice to fix the value of  $\rho_{\text{air}}$  for certain conditions and convert  $Q$  to those conditions, and not the reverse. The SDLs take the reference air density value as  $1.2930 \text{ kg m}^{-3}$ , which is the value for dry air at  $0^\circ\text{C}$  and  $101.325 \text{ kPa}$ . They then measure charge in the reference beams at  $20^\circ\text{C}$ ,  $101.325 \text{ kPa}$ , and 50% relative humidity (common reference conditions). They correct to dry air and to  $0^\circ\text{C}$  and  $101.325 \text{ kPa}$ , using the usual density corrections for dry air. The conversion from charge to absorbed dose to air also involves the

\* When performing such measurements, it is recommended to turn the detector through  $90^\circ$  rather than rotating the collimator or exchanging the X and Y dimensions of the collimator; doing this prevents the influence of the collimator settings on the monitor chamber being interpreted as a stem leakage effect (see also [Section 19.2.5](#) and [Section 23.2.1.13](#)).

value for  $(W_{\text{air}}/\epsilon)$ , and for consistency in Equation 15.18, the value to be used is that for dry air, i.e.  $33.97 \text{ J C}^{-1}$ .

When calibrating an ionisation chamber at the Standards Dosimetry Laboratory, the charge measured by a vented chamber depends on air temperature and pressure (and also humidity); therefore, the calibration factor must be given for stated reference values of these parameters. Most SDLs supply calibration factors to the user that have been corrected to  $\theta_0=20^\circ\text{C}^*$  and  $P_0=101.325 \text{ kPa}$  without humidity correction. Instead, the relative humidity during calibration is controlled within the range 45–55%, so the calibration factor applies for relative humidity around 50% (in fact, in the range from 20 to 70%, no correction is required<sup>†</sup>). A detailed treatment of the effect of humidity is given in [Appendix D, Section D.4](#).

In the user beam, the correction factor

$$k_{\theta P} = \frac{(273.2 + \theta)}{(273.2 + \theta_0)} \frac{P_0}{P} \quad (15.19)$$

should be applied to convert the measured charge to the reference conditions used for the chamber calibration at the Standards Dosimetry Laboratory.  $P$  and  $\theta(\text{ }^\circ\text{C})$  are the cavity air pressure and temperature at the time of the measurements, and  $P_0$  and  $\theta_0(\text{ }^\circ\text{C})$  are the reference values (usually 101.325 kPa and 20°C). The air temperature in a chamber cavity should be taken to be that of the phantom. This is not necessarily the same as the temperature of the surrounding air, and if a significant difference is observed, the phantom temperature must be checked regularly, or preferably, waiting a sufficient time should allow the phantom to reach the room temperature. In addition, for measurements in a water phantom, the chamber waterproof sleeve should be vented to the atmosphere in order to achieve rapid equilibrium between the ambient air and the air in the chamber cavity.

---

\* In some countries, the reference temperature is 22°C.

<sup>†</sup> In practice, a correction is required only in tropical countries.

## 16.1 INTRODUCTION

Among the wide choice of solid state detectors that can be used for applications in radiotherapy, brachytherapy, diagnostic radiology and radiation protection of the patient, radiothermoluminescent dosimeters (TLD) and diodes are currently the most used (see Figure 16.1). The purpose of this chapter is to give a brief description of the underlying theoretical principles, the materials used, and their main dosimetric characteristics, leaving the reader to refer to the specialized literature on the subject to get the in-depth information that is impossible to provide in a generalist handbook. The practical use of these detectors for in-beam measurements and for quality control of beam characteristics will be presented in Section 19.1.4 and Section 38.4 respectively. Their use for in-vivo dose measurements in external radiotherapy and brachytherapy and for dosimetric comparisons between centres will be presented in Section 40.2.

**FIGURE 16.1**  
(See colour insert following page 590.) Examples of solid state detectors of current use: (a) radiothermoluminescent dosimeters made of LiF or  $\text{Li}_2\text{B}_4\text{O}_7$  doped with Mn or Cu and (b) diodes (1: Sun Nuclear-QED 111200 for electrons; 2 and 3: Scanditronix EDD-5 and EDP-5 for organs at risks and cobalt 60, respectively; 4 and 5: Sun Nuclear QED 111500 and 111600 for 6–12 and 15–25 MV, respectively).

## 16.2 THERMOLUMINESCENT DOSIMETRY

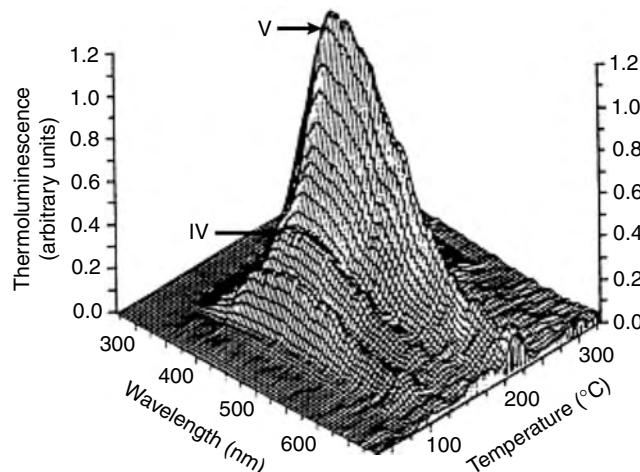

Thermoluminescent (TL) dosimetry has now become a well-established technique. TL materials are readily available commercially and do not require to be linked with a cable to the reading equipment. They also have the advantage of providing a very sensitive dosimeter with a small volume and which when correctly chosen, is equivalent to the different human tissues. The time required for readout is a drawback, but the time can be considerably decreased by choosing an automatic reader and a good methodology.

### 16.2.1 PRINCIPLES OF TL DOSIMETRY

Thermoluminescent dosimetry (TLD) is based on the ability of certain imperfect crystals to absorb and store the energy of ionising radiation that, upon heating, is re-emitted in the form of light. The light is detected, and the light output is correlated to the absorbed dose previously received by them. One of the possible mechanisms to explain it (McKinlay 1981; McKeever 1985) refers to the band theory of the multiatomic crystalline structures.

When *irradiated*, free electrons and holes are produced in the TL material. The electrons are free to travel through the conduction band for a short time. Three outcomes are then possible: they may be trapped at defects (i.e. in a *metastable energy state*); they may fall back into the valence band and recombine with holes either radiatively (fluorescence) or non-radiatively; or they may be captured at luminescence centres already activated by holes as a result of the irradiation and deactivate the centre with the emission of light.

When *heated*, the electrons trapped in the metastable energy states are given sufficient thermal energy to escape from the trap into the conduction band again, where they are free to travel and, as before, have three possible outcomes: either be retrapped at defects, fall into the valence band and recombine radiatively or non-radiatively with holes, or radiatively recombine at a hole-activated luminescence centre. The light emission phenomenon from the last process is called *thermoluminescence* (TL). The thermoluminescent light emission (or glow curve) varies with the mode of heating (linear or isothermal) and the heating temperature (Marinello et al. 1992). Corresponding to the different energy traps in the crystal, the glow curve exhibits several peaks (see Figure 16.2). The unstable low temperature peaks are

**FIGURE 16.2**

Readout thermoluminescence spectra of Bicron-Harshaw LiF 600 dosimeters, previously irradiated by x-rays. Peaks IV and V are stable peaks of light emitted with a wavelength around 450 nm when the dosimeter is heated at temperature around 100 to 200°C used for TL dosimetry. (From Townsend, P. D. et al., *Radiat. Effects*, 72, 245–257, 1983.)

eliminated by preheating. The more stable high temperature peaks, IV and V, are used for dosimetry with readers which allow temperatures up to 400°C and peaks VI and VII can be extracted at higher temperatures. An indication of the emission temperatures and wavelengths of stable peaks of TL materials of current use are shown in [Table 16.1](#).

After readout, the TL material either returns to its original state or requires a special heating treatment called *annealing* in order to restore it. For instance,  $\text{Li}_2\text{B}_4\text{O}_7:\text{Mn}$  or  $\text{Li}_2\text{B}_4\text{O}_7:\text{Cu}$  can be used and re-used many times without thermal treatments between the successive irradiations and readouts. On the contrary,  $\text{CaSO}_4$ ,  $\text{CaF}_2$  and  $\text{LiF}$  require annealing procedures depending on the manufacture of the TL material and on the dose previously received by it (Toivonen 1993; McKeever et al. 1995). The recommended procedure for Harshaw- $\text{LiF}:\text{Mg,Ti}$  is to carry out 4 cycles of 1 h at 400°C + controlled cooling + 20 h at 80°C prior to the first use (*initialisation*). This cycle is also used as an annealing process to allow reuse after irradiation if a dose greater than 0.5 Gy has been given (Driscoll et al. 1986). Some readers include an annealing cycle after each readout, but this lengthens the readout process by 40 s to 60 s per reading, depending on the system.

## 16.2.2 DETECTORS

TL detectors are either generated naturally or by doping phosphors with a very small percentage of *activators* ( $\text{LiF}:\text{Mg-Ti}$  is lithium fluoride doped with magnesium and titanium,  $\text{Li}_2\text{B}_4\text{O}_7:\text{Cu}$  is lithium borate doped with copper, etc.). It should be noted that the characteristics of the pure phosphor dosimeters may differ considerably from those of the composite and depend widely on the percentage of activators (Wall et al. 1982). They are available in the form of powder, solid dosimeters made of polycrystalline extrusions (rods, sintered pellets, or extremity chips) or powder bonded to a polypropylene and plastic substrate (Martin et al. 2000). Some examples are shown in [Figure 16.1a](#).

The TL material to be used is chosen by comparing the parameters of tissue and TLD material that are relevant to the main interactions taking place for the radiation being measured:

**For photon beams**, these are the effective atomic number for the photoelectric effect or pair production or the electron density for the Compton effect depending on the photon energy range (see [Chapter 4](#)). [Table 16.2](#) could be used to choose the TL material with the closest characteristics to those of the studied tissue.

**For electron beams**, the mass collision stopping ratio (ICRU 1984) is more relevant (see [Chapter 3](#)). On this basis,  $\text{LiF}$  and  $\text{Li}_2\text{B}_4\text{O}_7$  can be used for measurements in soft tissues and  $\text{CaSO}_4$  and  $\text{CaF}_2$  in bones because the variation of their mass collision stopping power ratio to that of these tissues is less than a few percent in the energy range from 200 keV to 50 MeV.

Although very useful for choosing the appropriate TL material, these theoretical data must not be used for accurate energy correction because the shape and size of the dosimeter and surrounding material may have a significant influence on its energy response (see [Section 16.2.4.9](#)).

## 16.2.3 READERS

Only commercially available readers used for routine applications in radiation physics and patient dosimetry will be considered in this chapter. Most of them are listed in [Table 16.3](#).

A reader has the following components (see also [Figure 16.3](#)):

*Heating system housed in a readout chamber*: Depending on the reader, the heating system may consist of a metallic support (planchet) heated by an electric current, isothermal fingers, hot nitrogen gas, an infrared sensor using an intense light pulse, or of a laser beam

**TABLE 16.1**

Emission Temperatures and Wavelengths of Dosimetric Peaks of Different TL Materials

Emission Temperature (°C)	300	368	380	400	450	478 and 571	480 and 577	500	600
80–90								CaSO <sub>4</sub> :Mn	
200									CaSO <sub>4</sub> :Sm
200–240	LiF:Mg,Cu,P [GR 200]						CaF <sub>2</sub> :Dy		
210–220				LiF:Mg,Ti [Harshaw]					Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> :Mn
220–250					CaSO <sub>4</sub> :Tm		CaSO <sub>4</sub> :Dy		
240–270	Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> :Cu								
260			CaF <sub>2</sub> :Nat						
300								CaF <sub>2</sub> :Mn	

The peak sensitivity of usual bialkali photocathodes is around 400 nm. As shown in this table, the nature of the doping material (indicated after the colon) has a great influence on the wavelength of the TL emitted light, and therefore, on the type of optical filters to be placed in front of the tube of the photomultiplier (PM) tube.

**TABLE 16.2**

Comparison between TL, Diode Detectors and Human Tissues Irradiated by Photon Beams of Different Energies

Material	Photoelectric Effect $Z_{\text{eff}}$	Compton Effect $e^-/\text{g}$	Pair Production $Z_{\text{eff}}$	Density $\text{g}/\text{cm}^3$
Silicon (diodes) <sup>a</sup>	14	$3 \times 10^{23}$	—	2.33
LiF (Mg,Ti) <sup>b</sup>	8.14	$2.79 \times 10^{23}$	7.50	2.64
LiF (Mg,Ti,Na) <sup>b</sup>	8.14	$2.79 \times 10^{23}$	7.50	2.64
Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> :Mn <sup>b</sup>	7.4	$2.92 \times 10^{23}$	6.90	2.30
Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> :Cu <sup>c</sup>	7.4	$2.92 \times 10^{23}$	6.90	2.30
CaSO <sub>4</sub> :Mn <sup>b</sup>	15.3	$3.02 \times 10^{23}$	—	2.61
CaSO <sub>4</sub> :Dy <sup>b</sup>	15.3	$3.03 \times 10^{23}$	—	2.61
CaF <sub>2</sub> :Mn <sup>b</sup>	16.3	$2.95 \times 10^{23}$	—	3.18
CaF <sub>2</sub> :Dy <sup>b</sup>	16.3	$2.95 \times 10^{23}$	—	3.18
Air <sup>d</sup>	7.64	$3.03 \times 10^{23}$	7.36	$1.293 \times 10^{-3}$
Water <sup>d</sup>	7.42	$3.34 \times 10^{23}$	6.60	1.00
Fat <sup>d</sup>	5.92	$3.48 \times 10^{23}$	5.2	0.91
Muscle <sup>d</sup>	7.42	$3.36 \times 10^{23}$	6.60	1.04

<sup>a</sup> Hall (1994).

<sup>b</sup> McKeever (1985).

<sup>c</sup> Visocikas et al. (1985).

<sup>d</sup> Tubiana et al. (1963).

(see Table 16.3). It must be possible to heat the TL dosimeter to two different temperatures: the preheating temperature used to clear unstable peaks and the readout temperature used to collect the information from dosimetric peaks. Stability and reproducibility of these temperatures must be carefully controlled, requiring close contact between the TLD and its support when a planchet or isothermal fingers are used.

The heating kinetics of TLD depend on the system and have an influence on the dosimetric properties. Heating can be linear (TL material progressively heated to preheating and readout temperatures) or isothermal (TL material quasi-instantaneously heated to both these temperatures). Readers that are designed for the readout of a large number of dosimeters in a short time generally have isothermal heating kinetics (Marinello et al. 1992) or heat the TL dosimeter in hot gas.

The readout chamber must be continuously flushed with nitrogen gas in order to reduce spurious phenomena (McKeever 1985).

*Light detection system:* The luminous flux emitted by the TL dosimeter is collected and guided by a light guide into a photomultiplier tube (PM) tube with a bialkali photocathode (peak sensitivity around 400 nm). This is well adapted to the blue emission of LiF:Mg,Ti or Li<sub>2</sub>B<sub>4</sub>O<sub>7</sub>:Cu, but not necessarily optimal for other TL materials (see Table 16.1). Optical filters placed in front of the PM window considerably improve the response, provided that they are adapted to both the spectral response of the PM and the wavelength of the light emitted by the TL material. A system enabling interchange of the associated filters is a benefit when practical applications requiring the use of different TL materials have to be performed.

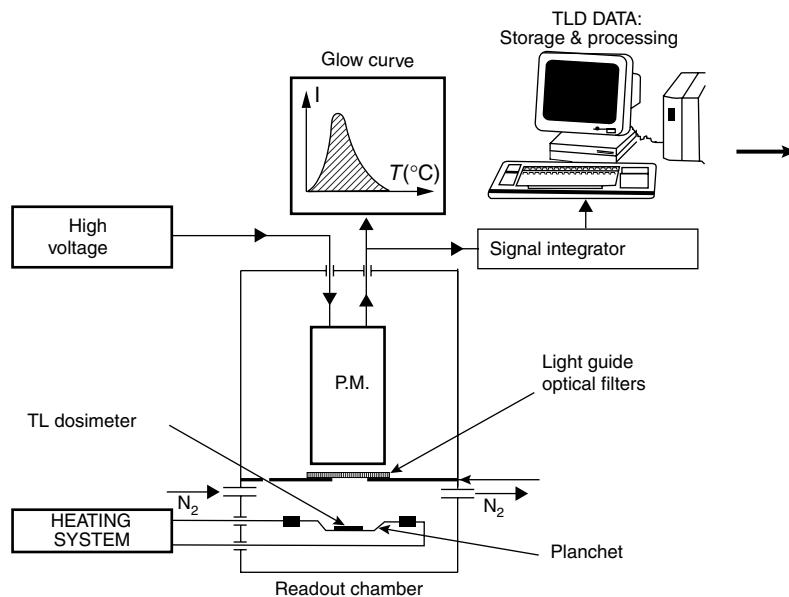

*Signal integrator:* The signal proportional to the light emission is either amplified and fed to an integrator (*d.c. operation continuous integration regimen*) or converted into pulses and fed to a scaler (*pulse counting regimen*). In most readers, glow curves are also displayed during dose measurements. Irrespective of the regimen, the voltage of the PM tube has to be correctly stabilised in order to achieve good reproducibility of measurements.

**TABLE 16.3**

Main Characteristics of TLD Readers Commercially Available in 2006

TLD Reader Companies	Model	Manual or Automatic	Heating Procedure	Maximum Temperature (°C)	Light Detection	TLD Nature	TLD Form
Thermo-Electron (USA)	Harshaw 3500	Manual	Planchet	400	Hamamatsu bialkali PMT fixed optical filter	LiF, CaSO <sub>4</sub>	Powder and solid detectors
Thermo-Electron (USA)	Harshaw 4500	Manual	Planchet and hot nitrogen gas	400 (Planchet) or 600 (Optional) 400 (Gas)	Hamamatsu bialkali PMT fixed optical filter	LiF, CaSO <sub>4</sub>	Powder, solid detectors, capton cards
Thermo-Electron (USA)	Harshaw 5500	Automatic 50 in/25 min	Hot nitrogen gas	400	Hamamatsu bialkali PMT fixed optical filter	LiF, CaSO <sub>4</sub>	Solid dosimeters
FIMEL (France)	LTM	Manual	Planchet	500	Hamamatsu bialkali PMT + interchangeable optical filters	All TL material	Powder and solid detectors
FIMEL (France)	PCL 3	Automatic 45 in/15 min	2 Isothermal fingers	600	Hamamatsu bialkali PMT + interchangeable optical filters	All TL material	Powder and solid detectors

All readers allow the preheating of TLD, and some of them annealing after readout.

**FIGURE 16.3**  
Different components of a TLD reader based on a planchet heating system.

**PC and Associated Software:** Results, which have to be converted to absorbed dose, are either read out and stored by the operator, or most often, automatically saved on a PC. Generally the PC both controls the reading process and allows data management. Computer programs are very different from one manufacturer to another. They may offer direct dose calculations provided individual calibration factors are entered. They may also perform statistical analysis (mean, standard deviation, etc.) and allow processing, display and printout of experimental results. In order to facilitate dosimeter management, some readers are mounted with a bar-code scanner that allows rapid identification of bar-coded TL dosimeters (see example on the top left corner of [Figure 16.1](#)).

#### 16.2.4 DOSIMETRIC PROPERTIES AND INFLUENCE FACTORS

Dosimetric properties should be established for the readout conditions used in practice because they depend upon the heating kinetics. Moreover, characteristics described in this section are only valid for TL materials in their original state or restored by correct annealing (see [Section 16.2.1](#)).

##### 16.2.4.1 Reproducibility

Achievable reproducibility is very dependent on the quality of the TL material, the type of reader used, and the purity of the nitrogen gas circulating in the readout chamber (use of N<sub>2</sub> containing less than 5 µL/L of O<sub>2</sub> is recommended to avoid non-dose-related luminescence). In addition, the operator must take care that the adjustments of the reader are correctly selected and check that the shape of the glow curve is normal (McKeever 1985; McKeever et al. 1995; Mayles et al. 2000).

The reproducibility can be evaluated by randomly taking ten samples of TL powder or dosimeters of the same batch, inserting them into a phantom made of tissue-equivalent material, and delivering them the same dose in the same irradiation conditions.

After readout (and annealing procedure when necessary), the operation is repeated several times. When readout parameters have been optimised, a standard deviation of  $\pm 2\%$  or less can routinely be obtained with either manual or automatic readers of good quality associated with reliable TL materials (Kirby et al. 1992; Marinello et al. 1992; Toivonen 1993).

#### 16.2.4.2 Background Signal

The background signal is the dose recorded with unirradiated dosimeters. It comes from several sources:

- The dark current of the photomultiplier, which can be very low if the PM power supply is permanently on and if the photomultiplier is not exposed to ambient light (if it happens accidentally, the instrument should be left for several hours to settle down)
- The background luminescence because of chemical interactions at the surface of the dosimeters or, with powder, to movements in the crystal lattice (tribothermoluminescence). It is reduced by reading out the dosimeters in an atmosphere of oxygen-free nitrogen (see [Section 16.2.3](#))
- Residual signals from previous irradiations that can be removed by the annealing procedure (see [Section 16.2.1](#)).

The background signal should be evaluated with unirradiated TL samples read out with the same reader. Although for most measurements in radiotherapy, it is not a significant problem; it is preferable to subtract background signal from measurements particularly when low doses are expected. Some readers allow this to be done automatically.

#### 16.2.4.3 Detection Threshold

The detection threshold is the minimum dose that can be detected by the TL material. It depends on the sensitivity of the material and on the background signal. As an indication, the detection threshold is approximately 10  $\mu\text{Gy}$  for LiF:Mg,Ti and 1  $\mu\text{Gy}$  for LiF:Mg,Cu,P (Wang et al. 1993; Zha et al. 1993) provided that they are read out with readers equipped with a PM tube and associated filters adapted to the wavelength of the emitted light. For lithium borate TLDs doped with Mn and Cu, the thresholds are approximately 40  $\mu\text{Gy}$  and 10  $\mu\text{Gy}$ , respectively (Wall et al. 1982).

#### 16.2.4.4 Fading

Fading is the decrease of TL response because of the loss of some of the charges initially trapped, between the end of the irradiation and the readout. It can be caused by the influence of heat, even at room temperature (*thermal fading*), or by an unwanted exposure to light (*optical fading*).

Thermal fading can be considerably reduced by appropriate preheating, but it can never be totally eliminated (see [Table 16.4](#)). In practice it is important:

- To avoid the use of TL materials that are subject to significant thermal fading (for instance CaF<sub>2</sub>:Mn) and to evaluate thermal fading with the reader together with the TL material intended to be used. If it is greater than the expected value indicated in the table (i.e. 1% per month or less for the different preparations of LiF or 1% per week or less for Li<sub>2</sub>B<sub>4</sub>O<sub>7</sub>, depending upon the doping), it means that optimal readout and annealing conditions have not been reached;
- To introduce a fading correction when a long delay separates irradiation from readout.

*Optical fading* can be avoided by manipulating the dosimeters in a room illuminated with incandescent light and wrapping them in opaque containers or envelopes when used in rooms illuminated with fluorescent light.

**TABLE 16.4**

Dosimetric Properties of Some TL Material

TL Material	Linear Zone (Gy)	Saturation (Gy)	Thermal Fading
LiF:Mg,Ti <sup>a</sup>	$5 \times 10^{-5}$ to 1	$10^3$	5% to 10% per year
LiF:Mg,P,Cu <sup>c</sup> [GR 200]	Up to 12	>40	No evidence over 100 days
Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> :Mn <sup>a</sup>	$10^{-4}$ to 3	$3 \times 10^4$	2.5% per month
Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> :Cu <sup>b</sup>	$5 \times 10^{-4}$ to 120	$10^3$	4% per month
CaSO <sub>4</sub> :Dy <sup>a</sup>	$10^{-6}$ to 30	$10^3$	1% to 5% per month
CaSO <sub>4</sub> :Mn <sup>a</sup>	$10^{-7}$ to 30	$10^2$	10% per month
CaF <sub>2</sub> :Dy <sup>a</sup>	$10^{-5}$ to 10	$10^4$	25% per month
CaF <sub>2</sub> :Mn <sup>a</sup>	$10^{-5}$ to 10	$10^3$	7% per day

Except Li<sub>2</sub>B<sub>4</sub>O<sub>7</sub>:Cu all TLD are distributed by Thermo-Electron (USA).<sup>a</sup> McKeever (1985).<sup>b</sup> Wang et al. (1993).<sup>c</sup> Visocekas et al. (1985).

#### 16.2.4.5 Mass

**TL Powder:** Because the TL signal is generally proportional to the mass, samples of equal weight must be used or a correction factor taking into account the mass of each sample introduced. It should be also noted that some TL material such as Li<sub>2</sub>B<sub>4</sub>O<sub>7</sub>:Cu or some LiF powders have a response that can be considered as independent of mass, within a certain range of masses, when they are read out with readers using isothermal kinetics (Marinello 1994). In this case, it is not necessary to weigh the samples; a simple volumetric measurement is sufficient.

**Solid TL Dosimeters:** For manufacturing reasons, variations in sensitivity within a batch of dosimeters are unavoidable. Two methods can be used to limit the effect of these variations (Van Dam and Marinello 1994).

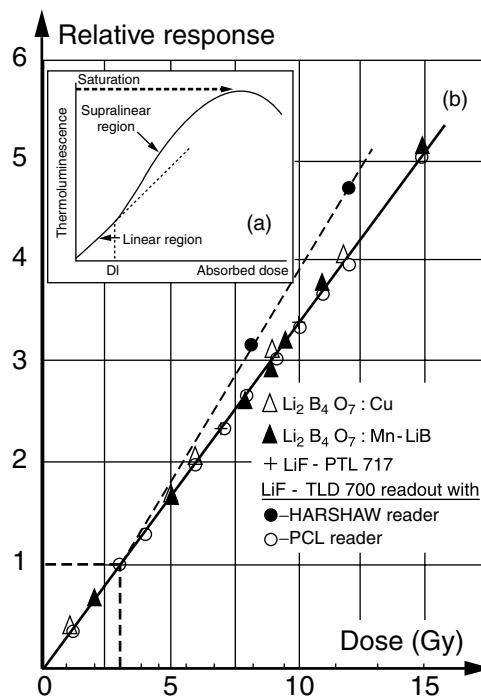

One consists of individually identifying each dosimeter, irradiating them all together in the same geometrical conditions, reading them out and attributing to each of them a sensitivity factor  $S_i$  equal to  $R_i/R$  where  $R_i$  is the TL readout from dosimeter number  $i$  and  $R$  the mean of all values of  $R_i$ . Sensitivity factors should be periodically checked in order to take into account a possible loss of material occurring when TL dosimeters are not handled carefully.

The other consists of separating the TL dosimeters into sensitivity groups (i.e. groups of dosimeters with a response less than  $\pm 1$  or  $\pm 2\%$  from the group mean response) and using a larger number of dosimeters used for each point of measurement. The distribution of sensitivities within a group should be periodically checked for the same reasons as explained above.

Both methods can achieve similar accuracy, the second one being faster when a large number of measurements have to be performed particularly if an automatic reader is available.

#### 16.2.4.6 Dose

Generally, the response variation curve of TL materials with dose comprises a linear, a supralinear, and a sublinear region followed by saturation (Figure 16.4a). The importance of the different regions depends on the TL material, the nature and the energy of the particles used to irradiate it and the readout parameters. For LiF, for instance, when the heating kinetics and maximum temperature of the readout system allow the extraction of nearly all the TL peaks, the dose curve is linear over a much greater range than when the reader allows the extraction of peaks IV and V only (see Section 16.2.1 and Figure 16.4b). With such optimal readout conditions, it has been shown that most lithium fluorides and borates irradiated with a cobalt-60 beam have a dose response curve that can be considered as linear up to 12 Gy

**FIGURE 16.4**

(a) General shape of a typical TL curve as a function of absorbed dose. (b) Results of measurements performed with different TL materials and different readers. The dose response curve (normalised to 1 for 3 Gy) for LiF-TLD 100 material obtained with the BICRON-HARSHAW reader, which uses isothermal heating kinetics, is linear (open circles) whereas it is supralinear in the same dose range with the FIMEL-PCL reader (closed circles and dashed line), which uses adiabatic heating kinetics. (From Marinello, G. et al., *Radiother. Oncol.*, 25, 63–66, 1992.)

(Marinello et al. 1992). Because of this dependence on the exact readout conditions, the dose response curve must be established with the reader and the TL material that are intended to be used. Data shown in Table 16.4 is given as an indication only and may be not valid for modern readers that allow for greater readout temperatures.

In practice, it is recommended that TL dosimeters are used in the linear region. When this is not the case, a correction should be applied to the signal from a curve established locally and this should be checked periodically. TL dosimeters must not be used in the sublinear region approaching saturation.

#### 16.2.4.7 Dose-Rate

TL dosimeters are, to a large extent, dose-rate independent. As shown by Tochilin and Goldstein (1966) and Goldstein (1972), LiF and  $\text{Li}_2\text{B}_4\text{O}_7:\text{Mn}$  are independent of the dose-rate up to 45 and 1000 Gy per pulse of 0.1  $\mu\text{s}$ , respectively. That means that no correction is needed in practice to take into account the dose-rate variations produced by beam modifiers, SSD variations, patient thicknesses, etc. This consideration also makes TLD very useful for dose measurements in intensity modulated beams.

#### 16.2.4.8 Temperature

As the temperature required to obtain the light signal out of the TL crystal is high compared to room or patient temperature, the response of TL dosimeters is independent of temperature in usual conditions of use. However, care should be taken not to store the dosimeters close to a heating device (such as a radiator).

### 16.2.4.9 Energy

As mentioned in [Section 16.2.2](#), it is very important to choose a TL material in agreement with the intended use.

*Photon energies below 300 keV:* For experiments performed in water or tissue-equivalent material irradiated with photon energies below 300 keV, TL dosimeters should be very thin and used without a build-up cap. Lithium borates are preferred to LiF and a fortiori to other TL materials because their effective atomic number is comparable to that of tissue in the photoelectric range (see [Table 16.2](#)). Theoretical data such as the mass energy absorption coefficient ratio to tissue can be used whenever the TL dosimeter is sufficiently small (Jayachandran 1970). For very low photon energies (below 50 keV), a theoretical calculation of the energy response is no longer possible because the shape and dimensions of the detector can induce considerable response variations within the dosimeter volume (Bassi et al. 1976; McKeever 1985; Davis et al. 2003). Moreover, the nature of the activator may also cause large differences in the response of TL materials in this energy range (Wall et al. 1982). The only solution consists of directly comparing the response of the TL dosimeters to a calibrated ionisation chamber specially designed and calibrated for low energy x-rays (see [Section 18.6](#)).

*High energy photon beams:* For dose measurements in media irradiated with high energy photon beams, all TL materials can be used except with very high energy photon beams that are sometimes contaminated by neutrons. LiF enriched with  $^6\text{Li}$  and  $\text{Li}_2\text{B}_4\text{O}_7$  responds to slow neutrons via reactions with  $^6\text{Li}$  and  $^{10}\text{B}$ , and for such high energy photons it is preferable to use LiF enriched with  $^7\text{Li}$  that is insensitive to neutrons. Except for superficial measurements (see [Section 40.2.3.1](#)), TL dosimeters should be surrounded by a suitable build-up cap corresponding to the energy and geometrical irradiation conditions, in order to ensure electronic equilibrium (Van Dam and Marinello 1994 and [Section 40.2.3.2](#)). When the build-up cap is made of tissue-equivalent material, it is theoretically possible to evaluate the absorbed dose in TL dosimeters knowing the relative variation of mass energy absorption coefficient between the TL material and water as a function of photon energy. In practice, because of the influence of the surrounding material (build-up cap and patient), the sizes and shapes of the TL dosimeters may modify the expected results by a few per cent (Mobit et al. 1996a). The heating conditions may also modify the results slightly (McKeever 1985). The most reliable method consists of directly comparing the TL dosimeter and its associated build-up cap to a calibrated ionisation chamber.

*High energy electron beams:* When the irradiation is performed with high energy electron beams, it is theoretically possible to evaluate the absorbed dose in TL dosimeters knowing the variation of the ratio of the mass collision stopping power of the TL material to that of tissue or water as a function of energy. This variation is less than 2% for LiF and less than 5% for  $\text{Li}_2\text{B}_4\text{O}_7$  in the energy range from 200 keV to 50 MeV (ICRU 1984). In practice, and for the same reasons as for photon beams, it is preferable to make a direct comparison between the response of the TL dosimeters to be used the dose measured with a calibrated ionisation chamber. The validity of the method has been verified by different authors (Holt et al. 1975; Bagne 1977; Mobit et al. 1996b; Marre et al. 2000).

### 16.2.4.10 Directional Effect

Irrespective of the conditions of use, no correction for directional effect is necessary except if the dosimeter container and associated build-up cap have an asymmetric shape (e.g. flat dosimeters should be oriented normal to the incident beam).

---

## 16.3 DIODE DOSIMETRY

Diodes are useful for dosimetric purposes (Huyskens et al. 2001; AAPM 2005) mainly because they have a high sensitivity within a small volume (see [Figure 16.1](#)), a good spatial

resolution, and a real-time response. They can yield accurate measurements provided that their response is regularly monitored and corrected by factors taking into account both the aging of the diode and the irradiation conditions (field size, dose-rate, etc.).

### 16.3.1 PRINCIPLES OF DIODE DOSIMETRY

Most diodes are made of silicon, which is a crystalline material in which atomic electrons are arranged in bands of energy. During irradiation, electron–hole pairs are created. Conduction occurs by movement of electrons in the conduction band and by motion of hole states in the valence band. The gap between the valence and the conduction band is large enough to prevent rapid thermal repopulation of electrons (or holes). The number of charge carriers is controlled by doping the material with impurities like phosphorus, arsenic, or boron. Depending on the element used, the crystal is given either an excess or a deficit of free electrons that can carry electrical current. An excess of electrons carries a negatively charged current, giving an *n-type* semiconductor; whereas, an electron deficit (often described as an excess of electron *holes*) carries a positively charged current giving a *p-type* semiconductor.

A diode is typically formed by implanting a high density of p-type atoms into a lightly doped n-type substrate. Using silicon as a substrate, there are two major classes of detectors: the Charge Coupled Device (CCD) that is based on arrays of Metal-Oxide-Silicon (MOS) capacitors, and the p–n junction diodes that will be the only one considered in this section. Details for both types of detectors can be found in Hall (1994) and Barthe (2001).

### 16.3.2 DETECTORS

Commercially available diodes are generally made of a small quantity of silicon doped with phosphorus (n-type diodes) or boron (p-type diodes). They are encapsulated in caps of various natures, shapes and dimensions. Their design depends on the manufacturer and is different for photon beams or electron beams ([Figure 16.1b](#)). The diode cap ensures mechanical protection and acts as build-up material for photon beams. For diodes dedicated to in vivo measurements, the cap is generally made of tissue-equivalent material (polystyrene or epoxy), but stainless steel or tantalum are sometimes used in the construction in order to reduce its bulkiness and to provide filtration, making diode response less dependent of photon energy. In practice, it is important to know the diode cap's characteristics before undertaking measurements and to check that its shape and thickness are well adapted to the irradiation conditions and do not cause too much perturbation of the dose distribution (Sen et al. 1996; Marre and Marinello 2004). The nature and thickness of the caps of most of the diodes that are commercially available in 2006 are shown in [Table 16.5](#). Intracavitary detectors that consist of diodes mounted within flexible probes and specifically designed for intracavitary measurements are not listed in the table.

Diodes from different manufacturers are generally easily identified by their shape and colour. As relatively large differences may occur between responses of diodes of the same type, it is recommended that each diode should be individually labelled with a number attached to its cable.

### 16.3.3 ELECTROMETERS

In order to minimize leakage, diodes for dosimetry are operated without external bias voltage, their signals are measured either in open-circuit mode (voltage) or in short-circuit mode (current). This last mode, most often encountered in commercial electrometers, offers

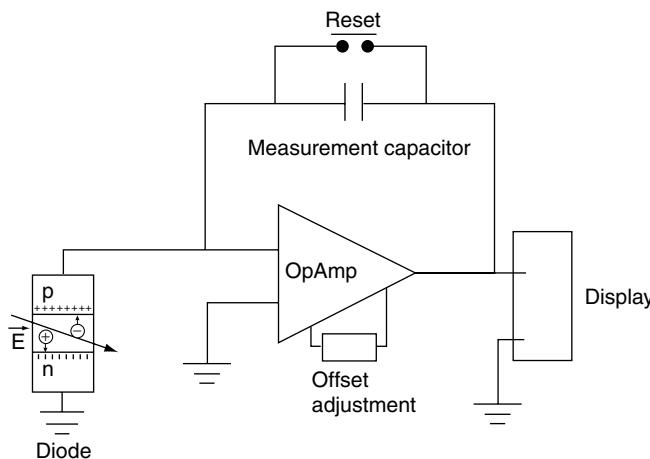

**TABLE 16.5**

Main Characteristics of Diode Systems Dedicated to Patient Monitoring (In Vivo Dosimetry) and Commercially Available in 2006

Company	Electrometers	Detector		Radiation Quality	Build-Up Cap		Pre-irradiation Dose
		Name	Type		Material	Thickness (g/cm <sup>2</sup> )	
Cardinal Health Radiation Management Services	Veridose PDMQC <sup>a</sup> (5 channels)	30-471	n or p	1–4 MV	Brass	0.732	20 kGy with high energy electrons
		30-472	n or p	5–11 MV	Brass	1.369

		QED 111200	n or p	Electrons	Acrylic	0.30	

Intracavitary detectors are excluded from this table.

<sup>a</sup> Can also be connected to a beam uniformity quality control device.<sup>b</sup> QED diodes were p-type from 1997 to 2002 and n-type from 2003.

**FIGURE 16.5**  
Principle of diode detection in short-circuit mode.

the advantage of producing a linear relationship between the charge generated in the diode and the dose (Figure 16.5).

Two types of equipment are generally available.

The devices dedicated to *patient dose monitoring* consist of multichannel electrometers (number of channels varying from 2 to 12), allowing the use of several individual diodes at the same time (Table 16.5). Most electrometers provide zero level adjustments for each diode, and also allow individual calibration factors to be applied to the diode signals so that readings can be directly displayed as absorbed dose. Some systems also provide a correction factor that accounts for differences between calibration and clinical conditions.

The devices dedicated to *quality control of linac beams* consist of electrometers linked to special phantoms in which diodes are embedded at fixed positions. At least five diodes are used to measure beam output as well as symmetry and uniformity. More recently, specific devices including arrays of several hundreds of diodes have been developed for quality control of intensity modulated beams (see Section 38.9.3).

Some electrometers are compatible with both of these applications.

Irrespective of their type, electrometers can often be interfaced with a standard printer that allows output of report including the date and time at which measurements were made, descriptions of the measurement conditions, and the results in terms of the dose delivered to the patient or linac quality control data. Most of the recent devices are computer controlled or can be interfaced with a PC providing long term storage and further processing of data.

#### 16.3.4 DOSIMETRIC PROPERTIES AND INFLUENCE FACTORS

Measurements with diodes should be performed under conditions of electronic equilibrium. If the built-in build-up is not sufficient for the particular energy, an additional build-up cap can be placed on the diodes or they can be inserted into a special phantom drilled with holes of the appropriate dimensions with enough material in front of them. It should also be noted that dosimetric properties are not only dependent on the diode design, but they are also influenced by the doses accumulated by the diode so that they must be determined for each diode and regularly checked.

##### 16.3.4.1 Repeatability and Reproducibility

The attainable repeatability and reproducibility depend on the quality of both the diodes and the associated electrometer. Repeatability can be evaluated by measuring the signal for at

least ten consecutive irradiations with the same dose delivered in the same conditions of irradiation. Assessment of reproducibility requires that measurements are repeated over a longer period of time (e.g. daily during one week). The standard deviation for both of them should be less than 1%.

#### 16.3.4.2 Fading

Fading is the drift of signal that can be observed after irradiation. It can be evaluated by measuring the signal at increasing delays after irradiation with the same dose delivered in the same geometrical conditions. The diodes and the associated electrometer should have a drift less than 1% in 1 h.

When diodes are intended to be used for continuous measurements during a long period of time such as when measuring the patient dose for low-dose-rate total body irradiations, the checks should be extended over a period of several hours.

#### 16.3.4.3 Detection Threshold

The detection threshold depends both on the electrometer and on the active volume and doping level of the semiconductor detector. The pre-irradiation dose and the doses subsequently accumulated also have an influence on it. For commercially available systems and new pre-irradiated diodes, the detection threshold varies from 0.1 cGy to some tenths of cGy.

#### 16.3.4.4 Background Signal

The background signal is due to thermally generated charge carriers. It causes problems only if the electrometer's input offset voltage is not zero. The effect is strongly temperature-dependent and appears to be greater for n-type diodes than for p-type diodes. Although the current can be zeroed out before measurements are taken, several minutes are necessary to obtain a satisfactory background measurement, and any subsequent change in temperature will upset the balance of the circuit and cause a change in diode response. This problem should be taken into account when diodes are used for in vivo measurements, because the temperature of the patient's body is different from the room temperature (see [Section 16.3.4.7](#)).

#### 16.3.4.5 Dose

All silicon diodes show a loss of sensitivity as a function of accumulated dose because of radiation damage that displaces silicon atoms from their lattice sites. This introduces recombination centres that capture charge carriers, leading to a reduction in sensitivity and increased dose-rate dependence (Rikner and Grusell 1983). The effect depends on the doping level of the diode and is more pronounced for *n-type* than for *p-type* diodes because holes are more easily trapped than electrons (Grusell and Rikner 1984, 1993; Van Dam et al. 1990). It is also more important when the irradiation is performed with electron beams than with photon beams: after Rikner and Grusell (1987) the amount of damage for a given dose is 20 times more important with 20 MeV electrons than 8 MV photons and increases as a function of energy for both the particles. Moreover Rikner and Grusell (1983) have shown that the steep decrease in sensitivity observed for new diodes was considerably reduced after an irradiation of 20 kGy with 18 MV x-ray beams or 5 kGy with 20 MeV electron beams. This is the reason why most companies sell pre-irradiated diodes ([Table 16.5](#)). It is recommended that diodes that have not been pre-irradiated by the manufacturer are given a high dose before use. Once this has been done, if the electrometer is used in integration mode, the variation of response of diodes as a function of dose is generally linear in the range 1 Gy to 11 Gy (Van Dam and Marinello 1994).

### 16.3.4.6 Dose-Rate

For the reasons previously given in [Section 16.3.4.5](#), diode sensitivity increases as dose rate or dose per pulse increases (Grusell and Rikner 1984; Van dam et al. 1990). The effect is essentially dependent on the doping level and not always more pronounced for n-type than for p-type diodes (Shi et al. 2003). Although reduced by an adequate pre-irradiation of the diode, it remains significant in the dose range encountered in practice and results either in a non-linearity of dose response with dose-rate for n-type detectors or in a limited linear dependence for p-type ones (Grusell and Rikner 1993). As pointed out by Van Dam and Marinello (1994), the dose-rate dependence of a diode should be taken into account for linacs that offer the choice of different monitor unit rates by variation of pulse intensity (not of pulse repetition frequency) or those where the field flatness is achieved by magnetically scanning an electron pencil beam of high intensity over the irradiation field. The dose-rate dependence of a diode also deserves special attention when depth-dose or dose-profile measurements are carried out. When wedge filters, compensators, or shielding blocks are used, they induce simultaneous variations in dose rate and beam quality. Similar problems can be encountered when diodes are used with intensity modulated radiation therapy. Diode response changes of several percent can be observed in such cases. Consequently, it is recommended that diodes are always calibrated in the dose-rate range for which they will be used and it is not advisable to use them when the dose-rate is likely to vary considerably as a function of time.

### 16.3.4.7 Temperature

Many authors (Grusell and Rikner 1986, 1993; Van Dam et al. 1990; Heukelom et al. 1991; Welsh and Reinstein 2001; Saini and Zhu 2002; Marre and Marinello 2004) have reported an increase of diode response with temperature probably because of an increase of the energy of the charge carriers that escape from recombination. The increase in sensitivity with temperature is reduced, or even eliminated, when diodes are correctly pre-irradiated. In practice, it is recommended that the increase in sensitivity with temperature is determined for each new diode and checked periodically. For in vivo measurements, as long as the variation remains less than 0.1% per °C, it is not necessary to correct for the difference between the room (where the calibration takes place) and the patient's skin temperature. It must, however, be ensured that the electrometer is zeroed out some minutes after the diodes have been placed on the patient. If it exceeds 0.4% per °C, the diode must be eliminated or correction factors must be introduced.

### 16.3.4.8 Energy

Because of their high effective atomic number compared to that of water or human tissues ([Table 16.5](#)), diodes are not tissue equivalent for photon energies below  $^{60}\text{Co}$ . This was experimentally confirmed by Heukelom et al. (1991) and Edwards et al. (1997) and is of particular concern for conventional x-rays or scattered radiation.

*Compensated diodes* as described by Rikner and Grusell (1985) can be used without problem for dosimetry in water or tissue-equivalent material irradiated by high energy photon beams because they are shielded from low energy scattered radiation. Nevertheless, care must be taken when making measurements at depths or in fields where low energy scattered radiation contributes a substantial fraction of the dose, as for instance when measuring doses under shielding blocks or beyond the edge of the irradiation field.

In the case of measurements performed in high energy electron beams, the stopping power ratios of silicon to water vary less than 3% between 3 MeV and 50 MeV (ICRU 1984). That means that diodes can give good results in practice provided their build-up cap is very thin and made of tissue-equivalent material (Eveling et al. 1999; Marre and Marinello 2004).

In any case, it is advisable to measure the energy response of a diode in the beam or energy range in which it is intended to be used.

#### 16.3.4.9 *Directional Effect*

This effect is related to the shape and construction of the diodes which do not always have a symmetrical shape in all directions (Figure 16.1b). Because of the lack of symmetry, the response of the detector can change according to the beam angle when the diode is on the beam axis, or when off-axis measurements are performed. The directional effect also depends on the beam parameters such as energy and field size, so its importance should be evaluated in the expected experimental or clinical conditions and with diodes that will be used for measurement. Generally, the correction can be neglected for incidence angles less than  $\pm 30^\circ$ , but it can reach more than 5% for some detectors for incidence angles larger than  $50^\circ$  (Van Dam and Marinello 1994; Marre and Marinello 2004). Moreover Mayles et al. (1993) have pointed out the asymmetrical response of domed diodes that can be as much as 15% when irradiated by mistake on the flat side instead of the domed one. They also mentioned that the symmetrical response of cylindrical detectors can be reduced by about 15% if irradiated from the tip.

---

## 16.4 CONCLUSIONS

Both TLD and diodes have the advantage, compared to ionisation chambers, that they do not need to be connected to a high voltage supply; but they both require correction for energy response. Diodes have an advantage over TLD because of their real time response but are inferior with respect to their need for a cable connection and their response variation as a function of accumulated dose, dose rate, and temperature and directional effects. Both detectors should be handled by physicists or operators who know the correction factors to be applied; otherwise, the results obtained will not be accurate. The equipment should also be checked regularly in order to maintain its performance. A typical list of checks to be performed can be found in the book chapter of Mayles et al. (1993) or in other specialized publications.

## 17.1 INTRODUCTION

Radiographic film is the dosimeter of choice for a wide range of therapeutic and diagnostic applications in radiation-therapy departments. It is particularly useful for qualitative measurements of ionising radiation beams (e.g. high and low energy x-rays and beams of electrons and protons) and the verification of clinical radiation treatments both prior to and during therapy. For many years, film has been used to verify light-field and radiation-field coincidence and beam homogeneity of a linear accelerator. Films are also often used to verify the correct set-up of a megavoltage therapeutic beam with respect to the patient by means of a portal image of the beam as it exits the patient (see [Section 40.1](#)). These applications all benefit from the primary strengths of film that include high contrast (image quality), high spatial resolution and high sensitivity. The limitations of radiographic film include a variation of response as a function of photon energy, a high sensitivity to processing conditions\*, and the fact that film is only useable in the form of thin two-dimensional (2D) sheets that do not easily lend themselves to the examination of complex dose-distributions in 3D. The advent of multi-detector arrays (Jursinic and Nelms 2002; Letourneau et al. 2004) which can be convenient, are near-real time, do not require processing, and can directly interface to computer read-out, has led to a decline in the use of film in many clinics. Recently, this trend has somewhat reversed as many clinics implement Intensity Modulated Radiation Therapy where it is common practice to compare 2D computed dose distributions with film measurements in the same conditions (Dogan et al. 2002; Bucciolini et al. 2004). Ideally, IMRT would be verified through a comprehensive measurement of the distribution in 3D, and this has led to the development of radiation sensitive gels and plastics that respond and can be imaged in 3D, giving more complete information for complex distributions. Gel dosimetry is a relatively new development to the field of dosimetry and is discussed further in the second part of this chapter (see [Section 17.3](#)).

---

## 17.2 FILM DOSIMETRY

### 17.2.1 THE RADIOGRAPHIC PROCESS

The basic physical mechanisms of image formation and development are the same for both radiographic and photographic film. The active component of radiographic film consists of a gelatin emulsion that suspends small radiation sensitive silver-halide crystals (e.g. silver-bromide AgBr). The emulsion is evenly coated onto both sides of a polyester base that provides the stiffness and mechanical stability of the film. Stiffness is required for handling purposes (e.g. viewing on a light-box), and stability is required to avoid film expansion during exposure to heat and chemicals during development. Adhesive is used to ensure that the emulsion remains attached to the base throughout development, and the whole film is coated with a strong protective gelatin super coat that protects the soft emulsion from scratches and skin oils during handling. Details of film manufacture and the active chemical ingredients can be found, for instance, in [Chapter 19](#) of Carlton and Adler (2005).

### 17.2.2 THE LATENT IMAGE

The key mechanism utilised by radiographic film is the formation of a latent image in the emulsion of the film by incident ionising radiation. The latent image is then amplified and

---

\* With the increased use of digital radiography leading to less use of film for other purposes, maintaining the stability of processors is becoming more of a challenge. Radiochromic film (see [Section 17.2.7](#)) provides a useful alternative to traditional silver based film. Computed radiography (CR) systems such as the Kodak 2000RT may also provide a partial solution.

rendered visible by chemical development. Gurney and Mott (1938) initially proposed the theory of latent image formation, and although some areas are still not fully understood, this theory remains largely unchallenged today. Each radiation sensitive crystal, or grain, in the emulsion can be thought of as a cubic lattice containing  $\sim 10^{10}$  atoms. The silver-bromide molecules orientate such that the halide ions (bromine and iodine) congregate on the surface of the grain, presenting a negatively charged exterior. The centre of the grain has a net positive charge because of the preponderance of silver ions. Both electrons and silver atoms (or ions) are able to drift through the lattice.

Incident photons generate free electrons inside the grain through the photoelectric, Compton and pair production effects. These electrons get trapped on impurity molecules known as sensitivity specks that are incorporated in the grain surface and may protrude out from the grain surface. The sensitivity speck becomes negatively charged and attracts mobile silver ions that then recombine to form silver atoms on the surface of the sensitivity speck. A single incident photon may free thousands of electrons for deposition at the sensitivity speck. Not all free silver atoms are deposited at the speck, but it is estimated that at least three must be deposited for the entire grain to be rendered developable. The latent image corresponds to the conglomeration of silver ions near the speck and to the deposition of, at least, three silver atoms on the sensitivity speck that stabilise the speck and allow it to act as an electron gate into the grain during the development of the film.

### 17.2.3 FILM PROCESSING

Film processing involves rendering the latent image visible by chemical amplification. It involves the following steps:

- (1) *Developing*—The alkaline, electron-rich reducing agents in the developer fluid supply electrons to the interior of the grain through the sensitivity speck that acts as an electron gate. Grains that were exposed to high doses of radiation have larger sensitivity specks that correspond to more efficient electron gates. When developing is stopped, the amount of black metallic silver deposited in the grain is in proportion to the size of the sensitivity speck gate. It is this proportionality that leads to the exquisite grey-level contrast in film images. If a film is left in the developer, electrons will eventually get into even those grains without a sensitivity speck gate. The presence of the gate differentiates between irradiated and un-irradiated grains, but only within the short term. Further details of latent image formation and amplification can be found in Chapter 3 of Herz (1969).
- (2) *Fixing*—the acidic environment of the fixing fluid (or stop bath stage) quickly stops the developing process of the latent image. Clearing agents (usually sodium thiosulphate) bond with undeveloped silver halide molecules, removing them from the emulsion. The darkened appearance of irradiated film is caused by black metallic silver deposited during latent image formation and amplified during developing that remains unaffected during fixing of the film.
- (3) *Washing*—the film is then washed in pure water to remove most of the fixer and developer from the film, and it is then air-dried. Poorly washed films will suffer silver and/or yellow emulsion staining under long-term residual chemical action.

### 17.2.4 FILM BLACKENING AND OPTICAL DENSITY

The degree of film blackening after irradiation and processing can be quantified by determining how much a beam of light is attenuated as it passes through the film. The degree of blackening thus measured is known as the light opacity and is defined as  $I_0/I$  where  $I_0$  is the light intensity measured in the absence of the film, and  $I$  is the intensity transmitted through the film in a perpendicular manner. A more useful quantity is the optical density (OD) of the film, defined as the  $\log_{10}$  of the light opacity (see below), because it is proportional to dose within

limiting conditions. Theoretically, this linearity can be understood with the following simplified model. If the average area obscured by a single grain of silver (i.e. the cross-section of a single developed silver bromide grain) is  $\alpha$ , and  $N$  is the number of developed grains per  $\text{cm}^3$ , then the intensity  $I(z)$  of light after passing through a depth  $z$  of film will follow Beer's law

$$I(z) = I_0 e^{-\alpha Nz} \quad (17.1)$$

where  $I_0$  is the light intensity without film.

If it is assumed that a single photon hit renders a grain of silver bromide developable and that all grains present the same area,  $\alpha$ , to the fluence, then the number of grains that are made developable is  $N = N_{\text{AgBr}} \alpha \phi$ , providing  $N \ll N_{\text{AgBr}}$ , where  $N_{\text{AgBr}}$  is the initial number of undeveloped grains in the unirradiated film, and  $\phi$  is the photon fluence. Substituting this into Equation 17.1 and taking the logarithm, the optical density is defined as:

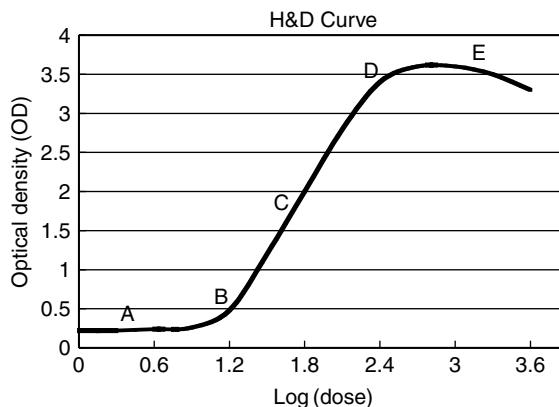

$$\text{OD} = \log_{10} \left( \frac{I_0}{I(z)} \right) = \alpha^2 N_{\text{AgBr}} z \phi \times 0.4343 \quad (17.2)$$

For low fluence where  $N \ll N_{\text{AgBr}}$ , the optical density is proportional to the fluence,  $\phi$ , and hence, the dose. In practice, the optical density is linear with dose only in the limited range before saturation effects occur. Equation 17.2 demonstrates that the most effective way to alter the speed of the film is to increase  $\alpha$ , the cross-section of the grain and then to increase the film's thickness. Extensions of this simplified theory are given in [Chapter 4](#) of Shani (2000).

The instrument used to measure the optical density of a film is called a *densitometer*. A simple densitometer consists of a calibrated light source, a stage on which to place the film to be measured, a light aperture to control the amount of light from the source and an optical sensor on a moveable arm. The densitometer is calibrated to read zero on an unirradiated part of the film prior to reading optical density values in the irradiated film. The amount of light transmitted through the film is measured and displayed by the densitometer, which normally gives a read-out calibrated to optical density values. More complex scanning densitometers automatically move the light source and sensor over the film in a Cartesian grid to build up the 2D image of the optical density variations across the film. In all cases, it is necessary to check the densitometer response using a calibrated optical wedge consisting of a film exposed to multiple known light intensities resulting in known optical density steps. Calibrated optical wedges are generally supplied with new densitometers. They can also be produced locally by exposing a piece of film to a special illuminating device called a *sensitometer*. Films exposed with sensitometers are used to check the constancy of film batches and film processing.

### 17.2.5 CHARACTERISTIC FILM CURVES

The responses of different films vary with many factors including the manufacturers, the radiation energy, and daily fluctuations in the relative chemical components in the developer unit. Manufacturers customarily use a characteristic curve to describe their film performance. Characteristic curves are commonly referred to as H&D curves after Hurter and Driffield who first described one in 1890. The H&D curve plots *optical density* versus  $\log_{10}(\text{dose})$  ([Figure 17.1](#)) and describes the film performance in terms of resolution, speed, contrast and latitude. It should not be used as a calibration curve because it does not account for the local processing conditions.

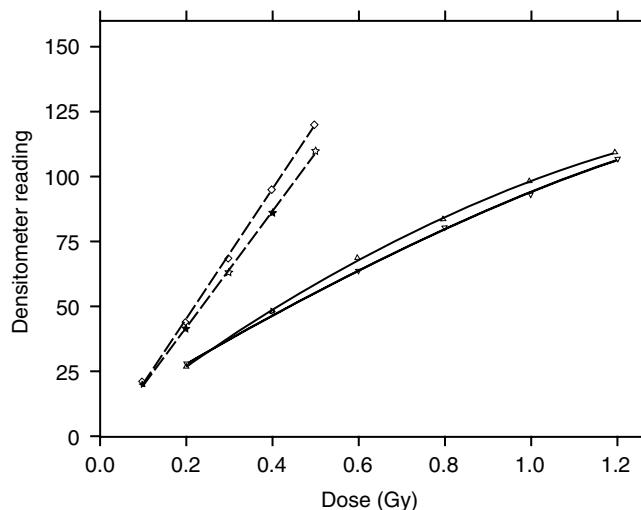

**FIGURE 17.1**

Typical H&D curve of x-ray film indicating (A) base + fog, (B) toe, (C) linear portion, (D) shoulder and (E) reversal or solarization region. The exact shape of this curve depends on the particular film type. The gradient in the straight line region is a measure of the inherent contrast of the film and is historically referred to as gamma.

### 17.2.6 MEASURING A DOSE DISTRIBUTION WITH FILM

Film has been used to measure relative dose distributions in radiotherapy since the 1950s (Gramke et al. 1952; Fleeman and Frantz 1954). It became popular in the 1960s, especially for dose measurements in electron beams (Dutreix and Dutreix 1969). For photon beams, the published results were somewhat contradictory, and the accuracy of film dosimetry was considered to be not as good as that of other detectors (Danciu et al. 2001). However, it has regained popularity in the last ten years, as a relative dosimetry Quality Assurance tool, in conjunction with the development of Intensity Modulated Radiotherapy.

In order to derive dose distributions from films, the first step is to determine a calibration (or sensitometric) curve of optical density versus dose (Figure 17.2) that describes the response

**FIGURE 17.2**

Calibration curves (6 MV radiation) for two different makes of therapy film; solid lines are Kodak X-OMAT V film, and the dashed lines are CEA films (Cheng and Das 1996). The steeper line for each film corresponds to radiation incident perpendicular to the plane of the film. The shallower line for each film corresponds to radiation incident parallel to the plane of the film. The ordinate axis is in relative units of optical density (OD). Note that the drop in film response when radiation is incident non-normally to the plane of the film is more pronounced for lower energy beams (Herz 1969). (Figure taken from Oldham, M. and Webb, S., *Med. Phys.*, 24, 827–836, 1997. With permission.)

of the film as a function of dose (Williamson et al. 1981). It is important to note that the calibration curve is linear before flattening out as it approaches saturation. This linearity makes relative dosimetry straightforward as the scanned optical density values represent the relative dose distribution without the need for the calibration constant to be known. Calibration films should be irradiated in the same orientation with respect to incident photons as the experimental film, to maintain consistent dose response.

The main problems in film dosimetry relate to the high atomic number of silver that results in an increase in film sensitivity compared to water-equivalent detectors for energies lower than about 400 keV. The calibration curves can be expected to change when the photon spectrum changes as a function of depth or field size or under blocks and at the edge of or outside the beam. Changes in the calibration curve are larger in the energy range 4 MV to 10 MV (and for cobalt-60 beams) than in the range 10 MV to 25 MV. Some variations have also been observed, depending on the film orientation with respect to the beam incidence (see Figure 17.2). These effects have been experimentally investigated and theoretical attempts are made to provide correction factors (Zhu et al. 2003; Palm et al. 2004).

To obtain accurate results, the dosimetric film is usually pressed firmly into a solid phantom\* consisting of slabs of water equivalent material, in order to eliminate dose distorting air pockets near the film surface. Film can be cut into shapes in a darkroom to fit into small phantoms, and opaque sealing tape should be used to protect from light exposure at the edges when necessary. Various solutions have been suggested to minimize the influence of spectral changes such as introduction of high atomic number filtering slabs within the phantom (Burch et al. 1997; Yeo et al. 1997) or the use of multiple sensitometric curves (Stern et al. 2004). If radiation incidence is parallel to the film plane, then sensitivity to beam hardening effects can be minimised by tilting the film a few degrees away from the incident direction.

The sensitivity of the film to be used must be such that the optical density remains within an acceptable range (i.e. below 3) for doses of clinical relevance. This is especially important for the verification of Intensity Modulated Radiotherapy where it is safer to check the dose distribution in situations resembling the treatment situation as much as possible. Therefore, specific types of films have been investigated in replacement of the very popular Kodak XV film. Examples are the CEA TVS film (Cheng and Das 1996) and the Kodak EDR2 film (Olch et al. 2002; Zhu et al. 2002) that yield an optical density of approximately 1.0 for a dose around 2 Gy.

After exposure, the dosimetric film is developed and may be digitised with a scanning densitometer. The variation of the overall film response is slightly dependent on the type of densitometer used and on the film batch (typical variation being 5–15%). However, the main variation comes from the processing conditions that can yield differences greater than 30%. Such differences can be overcome for relative measurements by using a normalised calibration curve (Bos et al. 2002; Georg et al. 2003), and for absolute measurements, by ensuring accurate quality control of the performance and stability of the processor and of the consistency between different films in the same batch. Under these conditions, the uncertainty may be reduced to about 2–3% for relative dose determination and to 3–5% for absolute dose determination.

### 17.2.7 RADIOMIC FILM

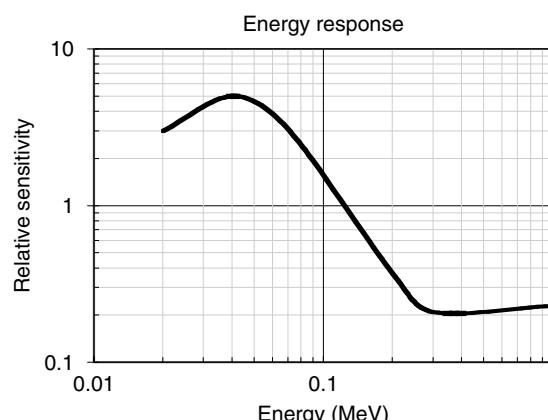

A promising and relatively new approach in film technology is radiochromic or Gafchromic film (Niroomand Rad et al. 1998; Rink et al. 2005), a transparent film that responds to

\* Most films can also be placed directly in water if required.

ultraviolet light and ionising radiation by turning blue and exhibiting absorption bands at 670 nm and 610 nm. The radiation induced colour change (a dye forming or polymerisation process) is formed directly, without the need for any chemical processing, and is stable at temperatures up to 60°C. The image can be read out by a He-Ne laser scanning densitometer (Reinstein and Gluckman 1997) or a regular transmission flat-bed-scanner (Devic et al. 2005). An attractive feature is that the photon mass energy absorption coefficients and electron mass collision stopping powers are very similar to those of water and skeletal muscle, making the film tissue equivalent and much less sensitive to spectral hardening than radiographic film. Furthermore, the film is easy to handle as it is insensitive to visible light. Historic challenges to radiochromic film were sensitivity (about a factor of 30 less than standard radiographic film) and non-uniformity of response, corresponding to the manufacturing-inhomogeneity of the dye layer (Cheng and Das 1996). However recent advances and the improved sensitivity of new formulations, associated with price reduction, are expected to lead to substantially increased use of radiochromic film for clinical applications (Devic et al. 2004; Rink et al. 2005).

### 17.2.8 PRACTICAL CONSIDERATIONS WHEN USING FILM AS A DOSIMETER

- (1) *Energy response:* Typically, film is 10 times more sensitive to 0.1 MeV photons than to 1 MeV photons because of the strong photoelectric interaction in AgBr below 150 keV (see Figure 17.3).
- (2) *Dose-rate:* an important rule concerning photographic exposure to x-rays and  $\gamma$ -rays is the reciprocity rule. This states that the photographic response is independent of dose rate. Without the reciprocity rule, film dosimetry would hardly be possible at all as one would always need to know the dose rate. Thankfully, provided the film is processed within a few days of irradiation, the reciprocity rule holds in essentially all film applications in radiation-therapy and dose-rate effects can be ignored. The latent image may fade in irradiated films left for long periods prior to processing (Chapter 4 of Herz 1969).
- (3) *Dose range:* Kodak EDR2 film: range 25 cGy to 400 cGy; saturates at 700 cGy. Kodak XV-2: range 0 to 100 cGy; saturates at 200 cGy. XTL film: range 1 cGy to 15 cGy; saturates at 30 cGy. Kodak PPL film: range 0.25 cGy to 5 cGy; saturates at 10 cGy. Older gafchromic film (e.g. MD55): range 0 to 30 Gy. More recent gafchromic EBT film: 0 to 6 Gy.
- (4) The main advantages of film as a dosimeter are its robustness and flexibility of application, high contrast and high spatial resolution ( $\leq 0.1$  mm in principle, but in practice, usually limited by the aperture of the scanning densitometer to  $\geq 0.3$  mm).

**FIGURE 17.3**  
Sensitivity of a typical radiographic x-ray film (irradiated without any additional screen) as a function of photon energy. (From Shani, G., *Radiation Dosimetry Instrumentation and Methods*, CRC Press Inc., Boca Raton, Florida, 1991.)

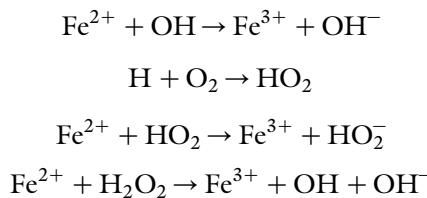

- (5) The problems of using film to measure absolute dose and beam data are rooted in (a) film production and processing fluctuations (for example, variations of 1°C in the developer bath can affect the optical density by as much as 10%), and (b) lack of tissue equivalence that causes variation in film sensitivity with the energy of incident radiation.
- (6) Film can be used to measure dose distributions from electron and neutron beams and is much less energy dependent with these modalities\*.

## 17.3 RADIATION SENSITIVE GELS

Traditional dosimeters such as ionisation chambers, radiographic films, thermoluminescent dosimeters and solid state detectors have limitations for the measurement of complex distributions produced by modern techniques such as intensity-modulated-radiation-therapy (see [Section 43.3.8](#)). One of the main limitations is that none of these dosimeters are truly 3D in that they measure dose at a single point or in a single plane. Ideally, a new technology is required that can produce an accurate high resolution 3D map of the delivered dose distribution. To this end, much recent effort has been invested into developing radiation sensitive gel-dosimeters that can capture the 3D distribution via chemical processes that are radiation dependent. Many chemical dosimeters have been found in nature, including ferrous sulphate (4 Gy to 400 Gy), ceric sulphate (400 Gy to  $4 \times 10^6$  Gy), chlorinated solutions (1 kGy), oxalic acid based solutions and polyacrylamide gels (PAG) (2 Gy to 30 Gy). Because of dose-range and ease of manufacturing, only the Fricke (ferrous sulphate) and PAG gel dosimeters have found applications in radiation therapy departments, although, new reports indicate a new material, PRESAGE, to be a promising alternative (Guo et al. 2006a, 2006b).

### 17.3.1 FRICKE GELS

Fricke and Hart originally proposed the ferrous-sulphate dosimeter in 1966 (Fricke and Hart 1966). The initial formulation was not a gel but an aerated solution containing 1 mmol/L ferrous sulphate ( $\text{FeSO}_4$ ), 1 mmol/L NaCl and 0.4 mmol/L sulphuric acid. When irradiated,  $\text{Fe}^{2+}$  ions are oxidised to  $\text{Fe}^{3+}$  along the following pathways:

The sensitivity of the Fricke solution to impurities is reduced by the presence of NaCl, but it is still necessary to use triple distilled water and pure high-grade chemicals. Since ferrous sulphate gradually oxidises with time, the solution must be freshly prepared before use.

### 17.3.2 CHEMICAL YIELD AND THE G VALUE

The radiation chemical yield of  $\text{Fe}^{3+}$  ions produced in solution is known as the G value and is measured either by chemical titration, or often more conveniently, by absorption

---

\* However, for neutron, proton, or ion beams, the film response as a function of dose may be misleading because, for high LET radiation, changes in LET (e.g. as a function of depth) may cause changes in optical density including saturation effects (see [Section 46.4.3](#)).

spectroscopy at 304 nm (ICRU 1969). The latter requires only 1 cm<sup>3</sup> of solution in a thermally equilibrated optical cell. The G value is the number of Fe<sup>3+</sup> ions produced by 100 eV of absorbed dose and has been determined to be 15.5±0.4 for megavoltage radiation (ICRU 1969). A G value should be measured at the local institution as a calibration of local equipment. The dose absorbed in a dosimetric Fricke solution is then determined from

$$D(\text{Gy}) = \frac{\Delta M}{\rho G} \times 0.964 \times 10^6 \quad (17.3)$$

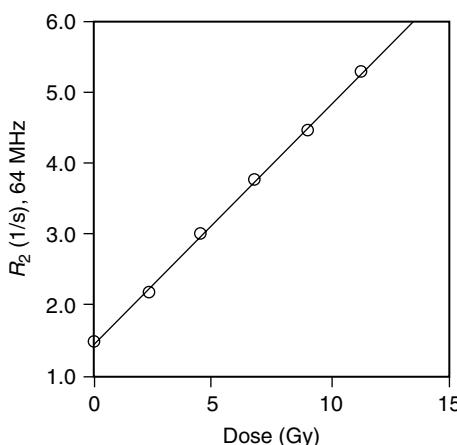

where  $\Delta M$  (moles/L) is the change in concentration of Fe<sup>3+</sup> ions, and  $\rho$  is the density of the solution.

Fricke solutions have limited use as the spatial distribution of dose is not preserved. However, Gore et al. (1984) showed that Fe<sup>3+</sup> ions produced in aqueous Fe<sup>2+</sup> solution sufficiently affect the magnetic resonance (MR)  $T_1$  relaxation time of water protons such that dose differences of 0–40 Gy can be resolved. They suggested that fixing the ferrous ions in a gel matrix could preserve spatial information and this was later demonstrated by Appelby et al. (1987). Subsequently, investigators have attempted to model the Fricke gel response (Podgorsak and Schreiner 1992; Audet and Schreiner 1997) and study performance issues associated with composition (Olsson et al. 1989; Schulz et al. 1990; Olsson et al. 1990; Hazle et al. 1991) and MR imaging (Johansson et al. 1998; Shortt 2001). Fricke gels have been applied to study many dosimetric situations encountered in the clinic including 3D conformal treatment planning (Chan and Ayyanger 1995), radiosurgery (Olsson et al. 1992; Schulz et al. 1993), brachytherapy (Olsen and Hellesness 1994; Schreiner et al. 1994), and to protons (Gambarini et al. 1997). The  $T_1$  image of an irradiated gel is converted to a dose map by the application of a calibration curve of  $T_1$  values for known dose in the same batch of Fricke gel. Two problems have hindered routine clinical application of Fricke gels. First, the Fe<sup>3+</sup> ions are not well fixed in the gel matrix and start to gradually diffuse through the gel immediately after irradiation; and second, access to expensive MR imaging facilities is required to obtain the  $T_1$  image and the dose distribution. The diffusion of ions through the gel leads to the loss of penumbra effects in a matter of hours (Balcom et al. 1995), so that a Fricke dosimeter gel must be imaged soon after irradiation. Some progress has been made to reduce the diffusion by changing the gelling environment (Chu et al. 2000).

### 17.3.3 POLYACRYLAMIDE GELS

Maryanski et al. (1993, 1994, 1996a) proposed a new type of radiation sensitive poly acrylamide gel (PAG). PAGs utilize the mechanism of radiation induced polymerisation of monomers where small monomer molecules join together under the influence of ionising radiation. The resultant long polymer chains are too big to move through the gel lattice eliminating image degradation due to diffusion. The initial PAG composition was called the BANG™\*, gel as its constituents by weight were Bis (3%) Acrylamide (3%) and Nitrogen and Gelatin (5%) mixed with water. Subsequent development led to the BANG-2 gel where acrylamide was replaced with acrylic acid and 1% of sodium. On irradiation, polymerisation and cross-linking occurs between the acrylic and bis monomers. Regions of the gel exposed to dose undergo polymerisation in proportion to the dose, and polymerised regions affect both the MR relaxivity of water protons and also the optical scattering power of the gel. The 3D-polymerisation distribution in the gel can be imaged either by taking a relaxivity image ( $R_2=1/T_2$ ) in an MR scanner (Figure 17.4) (Maryanski et al. 1996b) or by performing an optical CT scan (Gore et al. 1996; Kelly et al. 1998; Oldham et al.

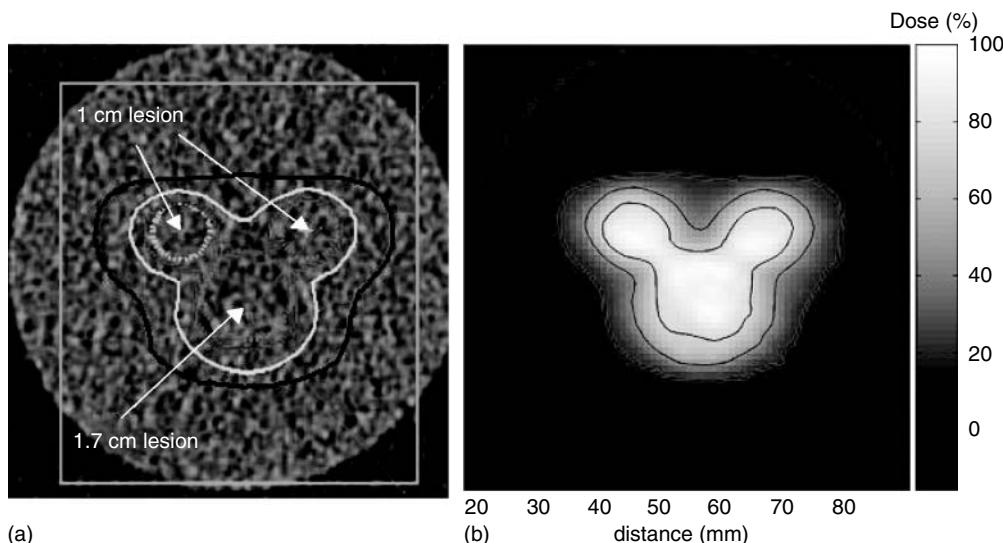

\* MGS Research Inc., PO Box 581, Guilford, Connecticut, 06437-0581 USA.

**FIGURE 17.4**

Dose response curve for BANG-2 gel irradiated with 6 MV x-rays. The relaxivity  $R_2$  data are fitted with a linear function  $R_2 = 1.45 + 0.34D$ . (From Maryanski M. J. et al., *Med. Phys.*, 23, 699–705, 1996b. With permission.)

2001). A slice through the dose distribution delivered by a 3 isocentre radiosurgery treatment as imaged by an optical-CT scanner is illustrated in (Figure 17.5). PAG dosimetry is a relatively recent technique, and there is still much to understand concerning the theoretical relations between dose and polymerisation and the corresponding changes in  $R_2$  or optical scattering (Lepage et al. 2001).

A relaxivity  $R_2$  image of an irradiated dosimetric gel is converted to dose by application of a calibration curve (Oldham et al. 1998). Because of the difficulty of manufacturing gels with the same radiation sensitivity, the calibration gel must be from the same batch as the dosimetric gel, and the thermal and temporal histories should be as identical as possible. To date, most work on PAG gels has involved characterisation of performance with respect to composition and MR imaging (Maryanski et al. 1997; Baldock et al. 1998; De Deene et al. 1998; McJury et al. 2000),

**FIGURE 17.5**

(See colour insert following page 590.) Illustration of the use of a gel-dosimeter in conjunction with optical-CT scanning to verify a 3 isocentre radiosurgery treatment. The left hand image is the dose-distribution calculated by the treatment planning system (isodoses 80%, 50% and 20%) superimposed onto the CT scan of the head-phantom. The right hand image is a dose map obtained from optical CT scanning through the central plane of the distribution (lines are also 80, 50 and 20%). (From Oldham, M. et al., *Med. Phys.*, 28, 1436–1445, 2001. With permission.)

but the optical CT approach is attractive as it is more amenable for high resolution dosimetry and obviates the need for expensive MR access and imaging time (Oldham et al. 2001). PAGs have been applied to conformal therapy (De Deene et al. 1998), tomotherapy (Gore et al. 1996), brachytherapy (Mc Jury et al. 1999; De Deene et al. 2001) and radiosurgery (Oldham et al. 2001).

### 17.3.4 COMPARISON OF FRICKE WITH PAG GELS

PAG gels have both advantages and disadvantages when compared with Fricke gels. PAGs can be difficult to manufacture, sensitive to light, oxygen and thermal history, and are toxic\*. Although a small long-term background post-irradiation polymerisation does occur with PAG gels (De Deene et al. 2000), they are much more stable than Fricke gels, allowing greater freedom to schedule imaging time. PAGs can measure doses in the range from 0 Gy to 10 Gy, whereas, Fricke gels are less sensitive with a useful range from 10 Gy to 40 Gy. The signal to noise ratio of Fricke gels is reduced by the intrinsically high electrical conductivity of the gel that attenuates the radiofrequency field. In contrast, PAGs show insignificant radiofrequency attenuation and a higher signal to noise ratio. The accuracy of relative dose measurements for a spatial resolution between 1 mm and 2 mm is reported as between 3% and 5% for PAG gels (Baldock et al. 1999; Mc Jury et al. 2000) and between 3% and 10% for Fricke gels (Hazle et al. 1991; Johansson et al. 1998). PAGs become increasingly opaque when irradiated, potentially allowing for optical CT scanning that would have major time and cost advantages (Oldham 2004).

### 17.3.5 PRACTICAL CONSIDERATIONS WHEN USING RADIATION-SENSITIVE GELS AS A DOSIMETER

- (1) Energy response: both Fricke and PAG gels show no significant dependence of sensitivity (i.e. <1%) on radiation energy within the therapy range (Maryanski et al. 1996b; Schulz et al. 1990; Shani 1991).
- (2) Dose rate: both Fricke and PAG gels show no dependence on dose-rate within the range normally produced by linear accelerators (Olsson et al. 1989; Schulz et al. 1990; Ibbott et al. 1997; Johanson et al. 1998; Shortt 2001). New formulations of BANG-3™ gels have been found to exhibit some non-linearity at high dose rates.
- (3) Dose range: PAGs are currently available that measure maximum doses of anywhere between 2 Gy and 20 Gy. As Fricke gels are less sensitive, they are generally used to measure doses of between 25 Gy and 30 Gy.
- (4) PAGs, prior to irradiation, may be sensitive to both the presence of light and oxygen. For this reason, if the gel container is made of oxygen porous material (e.g. polymethylmethacrylate [PMMA, Known as Perspex]) then it must be irradiated within a few hours after it has set or the dose-sensitivity will be reduced because of oxygen contamination. Containers can also be made from *Barex* (acrylonitrile) plastic.
- (5) For absolute dosimetry measurements, each gel batch must be independently calibrated.
- (6) MR imaging of the  $T_1$  distribution (Fricke) or  $T_2$  ( $=1/R_2$ ) distribution (PAGs) is a complex process. Image quality and accuracy of measured dose values depend on MR sequencing parameters and techniques and local scanner characteristics (e.g. distortion). Careful selection of sequences and parameters and good understanding of the characteristics of the local MR machine are required (De Deene et al. 2001).

\* A PAG formulation was recently proposed that is less sensitive to oxygen exposure during the manufacturing process, rendering the gels considerably easier to make (Fong et al. 2001).

## 18.1 INTRODUCTION

This chapter is concerned with the accurate determination of the absorbed dose in gray at the reference depth in a water phantom. This is sometimes known as *calibrating the beam* and is expressed in terms of a number of monitor units per gray for a given standard field size, Source to Surface Distance (SSD) and beam quality. For a better understanding of some of the concepts discussed in this chapter, the reader should consult Part E on the general characteristics of photon and electrons beams.

Whereas it is possible to determine the absolute value of the absorbed dose for the various clinical beam qualities from first principles, this would be an elaborate procedure involving expensive instrumentation; this is both impractical and inappropriate in a radiotherapy clinic. In practice, a *code of practice* or *dosimetry protocol* is followed, based on the use of an ionisation chamber having a calibration factor, traceable either directly to a Primary Standard Dosimetry Laboratory (PSDL) or to a Secondary Standard Dosimetry Laboratory (SSDL), itself, in turn, linked to a PSDL. Codes of Practice are generally issued by national or regional organisations such as AAPM (North America), SEFM (Spain), or IPEM (U.K.), but they are also established by international bodies such as the IAEA. This procedure ensures a high level of consistency in dose determination between different radiotherapy clinics in a given country and also between one country and another. This chapter deals with the theory and practice involved in the various codes, but it is emphasised that in any given clinical situation one particular code should be followed. Therefore, comprehensive sets of data such as stopping-power ratios and chamber correction factors have deliberately not been given. The reader should refer to the relevant codes of practice (either national or international) for the methodology to be followed and the data to be used.

The emphasis here is on the principles of the codes of practice for the dosimetry of megavoltage photon (including  $^{60}\text{Co}$   $\gamma$ -ray) and electron beams discussed in Section 18.2 through Section 18.5. There are separate sections on kilovoltage x-rays (Section 18.6) and heavy charged particle beams (Section 18.7). Although the recommended reference medium

is water, the use of other phantoms is discussed in [Section 18.8](#). More details on each of the components involved in the dose determination can be found in [Appendix D](#).

All codes of practice are based on the air-filled ionisation chamber as the dose measuring instrument (see [Chapter 15](#)). An ionisation chamber, often of a standard *reference* design, is provided with a calibration factor  $N_{S,Q_0}$  in terms of the radiation quantity  $S$  in a beam of a standard quality  $Q_0$ , and it is subsequently placed at the reference depth in water in the user's beam, of quality  $Q$ . A general form of the equation for calibration is then:

$$D_{w,Q} = M_Q N_{S,Q_0} f_{Q,Q_0}^{D,S} \quad (18.1)$$

where  $M_Q$  is the instrument (i.e. electrometer) reading, suitably corrected (see [Section 15.4](#)) in the user's beam, and  $f_{Q,Q_0}^{D,S}$  is any overall factor necessary to convert both from the calibration quantity  $S$  to dose  $D$  and from the calibration quality  $Q_0$  to the user's quality  $Q$ .

Until relatively recently, all megavoltage photon and electron beam codes were based on calibrating an ionisation chamber in a  ${}^{60}\text{Co}$   $\gamma$ -ray beam\* in terms of air kerma (e.g. IAEA 1987). This approach is still in use in many parts of the world, e.g. SEFM (1984, 1987), NCS (1986), IAEA (1987, 1997a, 1997b), IPEMB (1996a). However, in recent years there has been a concerted effort to move toward calibrations in terms of the quantity actually required, absorbed dose to water (e.g. IPSM 1990, AAPM 1999, IAEA 2000). The field is currently in a transition period, and consequently both approaches are described here: air kerma (see [Section 18.2](#)) and absorbed dose to water (see [Section 18.3](#)), as well as the relationship between the two (see [Section 18.4](#)) and quantities common to both approaches (see [Section 18.5](#)).

## 18.2 CODES OF PRACTICE BASED ON AIR-KERMA CALIBRATION

### 18.2.1 BACKGROUND

The ionisation chamber has been the instrument of choice for many years for the accurate determination of absorbed dose on account of its widespread availability, excellent reproducibility and stability. The long history of its use means that its properties are well understood (see [Chapter 15](#)). Originally, ionisation chambers were used for the dosimetry of kilovoltage x-ray beams, and Standards Dosimetry Laboratories (SDLs) provided calibrations in terms of exposure (charge per unit mass of air) over a range of radiation qualities, characterised by their half-value layer (HVL) in aluminium or copper (see [Section 21.2.2](#)). This method was subsequently extended to megavoltage photon beams (Greene and Massey 1966; ICRU 1969; HPA 1969) through the concept of the  $C_\lambda$  factor which corresponds exactly to  $f_{Q,Q_0}^{D,S}$  in Equation 18.1,  $Q_0$  here being  ${}^{60}\text{Co}$   $\gamma$ -rays.

The quantity *air kerma*,  $K_{\text{air}}$ , subsequently replaced *exposure* as the calibration quality realised at the Standards Dosimetry Laboratories; kerma has the same units as absorbed dose, i.e. gray (see [Section 6.3.2](#)).

The next two sections explain the principles of codes of practice based on air kerma calibration. The formalism, established by the Nordic Code (NACP 1980) and subsequently adopted by the IAEA (IAEA 1987, 1997a) and others (e.g. IPEMB 1996a), will follow.

There are three steps involved in an air-kerma based code: first, the determination of the  $N_K$  factor for the reference chamber at the SDL; second, the calculation of the  $N_{D,\text{air}}$  factor; and finally, the absorbed dose to water determination in the user's beam. These steps are outlined in the following sections.

\* In the U.K., a 2 MV Van der Graaf generator was used.

## 18.2.2 FROM AIR KERMA TO THE $N_K$ FACTOR

The starting point in the complete dosimetry chain is the realisation of air kerma at a specified point in a  $^{60}\text{Co}$   $\gamma$ -ray beam at the Standards Dosimetry Laboratory (e.g. Boutillon and Niatel 1973); this is illustrated on Figure 18.1. The so-called *primary standard chamber* (*a*) has an air volume known very precisely. Various correction factors are applied, principally for the attenuation and scattering by the chamber wall and also for its lack of air equivalence (Boutillon and Niatel 1973; Bielajew 1990; Bielajew and Rogers 1992). The Figure 18.1b illustrates the calibration of the *user's reference chamber*. For a chamber (including build-up cap) positioned with its centre at a point where the air kerma  $K_{\text{air}}$  is known and giving a reading (corrected to standard temperature and pressure)  $M_{Q_0}$ , the calibration factor, denoted by  $N_K$ , is given by

$$N_K = \frac{K_{\text{air}}}{M_{Q_0}} \quad (18.2)$$

It is this factor that is supplied by the Standards Dosimetry Laboratory and that constitutes the first step in the procedure. It may be noted that for many years the National Physical Laboratory in the U.K. would only provide a  $N_K$  factor for the designated secondary standard chamber, the NE2611, including buildup cap\*; the IPEMB (1996a) Code of Practice only considered this chamber. Generally, however, Standards Dosimetry Laboratories will supply any cylindrical chamber together with its appropriate build-up cap, such as a Farmer chamber (see Table 15.2), with an  $N_K$  factor.

## 18.2.3 FROM THE $N_K$ TO THE $N_{D,\text{AIR}}$ FACTOR

The second step in the procedure is the determination of the  $N_{D,\text{air}}$  factor; this is defined by:

$$N_{D,\text{air}} = \frac{\bar{D}_{\text{air}}}{M_{Q_0}} \quad (18.3)$$

where  $\bar{D}_{\text{air}}$  is the dose to the air averaged over the chamber cavity. This is identical in concept to  $N_{\text{gas}}$  in AAPM (1983)<sup>†</sup>.

$N_{D,\text{air}}$  is a calibration factor for the chamber to convert its corrected reading to mean absorbed dose in the sensitive air volume. Some insight into the nature of  $N_{D,\text{air}}$  can be gained as follows.  $D_{\text{air}}$ , is equal to the product of the charge per unit mass,  $J_g$ , (known as the *mass ionisation*) and the mean energy required to produce an ion pair in air, divided by the electron charge, ( $W_{\text{air}}/e$ ):

$$\bar{D}_{\text{air}} = J_g (W_{\text{air}}/e) \quad (18.4)$$

which can be expressed in terms of the volume of the air cavity,  $V$ , the air density,  $\rho$ , and the charge measured,  $Q$ :

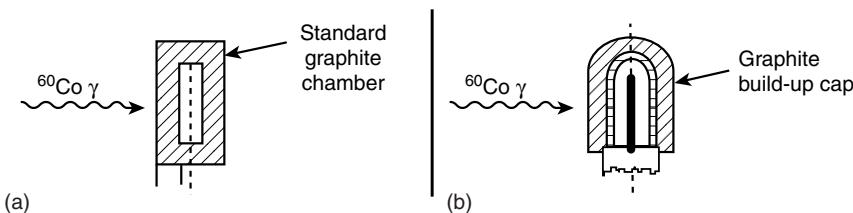

$$\bar{D}_{\text{air}} = \frac{Q}{\rho V} (W_{\text{air}}/e) \quad (18.5)$$

Combining Equation 18.3 and Equation 18.5 leads to

$$N_{D,\text{air}} = \frac{Q}{M_{\text{corr}}} \frac{1}{\rho V} (W_{\text{air}}/e) \quad (18.6)$$

\* Previously, the NE2561, taken to be equivalent to the NE2611 in this chapter.

<sup>†</sup>  $N_{D,\text{air}}$  was originally written as  $N_D$ , e.g. in NACP(1980) and IAEA (1987, 1997a), but *air* has recently been explicitly added (e.g. IPEMB 1996a; IAEA 1997b) in order to clearly distinguish it from the absorbed-dose-to-water factor  $N_{D,w}$ .

**FIGURE 18.1**

Air kerma determination (a) and dissemination (b) at a Primary Standard Dosimetry Laboratory (PSDL) in a  $^{60}\text{Co} \gamma$  beam.

where  $M_{\text{corr}}$  is the reading ( $M_{Q_0}$ ) corrected for recombination, polarity effect, temperature and pressure (see [Section 15.4](#)). Now, clearly the measured signal  $M_{\text{corr}}$  must be proportional to the charge  $Q$ , and the density  $\rho$  is a constant. Furthermore, there is very good evidence that  $(W_{\text{air}}/e)$  does not vary with radiation quality (except at electron energies below a few kiloelectron volts) (ICRU 1979). Consequently,  $N_{D,\text{air}}$  is simply inversely proportional to the volume of the air in the cavity,  $V$ , i.e. it is simply related to a fixed geometrical property of the chamber and *will therefore be constant irrespective of the radiation quality*.

The air kerma standard depicted in Figure 18.1 is realised by using a thick-walled cavity chamber, i.e. full build-up is achieved in the chamber wall, and there is charged particle equilibrium (CPE) in the cavity gas (in photon beams of lower energies, CPE is achieved by the use of a free-air chamber, e.g. Attix 1986) (see [Section 15.3](#)). Ideally, the build-up material should be air-equivalent. Furthermore, it should not attenuate or scatter the incident beam. In practice, therefore, correction factors are required. Referring to the Figure 18.1b, the mean absorbed dose  $\bar{D}_{\text{air}}$  in the air cavity of the user's ionisation chamber in a cobalt-60 beam is related to the air kerma (free in air),  $K_{\text{air}}$ , by

$$\bar{D}_{\text{air}} = K_{\text{air}}(1 - g)k_{\text{att}} k_m k_{\text{cel}} \quad (18.7)$$

where  $g$  is the fraction of the initial kinetic energy of the secondary electrons generated by  $^{60}\text{Co}$  photons that is converted to bremsstrahlung in air (see [Section 6.3.2](#)).

The correction factors  $k$  refer to the effect of the chamber on the radiation field (e.g. IAEA 1997a, 1997b and [Appendix D, Section D.2](#)):

- $k_m$  takes into account the lack of air equivalence of the ionisation chamber wall materials and build-up cap at the calibration in the  $^{60}\text{Co}$   $\gamma$ -ray beam;
- $k_{\text{att}}$  takes into account the attenuation and scatter of the photons in the ionisation chamber materials and build-up cap;
- $k_{\text{cel}}$  takes into account the non-air equivalence of the central electrode of a cylindrical ionisation chamber.

Dividing both  $D_{\text{air}}$  and  $K_{\text{air}}$  by the corrected meter reading for the irradiation in a cobalt-60 beam (Figure 18.1), it follows from Equation 18.2 and Equation 18.3 that\*

$$N_{D,\text{air}} = N_K(1 - g)k_{\text{att}} k_m k_{\text{cel}} \quad (18.8)$$

\* Note that the corresponding expression in IAEA (1987) did not include  $k_{\text{cel}}$  and, therefore, the  $N_D$  in that code of practice did not relate solely to the geometrical characteristics of the chamber (Equation 18.6). The factor  $k_{\text{cel}}$  was included in a global factor  $p_{\text{cel}}$  to account for the combined effect of the central electrode, both during the calibration of the chamber in air in a cobalt-60 beam and during subsequent measurements in photon and electron beams in a phantom. This was remedied in IAEA (1997b).

An expression for  $k_m$  for a single material, e.g. chamber wall and build-up cap both made of graphite, can be derived from cavity theory;  $k_m$  is then given by Equation 18.9 where  $\alpha=1$  (Bielajew 1986). However, in many cases, the cap and the wall materials differ, and the following approximate 2-component formula, based on similar ideas as for  $p_{\text{wall}}$  (see [Appendix D, Section D.2.2](#)), must be used:

$$k_m = \alpha s_{\text{air,wall}}(\mu_{\text{en}}/\rho)_{\text{wall,air}} + (1 - \alpha)s_{\text{air,cap}}(\mu_{\text{en}}/\rho)_{\text{cap,air}} \quad (18.9)$$

where  $\alpha$  is the fraction of ionisation because of electrons generated in the chamber wall.

This expression was evaluated for many materials of interest by Andreo et al. (1986) using a consistent set of stopping-power data. Values range from 0.965 to 1.006 for homogeneous cap and wall made of A-150 and of C-552 (approx. air equivalent) material, respectively.

The factor  $k_{\text{att}}$  has been obtained by Monte-Carlo simulation (Nath and Schulz 1981; Rogers et al. 1985) for a large number of chamber and cap combinations. Andreo et al. (1986) compared the product  $k_m k_{\text{att}}$  for a number of chamber and cap combinations in common use with experimental values from Mattsson and Johansson (1984); the latter had been determined by using the all-graphite wall and cap SSI chamber (i.e. constructed by the Swedish National Radiation Protection Institute) as reference (using the theoretical value  $k_m k_{\text{att}}=0.989$ ) and then determining the chamber-volume ratio in a high-energy electron beam where the effect of the different walls was assumed to be negligible. The agreement between theory and experiment was generally within 0.7%. A comprehensive table of  $k_m k_{\text{att}}$  is given in IAEA (1987) based on the data in Andreo et al. (1986).

The factor  $k_{\text{cel}}$  for cylindrical chambers with graphite and aluminium central electrodes was not explicitly included in IAEA (1987). Monte-Carlo simulations by Ma and Nahum (1993) showed that  $k_{\text{cel}}=1.006$  for both the Farmer NE2571 (solid Al central electrode) and the U.K. secondary standard NE2611 (hollow Al central electrode).

For a given ionisation chamber, Equation 18.6 shows that the  $N_{D,\text{air}}$  factor is a constant provided that  $W_{\text{air}}/e$  does not vary with energy. Therefore, the  $N_{D,\text{air}}$  factor derived at the cobalt-60 quality  $Q_0$  is also valid at the user quality  $Q$ . The factor  $N_{D,\text{air}}$  then allows the determination of the mean absorbed dose within the air cavity at the user beam quality  $Q$

$$\bar{D}_{\text{air},Q} = M_Q N_{D,\text{air}} \quad (18.10)$$

where  $M_Q$  is the corrected reading in that beam.

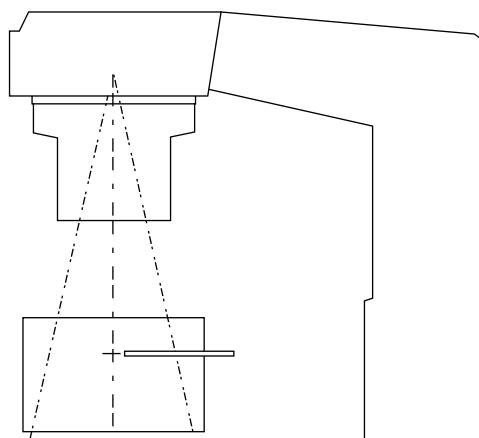

#### 18.2.4 USING THE $N_{D,\text{AIR}}$ FACTOR TO DERIVE THE ABSORBED DOSE TO WATER

The third, and final, step in the determination of the absorbed dose to water at the reference depth in the user's beam is illustrated in [Figure 18.2](#). The chamber is used without its build-up cap, but a thin waterproof sheath of polymethylmethacrylate (PMMA, known as perspex or lucite) or polystyrene is advisable for non-waterproof chambers.

The absorbed dose to water,  $D_{w,Q}$ , at a point in a phantom where the effective point of measurement of the chamber is positioned, is obtained from the dose to air ( $M_Q N_{D,\text{air}}$ ) using the Bragg–Gray principle

$$D_{w,Q}(P_{\text{eff}}) = M_Q N_{D,\text{air}}(s_{w,\text{air}})_Q p_Q \quad (18.11)$$

where  $M_Q$  is the dosimeter reading at the beam quality  $Q$  corrected for influence quantities;  $s_{w,\text{air}}$  is the stopping power ratio, water to air;  $p_Q$  is the overall perturbation factor of the ionisation chamber for in-phantom measurements at a beam quality  $Q$ ; and  $P_{\text{eff}}$  is the effective point of

**FIGURE 18.2**

The basic Bragg–Gray situation of a thimble chamber in a phantom irradiated by a megavoltage photon or electron beam. The geometrical center  $C$  of the chamber cavity is aligned on the beam axis. The effective point of measurement  $P_{\text{eff}}$  is on the same axis, slightly displaced from  $C$  in the source direction.

measurement of the chamber which is generally not situated at the chamber centre\* (see [Appendix D, Section D.2.1](#)). The effective point of measurement  $P_{\text{eff}}$  and the perturbation factor  $p_Q$  are required because the chamber does not behave as a perfect Bragg–Gray cavity, i.e. the electron fluence in the air cavity is *not* identical to that at the reference depth in the undisturbed medium. These two quantities are chamber specific. The remainder of any air-kerma based code of practice is essentially occupied with the correct choice of these quantities and that of the stopping-power ratio. These are dealt with briefly in [Section 18.5](#) and in more detail in Appendix D.

In principle, there is no difference between the procedures for photon and electron beams as the Bragg–Gray principle can be applied equally to either modality (see [Section 6.7.3](#)). In practice, however, plane-parallel chambers tend to be preferred to cylindrical ones for electron beams (see [Section 15.3.2.3](#) and Appendix D).

## 18.3 CODES OF PRACTICE BASED ON ABSORBED DOSE TO WATER CALIBRATIONS

### 18.3.1 INTRODUCTION

All codes of practice concern the determination of the quantity *absorbed dose to water*. It is, therefore, logical to provide ionisation chambers with a calibration factor in terms of this quantity, rather than in terms of *air kerma* if at all possible.

In 1988, the development of standards of absorbed dose to water at PSDLs became a major recommendation of the *Comité Consultatif pour les Étalons de Mesure des Rayonnements Ionisants* (*Section I—CCEMRI(I)* 1988). Although only the water calorimeter allows the direct determination of the absorbed dose to water in a water phantom, the required conversion and perturbation factors for other procedures (the ionisation method, chemical dosimetry and

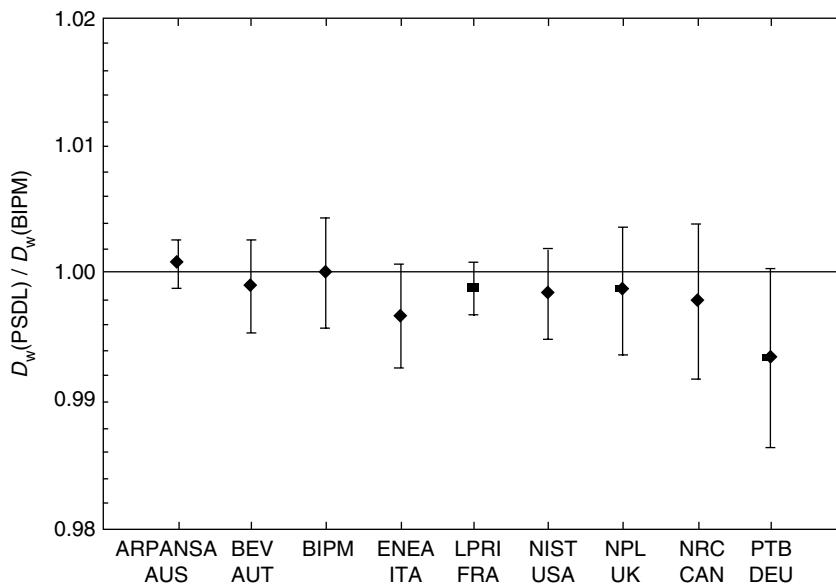

\* It should be noted that an alternative procedure used in some codes of practice is to position the centre of the chamber at the point of interest and use a modified  $p_Q$  that also includes a displacement correction. In U.K. codes of practice the effective point of measurement correction is not explicitly included because the National Physical Laboratory includes this correction in  $N_{D,w}$ , effectively defining the effective point of measurement as the centre of the chamber.

graphite calorimetry) are now well known at many laboratories (ICRU 2001). Many PSDLs already provide  $N_{D,w}$  calibrations for  $^{60}\text{Co}$   $\gamma$ -ray beams, and some laboratories have extended these calibration procedures to high-energy photon and electron beams (Burns 1994; McEwen et al. 1998) while others are developing the necessary techniques.

The procedure for the determination of absorbed dose to water based on standards of absorbed dose to water has been implemented in the national dosimetry recommendations by the IPSM (1990) based on calibrations over a range of megavoltage qualities, by DIN 6800-2 (1997) based on cobalt-60 calibrations and more recently, by the AAPM (1999) and the IAEA (2000).

The most significant advantages of calibrations in terms of absorbed dose to water and dosimetry procedures using these calibration factors can be summarised as follows:

- *Reduced uncertainty.* Measurements based on calibration in air in terms of air kerma require chamber-dependent conversion factors to determine absorbed dose to water (see [Section 18.2](#)). Conversion factors such as perturbation corrections and stopping-power ratios are derived from complex measurements or calculations based on theoretical models with uncertainties that are often difficult to estimate. In addition, they do not account for differences between individual chambers of a particular type. In contrast,  $N_{D,w}$  calibrations can be performed under similar conditions to those in the user's beam, thus accounting for the response of each individual chamber.
- *A more robust system of primary standards.* Although international comparisons of air-kerma standards have shown very good agreement, they are all based on the use of ionisation chambers as illustrated in [Figure 18.1](#), and are therefore subject to the same uncertainties. In contrast, primary standards of absorbed dose to water are based on a number of different physical principles with no assumptions or correction factors common to all of them. Therefore, the good agreement among these standards (see [Figure 18.3](#)) gives much greater confidence.

**FIGURE 18.3**

Comparisons of standards of absorbed dose to water in the BIPM cobalt-60 beam. The results are relative to the BIPM determination and are those for the most recent comparison for each PSDL, the oldest dating from 1989. The uncertainty bars represent the relative standard uncertainty of the  $D_w$  determination at each institute. Laboratories contributing were as follows: ARPANSA (Australian Radiation Protection and Nuclear Safety Agency); BEV (Bundesamt für Eich- und Vermessungswesen, Austria); BIPM (Bureau International des Poids et Mesures); ENEA (Italian National Agency for New Technologies, Energy and the Environment); LPRI (Laboratoire Primaire des Rayonnements Ionisants, France); NIST (National Institute of Standards and Technology, U.S.A.); NPL (National Physical Laboratory, U.K.); NRC (National Research Council, Canada); PTB (Physikalisch-Technische Bundesanstalt, Germany). (From Allisy-Roberts, P. J. and Burns, D. T., Report CCRI(I)/99-1, BIPM, Sèvres, France, 1999.)

- *Use of a simple formalism.* The formalism given in most air-kerma based dosimetry protocols is based on the application of several coefficients and correction factors to convert from air-kerma in cobalt-60 beam to in-phantom absorbed dose to water in the user's beam, i.e. Equation 18.8 and Equation 18.11. Information about physical characteristics of the chamber used, e.g. wall and build-up cap material, is also required. The simpler procedure starting from a calibration factor in terms of absorbed dose to water, and applying correction factors for all influence quantities, reduces the possibility of mistakes in the determination of absorbed dose to water (see Section 18.3.2).

### 18.3.2 $N_{D,w}$ -BASED FORMALISM

The formalism used here follows that in IAEA (2000), originally developed by Hohlfeld (1988) and extended by Andreo (1992) and Rogers (1992a).

The absorbed dose to water at the reference depth  $z_{\text{ref}}$  in water for a reference beam of quality  $Q_0$  and in the absence of the chamber is given by

$$D_{w,Q_0} = M_{Q_0} N_{D,w,Q_0} \quad (18.12)$$

where  $M_{Q_0}$  is the reading of the dosimeter under the reference conditions used at the SDL, and  $N_{D,w,Q_0}$  is the calibration factor in terms of absorbed dose to water of the dosimeter obtained from the SDL. The chamber centre is positioned at the reference depth. When a dosimeter is used in a beam of the same quality as that used at its calibration,  $Q_0$ , the absorbed dose to water is simply given by Equation 18.12 where the dosimeter reading  $M_{Q_0}$  is corrected to the reference values of pressure and temperature (and other relevant influence quantities) at which the calibration factor is valid. In general, the calibration or reference quality is  $^{60}\text{Co}$   $\gamma$ -rays, i.e. the same as that for the air-kerma standard. Ideally, an SDL would possess a linear accelerator and be able to calibrate the user's chamber at all high-energy photon and electron qualities,  $Q$ , used in a radiotherapy clinic:

$$D_{w,Q} = M_Q N_{D,w,Q} \quad (18.13)$$

where  $N_{D,w,Q}$  pertains to the user's quality.

#### 18.3.2.1 Correction for the Radiation Quality of the Beam, $k_{Q,Q_0}$

The commonest situation, that of  $N_{D,w}$  only being provided for a single reference quality, will now be dealt with. When a dosimeter is used in a beam of quality  $Q$  different from that used at its calibration,  $Q_0$ , the absorbed dose to water is given by

$$D_{w,Q} = M_Q N_{D,w,Q_0} k_{Q,Q_0} \quad (18.14)$$

where the factor  $k_{Q,Q_0}$  corrects for the differences in chamber response between the reference beam quality  $Q_0$  and the user quality  $Q$ . The beam-quality correction factor  $k_{Q,Q_0}$  is defined as the ratio of the calibration factors of the ionisation chamber, in terms of absorbed dose to water, at the qualities  $Q$  and  $Q_0$ ,

$$k_{Q,Q_0} = \frac{N_{D,w,Q}}{N_{D,w,Q_0}} = \frac{D_{w,Q}/M_Q}{D_{w,Q_0}/M_{Q_0}} \quad (18.15)$$

The most common reference quality  $Q_0$  used for the calibration of ionisation chambers is  $^{60}\text{Co}$   $\gamma$ -radiation where the simplified symbol  $k_Q$  is commonly used for the beam-quality correction factor.

At some PSDLs, high-energy photon and electron beams are directly used for calibration purposes, and the symbol  $k_{Q,Q_0}$  is used in these cases with  $Q_0$  to be specified. Ideally, the

beam-quality correction factor should be measured directly for each chamber at the same quality as the user's beam. However, this is not possible in most standards laboratories. Such measurements can be performed only in laboratories with access to the appropriate beam qualities; for this reason, the technique is, at present, restricted to a few PSDLs in the world as the procedure also requires the availability of an energy-independent dosimetry system, such as a calorimeter, operating at these qualities.

When no experimental data are available or when it is difficult to directly measure  $k_{Q,Q_0}$  in clinical beams, the correction factors can, in many cases, be calculated theoretically. By comparing Equation 18.13 with the  $N_{D,\text{air}}$  formalism given in Equation 18.6 and Equation 18.11,  $k_{Q,Q_0}$  can be written (Andreo 1992)

$$k_{Q,Q_0} = \frac{(s_{w,\text{air}})_Q}{(s_{w,\text{air}})_{Q_0}} \frac{(W_{\text{air}})_Q}{(W_{\text{air}})_{Q_0}} \frac{p_Q}{p_{Q_0}} \quad (18.16)$$

which is valid for all types of high-energy beams. It involves ratios, at the qualities  $Q$  and  $Q_0$  respectively, of water/air stopping-power ratios,  $s_{w,\text{air}}$  (see [Section 18.5.1](#) and [Appendix D, Section D.1](#)) of the mean energy expended in air per ion pair formed,  $W_{\text{air}}$ , and of the perturbation factors  $p_Q$  and  $p_{Q_0}$  for departures from the ideal Bragg–Gray detector conditions (see [Section 18.5.3](#) and [Appendix D, Section D.2](#)).

In therapeutic electron and photon beams, the assumption of  $(W_{\text{air}})_Q = (W_{\text{air}})_{Q_0}$ <sup>\*</sup> yields the simpler equation for  $k_{Q,Q_0}$  (Hohlfeld 1988)<sup>†</sup>

$$k_{Q,Q_0} = \frac{(s_{w,\text{air}})_Q}{(s_{w,\text{air}})_{Q_0}} \frac{p_Q}{p_{Q_0}} \quad (18.17)$$

The calculations of  $k_{Q,Q_0}$  are based on exactly the same data that are used in the calculations in the air-kerma based approach (see [Section 18.2](#)), but the parameters ( $s_{w,\text{air}}$  and  $p_Q$  in Equation 18.11) are used as ratios that have reduced uncertainties as compared to the individual values.

In the case of kilovoltage x-ray beams, Bragg–Gray conditions do not apply; therefore, Equation 18.17 cannot be used. In addition, the chamber-to-chamber variation in response is usually rather large. Kilovoltage absolute dose determination is covered in [Section 18.6](#).

### 18.3.2.2 A Modified $k_{Q,Q_0}$ for Electron Beams

For electron beams, when the calibration quality of the dosimeter  $Q_0$  is cobalt-60 the situation is the same as discussed above, i.e. for the user's electron beam quality  $Q$ , the beam quality correction factor  $k_Q$  is given by Equation 18.16 (or Equation 18.17). The alternative is the direct calibration of chambers in electron beams (Thwaites et al. 2003) which is not presently offered by many PSDLs (McEwen et al. 1998). However, the ongoing development of electron-beam primary standards will enable calibration at a series of electron beam qualities  $Q$ . In such cases the equation is simply

$$D_{w,Q} = M_Q N_{D,w,Q} \quad (18.18)$$

A third possibility (which in the absence of direct calibration in electron beams is the

<sup>\*</sup> Note that this is the same assumption as for the beam-quality independence of  $N_{D,\text{air}}$  (see Equation 18.6).

<sup>†</sup> It is emphasised that when experimental and theoretical values of  $k_{Q,Q_0}$  are compared, it is strictly the full Equation 18.16 that is relevant rather than Equation 18.17. A possible weak energy variation of  $W_{\text{air}}$  has been suggested (cf. Svensson and Brahme 1986).

preferred choice) in some  $N_{D,w}$  based dosimetry protocols (AAPM 1999; IAEA 2000) is the cross calibration of a plane-parallel chamber against a calibrated cylindrical chamber in a high-energy electron beam of quality  $Q_{\text{cross}}$ . Well designed plane-parallel chambers are preferred in electron beams because of the negligible perturbation they exhibit as discussed in [Section 15.3.2.3](#) and [Section 18.5.3](#). The  $N_{D,w}$  factor for the plane-parallel chamber is then given by

$$N_{D,w,Q_{\text{cross}}}^{\text{pp}} = \frac{M_{Q_{\text{cross}}}^{\text{ref}}}{M_{Q_{\text{cross}}}^{\text{pp}}} N_{D,w,Q_0}^{\text{ref}} k_{Q_{\text{cross}},Q_0}^{\text{ref}} \quad (18.19)$$

where  $M_{Q_{\text{cross}}}^{\text{ref}}$  and  $M_{Q_{\text{cross}}}^{\text{pp}}$  are dosimeter readings for the reference (cylindrical) chamber and the plane-parallel chamber, respectively and are corrected for influence quantities (temperature, pressure, etc.); *ref* and *pp* refer to the cylindrical and plane-parallel chambers, respectively.

Unfortunately, unless the quality  $Q_{\text{cross}}$  is specified beforehand, then for each chamber type a *two dimensional* table of  $k_{Q,Q_{\text{cross}}}$  factors is required for the subsequent use of this chamber in an electron beam of quality  $Q$ . A practical solution, adopted both in AAPM (1999) and in IAEA (2000), is to present the required data in a single table by introducing an arbitrary *intermediate* electron beam quality  $Q_{\text{int}}$ <sup>\*</sup>. The required  $k_{Q,Q_{\text{cross}}}$  factor is evaluated from

$$k_{Q,Q_{\text{cross}}} = \frac{k_{Q,Q_{\text{int}}}}{k_{Q_{\text{cross}},Q_{\text{int}}}} \quad (18.20)$$

The factor  $(k_{Q_{\text{cross}},Q_{\text{int}}})^{-1}$  converts the actual chamber calibration factor  $N_{D,w,Q_{\text{cross}}}$  into a calibration factor that applies at the intermediate quality  $Q_{\text{int}}$ . The factor  $k_{Q,Q_{\text{int}}}$  corrects this latter calibration factor into one that applies at  $Q$  so that the general Equation 18.13 for  $D_{w,Q}$  can be applied. The expressions for  $k_{Q,Q_{\text{int}}}$  and  $k_{Q_{\text{cross}},Q_{\text{int}}}$  follow from Equation 18.17, and the stopping-power ratios and perturbation factors at  $Q_{\text{int}}$  can be eliminated<sup>†</sup>.

### 18.3.3 $N_{D,w}$ AND $k_{Q,Q_0}$ OPTIONS AVAILABLE IN PRACTICE

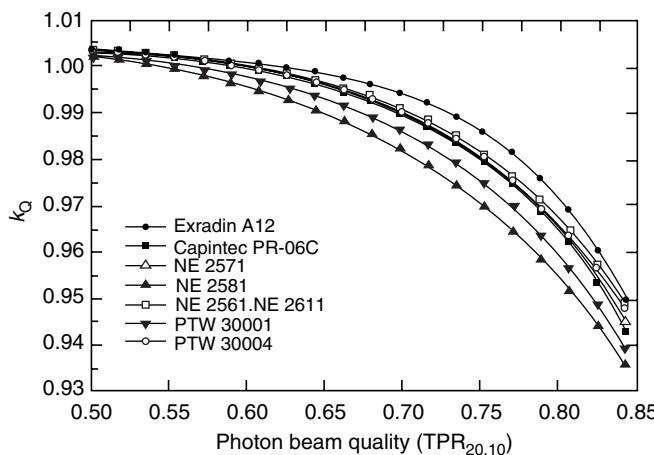

As already indicated, many Standards Dosimetry Laboratories provide calibrations of ionisation chambers in terms of absorbed dose to water in a cobalt-60  $\gamma$ -ray beam, and some laboratories have developed calibration procedures for high-energy photon and electron beams. The options available can be summarised as follows:

1. Users are provided with a calibration factor  $N_{D,w}$  at a reference beam quality  $Q_0$ , usually cobalt-60. For additional qualities  $Q$ , the SDL provides directly measured beam-quality correction factors  $k_{Q,Q_0}$  for that particular chamber.
2. Users are provided with a series of  $N_{D,w,Q}$  calibrations of the user's ionisation chamber at beam qualities  $Q$ .

Options 1 and 2 are very similar. The main advantage of either approach is that the individual chamber response in a water phantom irradiated by various beam types and qualities is intrinsically taken into account. For option 1, there is an advantage in presenting the data in the form of a single calibration factor  $N_{D,w,Q_0}$  together with directly measured values of  $k_{Q,Q_0}$ . Once directly measured values of  $k_{Q,Q_0}$  for a particular chamber have been

\* No measurements are made at  $Q_{\text{int}}$ . It is only a device to simplify the presentation of the data.

<sup>†</sup>This approach has another advantage. For a given  $Q$  and  $Q_{\text{cross}}$ , the value for  $k_{Q,Q_{\text{cross}}}$  is the same for all well guarded plane-parallel chamber types (as it only depends on a ratio of stopping-power ratios); for cylindrical chamber types, it depends also on the chamber radius  $r_{\text{cyl}}$ . The value chosen for  $Q_{\text{int}}$  (usually  $R_{50}=7.5 \text{ g cm}^{-2}$ ) minimises the differences for cylindrical chambers of different  $r_{\text{cyl}}$  over the range of beam qualities for which cylindrical chambers are used.

**FIGURE 18.4**

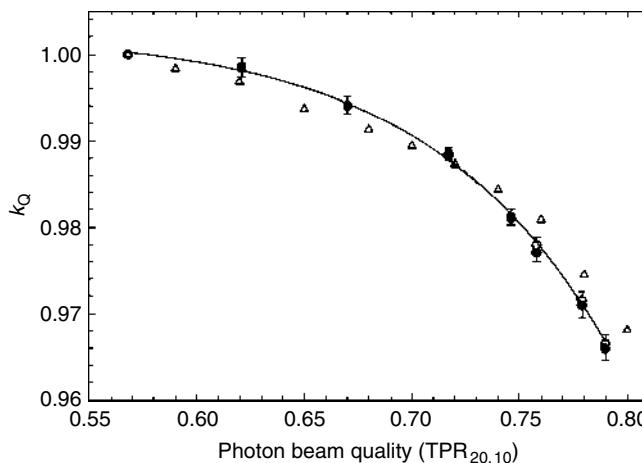

Calculated values of  $k_Q$  for various cylindrical ionisation chambers commonly used for reference dosimetry as a function of photon beam quality ( $TPR_{20,10}$ ). Open symbols correspond to graphite-walled ionisation chambers, solid symbols to plastic-walled chambers. (From International Atomic Energy Agency, Technical Report Series no. 398, IAEA, Vienna, 2000. With permission.)

obtained, it may not be necessary for the user to re-calibrate the chamber at all qualities  $Q$ ; it may be sufficient to do this only at the single reference quality  $Q_0$ ; the full calibration at all qualities to verify the quality dependence of that chamber can be performed less often. Furthermore, the calibration at the single reference quality need to be performed at the laboratory where the  $k_{Q,Q_0}$  values were measured (usually a PSDL). A possible limitation, common to options 1 and 2, lies in the difference between the beam qualities used at the PSDL and at the user's facility, which is of special relevance for high-energy beams (c.f. Andreo 1993) and which is still the subject of studies at some PSDLs. These two approaches are the preferred alternatives as they are based on the individual calibration of the user's chamber. However, it is acknowledged that for beam qualities other than cobalt-60, such possibilities are currently restricted to a small number of PSDLs. Two further approaches are possible:

3. Users are provided with a  $N_{D,w,Q_0}$  calibration factor for the ionisation chamber at the reference quality cobalt-60, and the *code of practice* gives theoretically derived beam-quality correction factors  $k_{Q,Q_0}$  for other beam qualities  $Q$  for that chamber type using Equation 18.17. This method, however, ignores chamber-to-chamber variations in response with energy for a given chamber type, and the calculations rely on chamber specifications provided by manufacturers. Nevertheless, this approach is currently the most common one.
4. Users are provided with a single measured  $N_{D,w,Q_0}$  for a given chamber, obtained at a selected reference quality, together with *generic*\* experimental values of  $k_{Q,Q_0}$  for that ionisation chamber type. In common with 3, this option does not take into account possible chamber-to-chamber variations for a given chamber type. IAEA (2000) recommends that such generic experimental  $k_Q$  or  $k_{Q,Q_0}$  values should be determined at an PSDL.

Figure 18.4 shows calculated  $k_Q$  for a number of cylindrical chambers in common use. Figure 18.5 shows a comparison between measured and calculated  $k_Q$ .

\* In the present context, *generic* means factors common to a specific ion-chamber type, in a specific form, as constructed by a given manufacturer.

**FIGURE 18.5**

Comparison of calculated values of  $k_Q$  (triangles) and mean values of  $k_Q$  measured at the NPL (Sharpe 1999) for Secondary Standard ionisation chambers of the type NE 2561 (open circles) and NE 2611 (filled circles). The solid line is a sigmoidal fit to the experimental data. The uncertainty bars represent chamber-to-chamber variations, determined as the standard deviations of samples of 13 NE 2561 (upper half of the error bar) and 11 NE 2611 (lower half of the error bar) chambers. The values of  $k_Q$  are normalized to a TPR<sub>20,10</sub> of 0.568 (cobalt-60 beam at the NPL). Note that the calculated values do not distinguish between the two types of chamber. (From International Atomic Energy Agency, Technical Report Series no. 398, IAEA, Vienna, 2000. With permission.)

## 18.4 INTER-RELATIONSHIP BETWEEN $N_K$ - $N_{D,\text{AIR}}$ AND $N_{D,\text{W}}$ CODES OF PRACTICE

In this section, the inter-relationship between the air-kerma and the absorbed-dose-to-water formalisms is discussed. In comparing Equation 18.11 and Equation 18.12 for the same reference beam quality  $Q_0$ , it follows that

$$N_{D,\text{w},Q_0} = N_{D,\text{air}}(\sigma_{\text{w},\text{air}})_{Q_0} p_{Q_0} \quad (18.21)$$

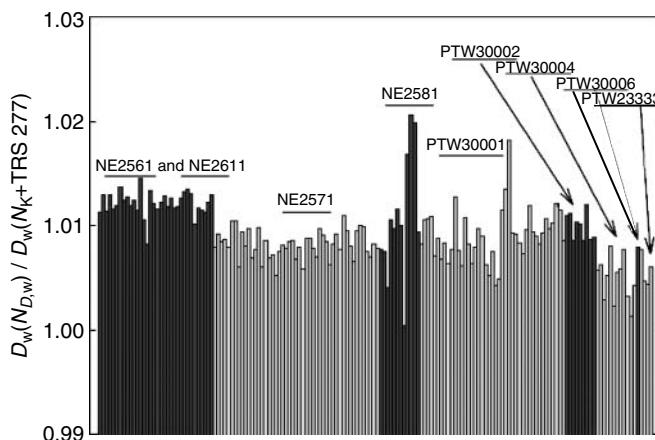

or in expanded form,

$$N_{D,\text{w},Q_0} = [N_K(1 - \rho)k_{\text{att}}k_m k_{\text{cel}}]_{\text{Co}}(\sigma_{\text{w},\text{air}})_{Q_0}[p_{\text{cav}} p_{\text{dis}} p_{\text{wall}} p_{\text{cel}}]_{Q_0} \quad (18.22)$$

where  $Q_0$  usually refers to cobalt-60  $\gamma$ -rays. The separate components of the overall perturbation factor  $p_{Q_0}$  shown in Equation 18.22 are listed in [Section 18.5.3](#) and discussed in [Appendix D, Section D.2](#).

The adoption of absorbed-dose-to-water-based codes of practice inevitably introduces small differences in the value of the absorbed dose to water determined in clinical beams compared with air-kerma based codes. However, any conclusions drawn from comparisons between these two types of protocols must take account of differences between primary standards. For a given primary standard, the results of a comparison will depend on the type and quality of the beam and on the type of ionisation chamber.

For a cobalt-60 beam, which is generally better characterised than other modalities, determination of  $D_w$  based on the two different types of protocol differs by typically 1%. [Figure 18.6](#) shows the ratio of absorbed dose to water in cobalt-60 determined using  $N_{D,\text{w}}$  to that using  $N_K$  following the IAEA TRS-277 *Code of Practice* (IAEA 1987) for a number of individual ionisation chambers of various types commonly used in clinical dosimetry. Discrepancies of this order can be expected when  $N_{D,\text{w}}$  and  $N_K$  calibrations, traceable to the BIPM and to most PSDLs, are used in hospitals and SSDLs. The change may be greater or smaller when calibrations are traceable to laboratories lying at the extremes of the distributions shown

**FIGURE 18.6**

The ratio of the absorbed dose to water in cobalt-60 determined with calibration factors in terms of absorbed dose to water,  $N_{D,w}$  (IAEA 2000), to the absorbed dose determined with calibration factors in terms of air kerma,  $N_k$  (IAEA 1987), for a large number of cylindrical ionisation chambers commonly used in radiotherapy dosimetry. Both calibration factors are traceable to the BIPM. Results for a given chamber type show chamber-to-chamber variations. The large variation for NE 2581 chambers is considered to be caused by the hygroscopic properties of the A150 plastic walls. (Reproduced from International Atomic Energy Agency, Technical Report Series no. 398, IAEA, Vienna, 2000. With permission.)

in Figure 18.6. Any systematic discrepancy between the two methods is probably due to inaccuracies in the numerical factors and expressions (for example,  $k_m$ ,  $p_{\text{wall}}$  etc.) used in the  $N_k$ -based formalism; in addition, there is the possibility of a systematic error in the air-kerma primary standards (Bielajew and Rogers 1992).

In the case of high-energy photon and electron beam calibrations, only the situations involving theoretically derived values of  $k_Q$  (category 3 in [Section 18.3.3](#)) are discussed here. The change in  $D_w$  at cobalt-60 is simply propagated through to high-energy beams as most of the coefficients and factors involved in the calculation of  $k_Q$  factors are approximately the same as in previous protocols, and no other differences are expected. For electron beams, in addition to the propagated change in  $D_w$  at cobalt-60 quality, the second largest contribution will be due to the implementation of stopping-power ratios  $s_{w, \text{air}}^{\text{SA}}$  for *clinical* beam qualities, as the basic data (i.e.  $s_{w, \text{air}}^{\text{SA}}$  for mono-energetic beams) has remained practically the same (see [Section 18.5.1](#) and [Appendix D, Section D.1](#)); this will result in changes of the order of 0.5%. As with cobalt-60, the differences lie within the combined standard uncertainty of the two types of codes of practice (see [Appendix D, Section D.5](#)).

## 18.5 QUANTITIES COMMON TO BOTH APPROACHES

The air-kerma based formalism for the determination of absorbed dose to water in reference conditions presented in [Section 18.2](#) includes stopping-power ratios and correction factors for so-called perturbation effects, the latter being detector-dependent. Some of the analytical models employed for the calculation of perturbation correction factors also include mass energy-absorption coefficient ratios. Concerning the absorbed-dose-to-water formalism presented in [Section 18.3](#), the approach most commonly used today relies on theoretically determined beam quality factors  $k_Q$  that are also based on stopping-power ratios and perturbation correction factors. These latter two quantities, common to the two formalisms, are briefly discussed here. The stopping-power ratios are discussed in [Section 18.5.1](#), the mass energy-absorption coefficient ratios in [Section 18.5.2](#), and the perturbation factors in [Section 18.5.3](#). Another important quantity common to both approaches is the mean

energy required to produce an ion pair in air, divided by the electron charge, ( $W_{\text{air}}/e$ ), which is dealt with in [Section 18.5.4](#). Finally, in order to be able to select the appropriate values of stopping-power ratio and the perturbation factors, the user's beam quality must be known. Therefore, beam quality specification, a crucial component of any code of practice, is covered in [Section 18.5.5](#). More detailed treatments of each of these components are given in [Appendix D](#).

### 18.5.1 STOPPING-POWER RATIOS

#### 18.5.1.1 General

The determination of the absorbed dose in a medium using an ionisation chamber is based on the Bragg–Gray principle (see [Section 6.7.3](#) and [Section 18.2.4](#)) which relates the absorbed dose at a point in the medium (water),  $D_w$ , to the mean absorbed dose in the detector (air),  $\bar{D}_{\text{air}}$ , through the mass (collision) stopping power ratio, water/air

$$D_w = \bar{D}_{\text{air}} s_{w,\text{air}} \quad (18.23)$$

The key Bragg–Gray assumption is that the electron fluence present in the detector is identical to that in the (undisturbed) medium at the position of interest (see [Section 6.7.3](#)). The gas-filled ionisation chamber behaves to a good approximation as a Bragg–Gray detector in megavoltage photon or electron beams. Any deviations from perfect Bragg–Gray behaviour are corrected for by perturbation factors which are the subject of [Section 18.5.3](#) and [Appendix D, Section D.2](#).

The stopping-power ratio applies to the electron spectrum at the point of interest in the *undisturbed* medium and is independent of the detector\*. The determination of this stopping-power ratio is the task of cavity theory and is described in [Appendix D, Section D.1](#).

#### 18.5.1.2 Stopping-Power Ratios for Electron Beams

The most important characteristic of electron stopping-power ratios is their strong dependence on energy and depth (see [Figure 18.7](#)), which is due to a combination of the considerable differences in energy spectra at the various depths and the strong energy dependence of the quantity  $[S_{\text{col}}(E)/\rho]_{\text{water}}/[S_{\text{col}}(E)/\rho]_{\text{air}}$  in the megavoltage energy range†.

The selection of the appropriate stopping-power ratio for the user's beam at a particular depth (e.g.  $(s_{w,\text{air}})_Q$  in [Equation 18.11](#)) is dealt with in [Appendix D, Section D.1.2](#).

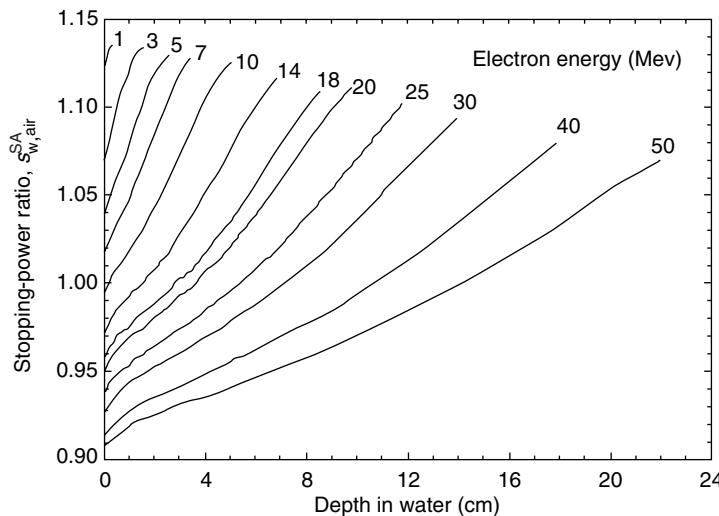

#### 18.5.1.3 Stopping-Power Ratios for Photon Beams

Stopping-power ratios in high-energy beams are calculated in the same way as for high-energy electron beams, i.e. by averaging  $[S_{\text{col}}(E)/\rho]_{\text{water}}/[S_{\text{col}}(E)/\rho]_{\text{air}}$  over the spectrum of (secondary) electrons present at the depth of interest. In contrast to the electron-beam case, the depth dependence of  $s_{w,\text{air}}$  for photon beams is negligible except possibly in the build-up region close to the surface; this lack of dependence on depth is essentially due to the establishment of quasi charged-particle equilibrium beyond the depth of maximum dose. Therefore, only one value of  $s_{w,\text{air}}$  per beam quality is required. A much more detailed treatment is given in [Appendix D, Section D.1.3](#).

[Figure 18.8](#) shows the variation of  $s_{w,\text{air}}$  with photon beam quality, characterised here by the widely established parameter  $TPR_{20,10}$  (see [Section 18.5.5](#) and [Appendix D, Section D.3.1](#));

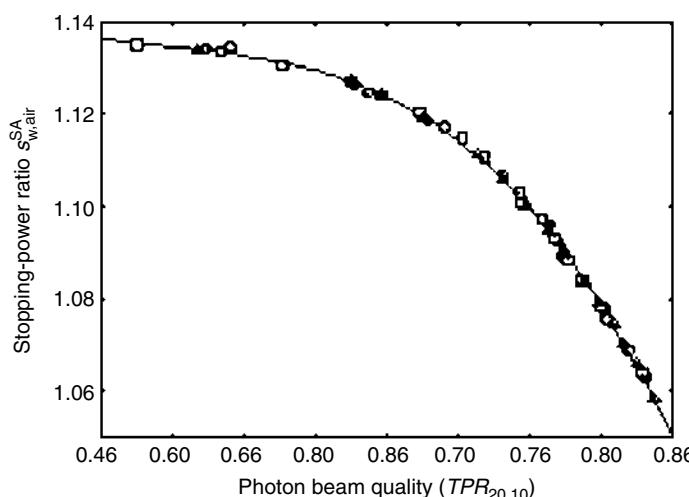

\* There is a minor dependence on air-cavity size expressed through the cutoff  $\Delta$  in the Spencer-Attix stopping-power ratio.

† This strong dependence on electron kinetic energy  $E$  is, in turn, due to the influence on  $[S_{\text{col}}(E)/\rho]_{\text{water}}$  of the density or polarisation effect at relativistic energies (see [Section 3.2.3](#)).

**FIGURE 18.7**

Depth variation of the Spencer-Attix water/air stopping-power ratio,  $s_{w,air}^{SA}$ , for  $\Delta = 10$  keV, derived from Monte-Carlo generated electron spectra for broad, monoenergetic, plane-parallel electron beams. (From Andreo, P., *Nucl. Instr. Meth. B*, 51, 107–121, 1990; and International Atomic Energy Agency, Technical Report Series no. 381, IAEA, Vienna, 1997. With permission.)

low values of  $TPR_{20,10}$  correspond to low photon (megavoltage) energies and vice versa. One can see from Figure 18.8 that the total variation in  $s_{w,air}$  over the quality range from  ${}^{60}\text{Co}$   $\gamma$ -rays to 50 MV x-ray beams is only around 6%, i.e. much less than that in electron beams (Figure 18.7).

**FIGURE 18.8**

Spencer-Attix ( $\Delta = 10$  keV) water/air stopping-power ratios at the reference depth for clinical photon beams versus the photon beam quality specifier  $TPR_{20,10}$ . Circles correspond to spectra published by different authors (Table 2 in Andreo and Brahme 1986), and squares represent the calculated spectra in the same reference. The solid line is a fit of the stopping-power ratios to the beam quality specifier  $TPR_{20,10}$ . (From Andreo, P., *Med. Phys.*, 27, 434–440, 2000.)

### 18.5.2 MASS ENERGY ABSORPTION COEFFICIENT RATIOS

The role of mass energy-absorption coefficient ratios in modern dosimetry protocols is mainly restricted to their use in calculating perturbation (principally  $p_{\text{wall}}$ ) and other correction factors for ionisation chambers in cobalt-60  $\gamma$ -ray and high-energy photon beams\*. In general they are associated with the fraction of energy deposited within a detector due to electrons generated by photon interactions in the detector material itself (i.e. the large cavity component—see [Section 6.7.2](#)).

Depending on the medium, the photon fluence spectrum may change appreciably with depth or material thickness, and it also depends on the field size of the incident beam. Cunningham et al. (1986) investigated the effects of spectral changes within a phantom on the mean mass energy-absorption coefficients using Monte-Carlo techniques. They showed that only for large field sizes or for low-energy photon beams is there more than a 0.5% variation in  $(\bar{\mu}_{\text{en}}/\rho)_{w,m}$ , the mass energy absorption coefficient ratio of water,  $w$ , to medium,  $m$ , for tissue-like materials.

Spectrum-averaged mass energy-absorption coefficient ratios are calculated according to

$$(\bar{\mu}_{\text{en}}/\rho)_{w,m} = \frac{\int_0^{E_{\text{max}}} \Phi_{E,w}(\mu_{\text{en}}(E)/\rho)_w E \, dE}{\int_0^{E_{\text{max}}} \Phi_{E,w}(\mu_{\text{en}}(E)/\rho)_m E \, dE} \quad (18.24)$$

where  $\Phi_{E,w}$  is the photon fluence, differential in energy at the point of measurement, assumed to be the same both in water,  $w$ , and in material,  $m$ ; and  $\mu_{\text{en}}(E)/\rho$  is the mass energy-absorption coefficient at energy  $E$  for each of the two materials respectively (see [Section 6.7.2](#)). For materials other than water, a similar relationship is applied.

The same set of bremsstrahlung spectra used by Andreo and Brahme (1986) to calculate stopping-power ratios has been used as input for calculations of  $\mu_{\text{en}}/\rho$ -ratios by Cunningham (c.f. IAEA 1987) to produce a consistent set of data for photon dosimetry that is used in most dosimetry protocols.

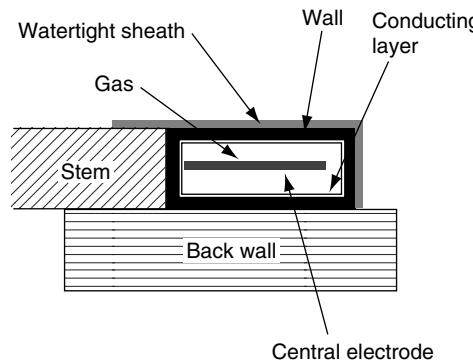

### 18.5.3 PERTURBATION CORRECTION FACTORS

For a detector to behave as a Bragg–Gray cavity, the electron fluence in the sensitive medium of the detector must be identical to that at a specified point in the uniform medium. The only possible true Bragg–Gray detector would be a small air bubble; all the codes of practice for absolute dose determination are, in fact, based on air-filled ionisation chambers.

For megavoltage photon radiation, the Bragg–Gray conditions (see [Section 6.7.3](#) and [Section 15.3.2.1](#)) are adequately fulfilled for air cavities of the size encountered in practical ionisation chambers, i.e. the ranges in air of the secondary electrons generated in megavoltage photon beams are much greater than the cavity dimensions (Ma and Nahum 1991). However, as [Figure 18.9](#) illustrates, an ionisation chamber does not only consist of an air cavity. There will always be a wall that, in general, will not be perfectly medium-equivalent (and is often made of graphite), whereas, the medium is usually water. For cylindrical chambers there is a central electrode which is frequently aluminium. There may be other materials around

---

\* The mass energy-absorption coefficients play a key role in photon dosimetry with so-called thick-walled chambers where the thickness of the chamber wall (or wall plus build-up cap) is greater than the range of the photon-generated secondary electrons (see [Appendix D, Section D.2.2](#)). Under the assumption that secondary charged-particle equilibrium exists (e.g. in the chamber wall), the absorbed dose to a medium,  $D_m$ , for a given photon fluence differential in energy  $\Phi_E$  is given by ([Section 6.4.2](#))  $D_m = \int \Phi_E (\mu_{\text{en}}/\rho)_m E dE$ .

**FIGURE 18.9**

An imaginary ionisation chamber. (From Nahum, A. E., *Phys. Med. Biol.*, 41, 1531–1580, 1996. With permission.)

the chamber such as a stem for cylindrical chambers and a back wall in the case of plane-parallel designs. All of these features can introduce deviations from perfect Bragg–Gray behaviour.

These deviations are generally dealt with by introducing one or more correction factors, often known as *perturbation* factors, into the expression for the absorbed dose, i.e. the factor  $p_Q$  in Equation 18.11. This overall factor is often written as the product of a number of perturbation factors, each one accounting for a different effect, assumed to be independent of the others (Equation 18.22). The word *perturbation* is used in the sense of a perturbation by the detector of the electron fluence present at the position of interest  $P$  in uniform medium,  $\Phi_{\text{med}}(P)$ . Naturally, it is the *fluence in the detector*, inevitably a mean value over a finite volume,  $\bar{\Phi}_{\text{det}}$ , that gives rise to the signal, i.e. the fluence in the air in the case of an ionisation chamber. Therefore, one can define the overall perturbation factor  $p$  with complete generality through (Nahum 1996)

$$\Phi_{\text{med}}(P) = \bar{\Phi}_{\text{det}} p \quad (18.25)$$

The different components of the overall perturbation factor are the following:

- $p_{\text{dis}}$  accounts for the displacement of a certain volume of medium by the air of the cavity, and the corresponding modification of the beam attenuation at the measuring point assumed to be located at the centre of the cavity. The displacement effect is most often treated by referring the measured dose to an effective point of measurement,  $P_{\text{eff}}$ , which is shifted toward the source of radiation by a distance expressed as a fraction of the detector radius,  $r$ , for cylindrical chambers (e.g. 0.6  $r$ ) or located on the inside of the entrance wall for plane-parallel chambers
- $p_{\text{wall}}$  accounts for the fact that the nature and composition of the chamber wall, which is responsible for a large proportion of secondary electrons contributing to the chamber signal, is different from water. This effect is considered to be negligible in electron beams
- $p_{\text{cel}}$  accounts for the lack of *air* equivalence of the central electrode of cylindrical chambers
- $p_{\text{cav}}$  accounts for the perturbation of the electron fluence in the air of the cavity; this effect is important for electron beams but is negligible for photon beams

The values of the perturbation factors which should be used in practical dose determination depend on the nature and quality of the radiation and on the characteristics of the detector. They are given in each code of practice. More details on the methods that have been used to obtain these factors and their order of magnitude can be found in [Appendix D, Section D.2](#). The general conclusions are presented here.

In both photon and electron beams, account must be taken of the displacement effect. This is most conveniently done by assigning the chamber reading to an effective point of measurement  $P_{\text{eff}}$ . For photon beams, the effect of the chamber wall is important, and an approximate formula for  $p_{\text{wall}}$  is generally used in air-kerma based codes of practice (e.g. AAPM 1983; IAEA 1987, 1997a); this is acceptably accurate for cylindrical, but not for plane-parallel chambers. For electron beams, the *in-scattering* effect is important for cylindrical chambers at energies  $E_z$  below around 10 MeV and experimentally derived values for  $p_{\text{cav}}$  are given in the codes. Plane-parallel chambers can be designed which minimize this perturbation. Wall effects are generally unimportant in electron beams, and *in-scattering* is unimportant in photon beams. The effect of the central electrode in cylindrical chambers can be separately taken into account through  $p_{\text{cel}}$ , which is significantly different from unity for aluminium central electrodes in low-energy photon beams.

#### 18.5.4 MEAN ENERGY EXPENDED IN AIR PER ION FORMED, ( $W_{\text{air}}/e$ )

It is generally assumed that a constant value of  $W_{\text{air}}$  can be used for the complete photon and electron energy range used in radiotherapy dosimetry, and therefore,  $(W_{\text{air}})_Q = (W_{\text{air}})_{Q_0}$ . There is a lot of indirect support for such an assumption. However, the data available has been obtained from measurements at a narrow range of photon qualities,  $^{60}\text{Co}$  and  $^{137}\text{Cs}$   $\gamma$ -ray beams and 2 MV x-rays. The value  $(W_{\text{air}}/e) = 33.85 \pm 0.15 \text{ J/C}$ , recommended by ICRU report 31 (1979), was derived from a weighted mean value of the available experimental data, mainly obtained from absorbed dose measurements that use a graphite calorimeter and a graphite ionisation chamber in a graphite phantom where

$$(W_{\text{air}}/e) = \frac{D_{\text{calorimetry}}}{J_{\text{air}} s_{\text{graphite,air}}} \quad (18.26)$$

This method of evaluation requires a change in  $(W_{\text{air}}/e)$  if the stopping-power ratio  $s_{\text{graphite,air}}$  is changed (Andreou et al. 1987). Following the introduction of new electron stopping power data by ICRU (1984b), the value of  $(W_{\text{air}}/e)$  has been modified by the CCEMRI(I) (1985) to  $(W_{\text{air}}/e) = 33.97 \pm 0.06 \text{ J/C}$ , based on the work by Boutillon and Perroche-Roux (1987).

Svensson and Brahme (1986) analysed the then available experimental data at higher energies, mainly for electron beams, and concluded that a small but non-negligible energy dependence in  $(W_{\text{air}}/e)$  could not be excluded, but experimental uncertainties and the use of different stopping-power ratios over the years do not allow a definitive conclusion to be reached.

#### 18.5.5 BEAM QUALITY SPECIFICATION

A key issue in practical dosimetry is how to characterise the beam qualities available in radiotherapy clinics so that appropriate values of the energy-dependent stopping-power ratios and perturbation factors can be chosen. Ideally, these quantities should be available for the user beam and detector configuration in the measurement conditions at the particular hospital. In the near future, however, Monte-Carlo calculations may become available for every possible user configuration; the only option widely available today is to correlate the relevant quantities to beam-quality specifiers or indices related to the penetration properties of clinical beams. The most common methods of quality specification used in the various codes of practice are the following:

- For megavoltage photon beams, instead of specifying the quality in terms of *nominal energy*\* (in MV), it is clearly recognised that it is much better to use the beam *attenuation* in water\* as a means to select the best values for  $s_{w,\text{air}}$  and for the perturbation effects. This attenuation is generally expressed by the quantity  $TPR_{20,10}$  defined as the ratio of absorbed dose to water on the beam axis at the depths of 20 cm and 10 cm in a water phantom, obtained with a constant source-detector distance and a 10 cm  $\times$  10 cm field size at the position of the detector.
- For electron beams, the indices most commonly used are the mean energy at the surface,  $\bar{E}_0$ , and the mean energy at depth  $z$ ,  $\bar{E}_z$ , calculated from the ranges obtained from depth dose curves (see [Section 24.2](#)) from the following relationships:

$$\bar{E}_0[\text{MeV}] = CR_{50} \quad (18.27)$$

where  $C=2.33 \text{ MeV cm}^{-1}$  and  $R_{50}$  is the depth where the absorbed dose has decreased to 50% of its maximum value and is expressed in centimetres.

$$\bar{E}_z = \bar{E}_0(1 - z/R_p) \quad (18.28)$$

where  $R_p$  is the practical range defined as the depth where the tangent at the steepest point (the inflection point) on the almost straight descending portion of the depth-dose curve meets the extrapolated bremsstrahlung background.

More details on the specification of radiation quality can be found in [Appendix D](#), [Section D.3](#).

## 18.6 KILOVOLTAGE X-RAY BEAMS

### 18.6.1 INTRODUCTION

During the past 30 years or so, there has been a great deal of development in the dosimetry of high-energy, i.e. megavoltage, photon and electron beams as the above sections clearly demonstrate. However, the dosimetry of low-energy or *orthovoltage* (below 400 kV) x-ray beams (referred to in what follows as *kilovoltage* and described in [Chapter 21](#)) remained more or less static until the late 1980s. As an example, in the U.K. Code of Practice for photon dosimetry (HPA 1983) so-called *medium-energy x-radiation* was confined to a short appendix. Despite this, kilovoltage beams are still in widespread use for the treatment of superficial lesions (Ma et al. 1996; Poen 1999). Furthermore, radiobiologists have continued to use such qualities in cell-irradiation experiments, and the validity of RBE values, for example, depend on the ability to determine the dose accurately in kilovoltage x-ray beams, often in much more complicated geometries than are encountered in clinical radiotherapy. The IAEA (1987) Code of Practice devoted a separate, detailed section to kilovoltage x-rays, setting out a new air-kerma based formalism, and this was followed by national codes on kilovoltage x-ray dosimetry (DIN 1988, 1996; IPEMB 1996b; NCS 1997; Ma et al. 2001 for the AAPM).

The emphasis here is on *air-kerma* based dosimetry. However, with kilovoltage x-rays, as with all other external-beam radiotherapy modalities, there is a move toward absorbed-dose-to-water standards (see [Section 18.6.7](#)).

---

\* This concept is somewhat similar to the Half Value Layer approach for kilovoltage x-rays, but water is preferred to layers of metal for megavoltage beams because the variation of the attenuation coefficient as a function of the energy is more rapid, and therefore, yields a more accurate index.

### 18.6.2 SOME BASIC PHYSICS

The dosimetry of kilovoltage x-rays was originally based on the concept of treating the dosimeter as an *exposure meter* (e.g. Attix 1986), i.e. the chamber was calibrated in terms of exposure at the quality of interest, and its reading in the phantom was interpreted as measuring exposure at the chamber centre. Air kerma has now replaced exposure, but the concept remains identical. The original kV dosimetry formalism involved so-called  $F$ -factors that converted from roentgen, the unit of exposure, to rad, the old unit of dose ( $1 \text{ Gy} = 100 \text{ rads}$ );  $F$  is essentially the product of  $(\mu/\rho)_{w,\text{air}}$  and  $(W_{\text{air}}/e)$  (see, for example, Nahum 1999b). This *exposure meter* approach was carried over into megavoltage photon dosimetry through the  $C_\lambda$  concept (e.g. ICRU 1969) though it was subsequently replaced by the  $N_{D,\text{air}}$  formalism (see [Section 18.2](#)) which is conceptually much clearer because the ionisation chamber can be explicitly treated as a Bragg–Gray cavity.

In the case of kilovoltage x-rays, however, the secondary electrons have extremely short ranges because of their much lower initial energy coupled with the rapid increase of the collision stopping power at sub-relativistic energies (see [Section 3.2](#)). The Bragg–Gray principle ([Section 6.7.3](#)) can no longer be applied to such qualities, i.e. the electron fluence in the air cavity of the ionisation chamber is not exclusively determined by the electron interactions in the surrounding medium. This had been understood for many years; Ma and Nahum (1991) used Monte-Carlo simulation to estimate the fraction,  $F_{\text{air}}$ , of the ionisation in an air cavity that originated from photon interactions in the air itself. Their results are given in Table 18.1.

The numbers in this table show that at 240 kV, almost 30% of the signal in the chamber comes from photon interactions in the air, compared to less than 1% for cobalt-60  $\gamma$ -rays and above. Clearly, one cannot base a formalism for kilovoltage x-ray dosimetry on Bragg–Gray assumptions and therefore on stopping-power ratios. However, if it is a disadvantage that ionisation chambers cannot be treated as Bragg–Gray cavities in kilovoltage x-ray beams, then one has the compensating advantage that dose can be equated to kerma to a very good approximation, and also  $g$ , the fraction of kerma re-radiated as bremsstrahlung, can be assumed to be zero (see [Section 6.3.2](#)).

Another important difference between kilovoltage and megavoltage x-ray dosimetry lies in the nature of the calibration factor. Air-kerma based megavoltage dosimetry (see [Section 18.2](#)) employs the factor  $N_K$  which is *realised* only at one quality,  $^{60}\text{Co}$   $\gamma$ -rays. The reason for this is that it is increasingly difficult to determine air kerma (originally exposure) for any higher photon energies because of the increase in electron ranges, making the establishment of charged particle equilibrium (CPE) virtually impossible; very thick build-up caps would be required with correspondingly large correction factors ( $k_m$ ,  $k_{\text{att}}$ , etc.). Then, as has been

**TABLE 18.1**

Origin of the Ionisation in a Cavity for a Range of Photon Energies

Incident Beam			$F_{\text{air}}$
Tube Potential	HVL (mm Al)	In Vacuum	5 cm Depth in Water
50 kV	1.62	0.26	0.18
150 kV	5.01	0.27	0.29
240 kV	7.30	0.27	0.27
240 kV	17.4	0.18	0.23
Cobalt-60		0.0037	0.0060
4 MV		0.0014	0.0098

$F_{\text{air}}$  is the ratio of the ionisation due to photon interactions in the air itself to the total ionisation measured in the air of the cavity for a range of photon beam qualities. The cavity size is 6 mm in thickness and diameter. The kilovoltage photon beams are characterized by both tube potential and first half-value layer (HVL).

Source: From Ma, C.-M. and Nahum, A. E., *Phys. Med. Biol.*, 36, 413–428, 1991. With permission.

mentioned in earlier sections, stopping-power ratios are required to convert from cobalt-60 to other qualities, based on Bragg–Gray principles. However, at kilovoltage qualities, air kerma can *always* be realised; CPE can be established as the electron ranges are so much shorter (see Table 6.1 in Section 6.5). In fact, in kilovoltage beams, air kerma is determined at PSDLs using free-air chambers (see Section 15.3.1) where CPE is actually established in the air itself, rather than in the thick wall of a cavity chamber as it is in a cobalt-60 beam (as depicted in Figure 18.1). Consequently, SDLs provide  $N_K$  for the user's chamber over a range of kilovoltage photon qualities.

A third difference lies in the way that kilovoltage beam quality is specified. This is done in terms of the *Half-Value Layer* (HVL, see Section 21.2.2), generally expressed in millimetres of aluminium or, at the top end of the energy range copper. The HVL is that thickness of material that reduces the air kerma to half its value. It must be measured in narrow-beam geometry such that the influence of photon scatter generated in the attenuating material is negligible (see Section 21.2.2). It should be noted that beams with widely differing generating potentials can have similar HVL because of the marked effect of different filtrations (e.g. Knight and Nahum 1994 and Table 21.1). Therefore, the user must determine the HVL of the beam of interest and then choose  $N_K$  values for the calibrated chamber for that beam using the calibration curve supplied by the SDL.

### 18.6.3 BACKGROUND TO AIR-KERMA BASED CODES OF PRACTICE

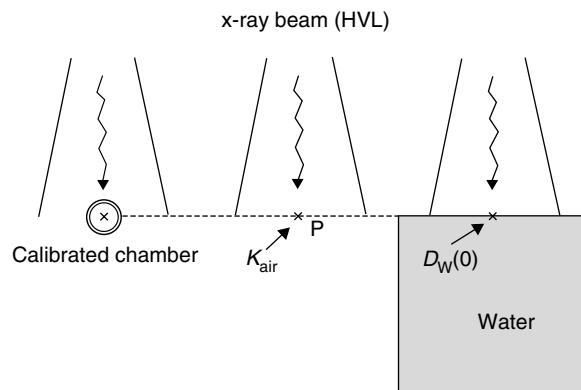

In the case of kilovoltage x-rays, codes of practice generally recommend two entirely separate methods: one to be used at *medium* energies that involves placing the calibrated chamber in a water phantom at a specified depth (as for megavoltage beams), and the other to be used at *low* energies that is based on a measurement *free-in-air*, i.e. with no phantom involved at all. In the German and U.K. protocols, there is even a third method at *very low* energies.

The IAEA (1987) Code of Practice established an air-kerma based formalism for kilovoltage x-rays with clear expressions containing all the factors. Furthermore, IAEA (1987) also contained new values of the backscatter coefficient  $B$  and the correction factors for the in-phantom ionisation chamber at medium energies; previously, the latter had been implicitly assumed to be equal to unity in the exposure-based codes of practice (ICRU 1973; HPA 1983).

If one compares the dose derived following the IAEA (1987) Code of Practice to that derived following the ICRU (1973) Code or equally well the HPA (1983) Code, one finds a difference of nearly 10% in the dose at 5 cm depth in water at  $\approx 100$  kV. For a beam with an HVL of 0.44 mm of Al and a 10 cm diameter field the difference is nearly 6% in the dose at the surface. These differences, which were due to an error in IAEA (1987) (see Section 18.6.5), were largely responsible for a *renaissance* in the dosimetry of low-energy x-rays. New national protocols specifically on kilovoltage x-ray dosimetry have appeared (DIN 1988, 1996; IPEMB 1996b; NCS1997; Ma et al. 2001 for the AAPM). They are all quite similar in their formalisms and have been summarised and compared by Peixoto and Andreo (2000). The basic ideas common to these protocols are given in the following sections.

### 18.6.4 THE BACKSCATTER METHOD (LOW ENERGIES)

Clinically, the dose is most often prescribed on the skin surface (strictly just below the skin where CPE is established). This has led to the most widely used method of determining the absorbed dose. The principle is straightforward. A chamber is positioned free-in-air, i.e. with no phantom involved, at a position corresponding to the centre of the field on the

**FIGURE 18.10**

A schematic illustration of the *backscatter method* for determining the dose at the surface of a water phantom.

patient's skin surface. The reading of the (calibrated) chamber yields air kerma. This is then converted into dose to water at the field size of interest by the application of a backscatter factor  $B$  that is a function of field size and the HVL of the beam (Figure 18.10). The energy, or quality range, for this method differs slightly from code to code, but all of them denote it by the term *low energy*; in IPEMB (1996b), for example, this refers to HVLs in the range 1 mm to 8 mm in aluminium, covering approximately 50 kV to 160 kV beams; in IAEA (1987), this range is 10 kV to 160 kV.

In IPEMB (1996b), NCS (1997) and AAPM (2001), the following theoretical route has been chosen:  $K_{\text{air}}$  is converted into water kerma,  $K_w$ , (through the mass-energy absorption coefficient ratio, water to air) but still under *free-in-air* conditions, i.e. for the primary beam spectrum. This has the advantage that  $(\bar{\mu}/\rho)_{w,\text{air}}$  is independent of field size. Then the backscatter factor  $B_w$  converts  $K_{w,\text{primary}}$  into the water kerma at the surface of a water phantom\* (Nahum and Knight 1994).

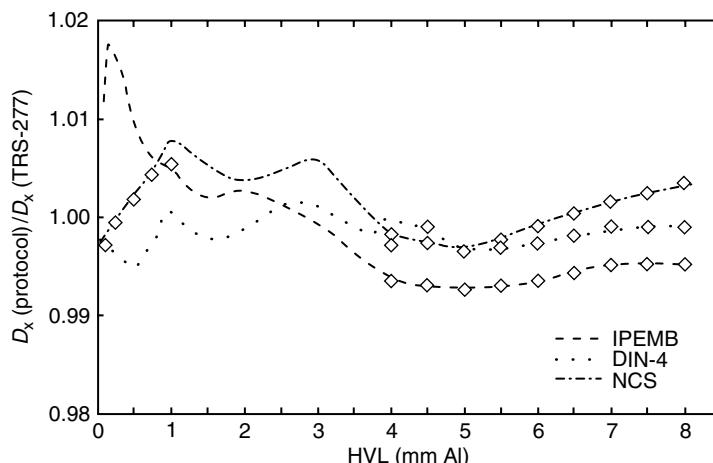

Following the nomenclature in IPEMB (1996b), the absorbed dose to water at the surface is given by

$$D_{w,z=0} = M N_K B_w \left[ \left( \frac{\bar{\mu}_{\text{en}}}{\rho} \right)_{w,\text{air}} \right]_{\text{air}} \quad (18.29)$$

where  $M$  is the instrument reading corrected to standard conditions,  $N_K$  is the air-kerma chamber calibration factor for the HVL of the user's beam,  $B_w$  is the backscatter factor (see above) for the field size, HVL, and Source to Surface Distance of the user's beam and  $\left[ (\bar{\mu}_{\text{en}}/\rho)_{w,\text{air}} \right]_{\text{air}}$  is the mass energy-absorption coefficient ratio, water to air, for the *free-in-air* (i.e. *primary*) spectrum. The factor  $B_w$  is written with the subscript  $w$  to emphasise that it is a ratio of *water* kermas (explicitly for the spectrum at the water-phantom surface to that of the primary beam).

IAEA (1987) gave values of the backscatter factor that differed considerably (by several percent for certain combinations of HVL and field size) from the values given in BIR (1983) that had been recommended in earlier codes such as HPA (1983). These new IAEA factors

\* The backscatter factor  $B_w$  is here a ratio of *water* kermas. This differs from IAEA (1987) in which the backscatter factor is a ratio of *air* kermas (though this was never made explicit), and the mass-energy absorption coefficient ratio is field-size dependent; the two routes are formally equivalent. Numerically, there is very little difference between  $B_w$  and  $B_{\text{air}}$  but conceptually the distinction is important.

**FIGURE 18.11**

Ratios of absorbed dose to water in reference conditions at the surface of the phantom for x-rays in the range 10 kV to 160 kV determined using the protocols IPEMB (1996b) DIN-4 (1988) and NCS (1997) normalized to that determined using IAEA (1997a). Symbols correspond to extrapolated data (the first symbol in each extrapolated region corresponds to the last value tabulated in the protocol). (Reproduced from Peixoto J. G. P. and Andreo, P., *Phys. Med. Biol.*, 45, 563–575, 2000. With permission.)

were computed by Grosswendt (1984) using Monte-Carlo simulation, and subsequently confirmed by Knight (1993, 1996). Measurements of  $B$  by Klevenhagen (1989), using a specially constructed thin-window parallel-plate chamber, and by Coudin and Marinello 1998, using thin lithium borate TLD chips, generally agreed much better with the Monte-Carlo values than with those given in BIR (1983).

In principle, the type of ionisation chamber has no significance when one utilizes the backscatter method to determine the surface dose; one is merely using the chamber as a means of transferring the air kerma from the Standards Dosimetry Laboratory to the user's beam. In practice, however, the chamber should show a small, preferably negligible, variation in  $N_K$  with  $HVL$  over the full quality range. In the IPEMB Code of Practice, the U.K. secondary standard instrument, formerly the NE2561 now replaced by the NE2611, is to be used over the complete *medium* and *low* energy range. The IAEA (1987) code recommended a thin-window plane-parallel chamber for the *low* energy range.

A comparison of the absorbed dose to water at the surface determined using four different kV codes, with the IAEA 1997a code as a reference, is given in Figure 18.11. The differences are mostly within 1%.

### 18.6.5 THE IN-PHANTOM METHOD (*MEDIUM* ENERGIES)

For so-called *medium* energy x-ray beams, defined in IPEMB (1996b) as being in the range of approximately 160 kV to 300 kV\*, 0.5 mm to 4 mm HVL in copper or >8 mm in aluminium, it is recommended that the dose be determined at a reference depth in a water phantom. The various codes differ in their specification of this reference depth. IAEA (1987) specifies a depth of 5 cm. In IPEMB (1996b), NCS (1997) and Ma et al. (2001) this is 2 cm, which is more representative of clinical practice.

\* IAEA (1987) specified this as 100 kV to 300 kV.

Using again the IPEMB (1996b) nomenclature, the absorbed dose to water at 2 cm depth,  $D_{w,z=2}$ , is given by

$$D_{w,z=2} = M N_K k_{ch} \left[ \left( \frac{\bar{\mu}_{en}}{\rho} \right)_{w,air} \right]_{z=2,\phi} \quad (18.30)$$

where  $M$  is the instrument reading corrected to standard conditions,  $N_K$  is the air-kerma chamber calibration factor for the HVL of the user's beam,  $[(\bar{\mu}_{en}/\rho)_{w,air}]_{z=2,\phi}$  is the mass energy-absorption coefficient ratio, water-to-air, for the photon spectrum at 2 cm depth in water and for field size  $\phi$  of the user's beam, and  $k_{ch}$  is an overall correction factor\*.

The factor  $k_{ch}$  corrects for several different effects. It converts from *air kerma* at the centre of a *hole* in the phantom made by the outer surface of the chamber wall, corresponding to the free-in-air calibration situation, to the air kerma at the centre of the water volume that replaces the chamber. Then  $(\bar{\mu}_{en}/\rho)_{w,air}$  converts from *air kerma* to water kerma, and finally, dose to water is equated to water kerma as there is CPE (Nahum and Knight 1994). The different effects in  $k_{ch}$  include the displacement of water by the chamber, the change in photon energy and angular distributions between the *in-air* and *in-phantom* situations and chamber stem effects (e.g. Hohlfeld 1996).

IAEA (1987) effectively gave  $k_{ch}$  values (denoted by  $p_u$ ) that steadily increased with decreasing kV or HVL to 1.10 at 100 kV (4 mm Al); these were for Farmer-like cylindrical chambers such as the NE2571 (see [Table 15.2](#) in [Chapter 15](#)).

Following the publication of IAEA (1987), the factor  $k_{ch}$  was extensively investigated, mostly for the NE2611 and NE2571 cylindrical chambers (e.g. Ma and Nahum 1994, 1995a, 1995b; Hohlfeld 1996; Seuntjens and Verhaegen 1996; Seuntjens et al. 1999). There was agreement that the IAEA (1987) values were incorrect. The IAEA officially withdrew their 1987 numbers, and IAEA (1997a) includes a revised table of  $p_u$  values that vary from 1.0 at around HVL=3 mm Cu to 1.03 at 0.2 mm Cu with the uncertainty estimated to be 2% (1 SD). There is now a reasonable consensus on the values of the overall correction factor as given in IAEA (1997a) and IPEMB (1996b); these are for the NE2571 and NE2611 chambers as a function of the HVL in Al and Cu. Additionally, the AAPM code (Ma et al. 2001) gives values for a number of other chambers, including the Capintec PR-06C, Exradin A12 and NE2611. All of these go through a maximum around 0.5 mm to 0.6 mm Cu. This consensus is within 1.5%; none of the values given in any of the codes is below 0.99 or above 1.04.

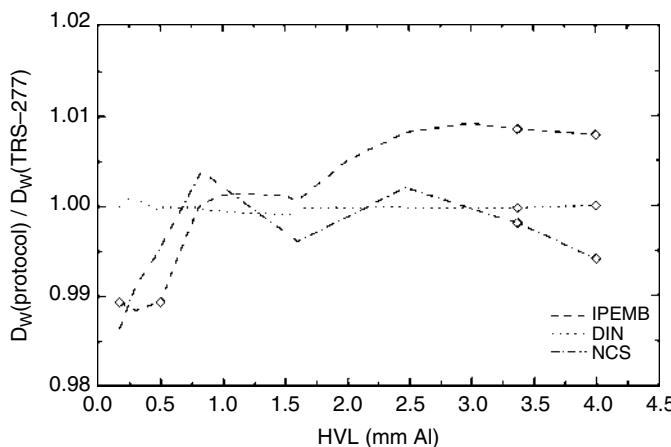

The factor  $(\bar{\mu}_{en}/\rho)_{w,air}$  has been evaluated by Monte-Carlo simulation by, for example, Knight (Knight and Nahum 1994; Knight 1996). The values by various investigators agree within 1% or so; the factor  $(\bar{\mu}_{en}/\rho)_{w,air}$  only depends weakly on field size or depth.

[Figure 18.12](#) shows how the various codes (but not including AAPM—Ma et al. 2001) differ in dose determinations at 2 cm depth in water; the range is within 1.5% at all qualities of interest.

## 18.6.6 VERY LOW ENERGIES

IPEMB (1996b) has defined a third energy range: *very low* (0.035 mm to 1.0 mm Al, approximately 8 kV to 50 kV); this category was necessary for several reasons. Firstly, in the U.K. (and also in France and Sweden, for example), such low energies are used for certain treatments (e.g. so-called Buckytherapy or Grenz-ray therapy). Secondly, the secondary standard chamber cannot be used at these energies as its response, i.e. the  $N_K$  vs HVL calibration curve, is no longer approximately flat. Instead, a thin-window parallel-plate

\* In IAEA (1987) this factor is denoted by the product of  $k_u$  and  $p_u$ , and by  $P_{Q, cham}$  in AAPM (2001).

**FIGURE 18.12**

Ratios of absorbed dose to water in reference conditions at 2 cm depth in water for x-rays in the range 100 kV to 300 kV determined using the protocols IPEMB (1996b) DIN-5 (1996) and NCS (1997), normalized to that determined using IAEA (1997a). Symbols correspond to extrapolated data (the first symbol in each extrapolated region corresponds to the last value tabulated in the protocol). (Reproduced from Peixoto J. G. P. and Andreo, P., *Phys. Med. Biol.*, 45, 563–575, 2000. With permission.)

chamber is recommended. Furthermore, the backscatter method may be invalid for the very small field sizes sometimes clinically employed in such low-energy beams, i.e. the field size can be insufficient to completely cover the chamber, and consequently the value of the product  $M \times N_K$  will no longer yield the correct value for air kerma free-in-air in the user's beam.

For this *very low* energy region, IPEMB (1996b) recommends that a parallel-plate chamber be placed at the surface of a water phantom and the dose at the surface be determined; DIN (1988) also specifies this method. The relevant expression is identical to that for the in-phantom *medium-energy* method (see [Section 18.6.5](#)) except that, now, the factor  $k_{ch}$  refers to the specific parallel-plate chamber employed and pertains to the surface dose rather than that at 2 cm depth and is consequently designated  $k_{pp,z=0}$ . At the time of the publication of the IPEMB code, no values of  $k_{pp,z=0}$  had been determined either experimentally or theoretically, and therefore this factor was simply assumed to be equal to unity. However, this cannot be correct as it assumes that the scatter from the body of the chamber is negligible (cf. the hole involved in determining  $k_{ch}$  for a cylindrical chamber in [Section 18.6.5](#)); effectively  $k_{pp,z=0}$  has to *put this scatter back*. Ipe et al. (1999) have since experimentally determined  $k_{pp,z=0}$  and found that it varies from about 1.01 to 1.08 for a field diameter of 5.4 cm (at a focal distance of 50 cm) depending on the chamber, beam quality and phantom.

Perrin et al. (2001) determined  $k_{ch}$  for three different chamber types: PTW 23344 large-volume and PTW 23342 small-volume soft x-ray chambers and a Markus parallel-plate electron chamber, as a function of FSD, applicator size and beam quality; their experimental method involved effectively extending the energy range of the backscatter factor method (see [Section 18.6.4](#)). For each of the chamber types, an additional 0.1 mm polythene sheet was placed over the entrance window to increase the (total) window thickness to greater than  $8.5 \text{ mg cm}^{-2}$  as recommended in IPEMB (1996b). No variation of  $k_{ch}$  was found with FSD. For the PTW 23344 chamber,  $k_{ch}$  increased approximately linearly with HVL from  $1.01 \pm 0.005$  at 0.04 mm Al to  $1.075 \pm 0.005$  at 0.98 mm Al for a 50 mm diameter field; Ipe et al. (1999) had obtained values approximately 1% higher. For the PTW23342 chamber, Perrin et al. found very similar  $k_{ch}$  values in the 0.04 mm to 0.6 mm Al range and  $k_{ch} \approx 1.06$  at 0.98 mm Al. The variation with applicator size/field diameter was found to be much less than with HVL,  $k_{ch}$  decreasing by around 1% as the field diameter was increased from 2 mm to 15 mm for both PTW chamber designs, but a clear trend was difficult to discern. For the

Markus chamber, the trend was toward increasing  $k_{ch}$  as the field size increased; however, this chamber type should not be used for absolute dose determinations at very low energies as its  $N_K$  varies by more than the 5% over this quality range. They concluded that the use of  $k_{ch} = 1$  given provisionally in the IPEMB kV code (IPEMB 1996b) could result in a significant *underestimation* of the dose in this *very low* energy region.

### 18.6.7 ABSORBED DOSE TO WATER CALIBRATION

All of the above applies to air-kerma calibrations. Standards of absorbed dose to water in the kilovoltage x-ray range are not generally available. However, it is possible to derive calibration factors in terms of absorbed dose to water from air-kerma calibration factors using one of the accepted codes of practice (see IAEA 2000). In this way any calibration laboratory with standards of air kerma can provide (derived) calibration factors in terms of absorbed dose to water. Even though this is formally equivalent to the user obtaining an air-kerma calibration and individually applying the same air-kerma code of practice as used by the calibration laboratory, it has the advantage of extending the use of the unified methodology of absorbed dose to water standards to kilovoltage x-rays for which such standards have yet to be developed.

---

## 18.7 PROTONS AND HEAVY CHARGED PARTICLES

The use of proton and heavy-ion beams in radiotherapy has been increasing in recent years (see Chapters 46 and 49). Practical dosimetry at these qualities is also based on the use of ionisation chambers that can be provided with calibrations both in terms of air kerma and in terms of absorbed dose to water. This section presents an overview of the different procedures for the calibration of clinical proton and heavy-ion beams, extending the review of proton beam dosimetry provided by Medin (1997) to all types of heavy charged particles.

Although protons have been used for radiotherapy since the mid-1950s, no dosimetry recommendations were issued until 1986. Proton and heavy-charged particle beam dosimetry was largely based on Faraday cups and calorimeters used together with ad hoc procedures for ionometry. This situation contrasts with the much longer tradition of codes of practice for high-energy photon and electron beam dosimetry. The pioneer dosimetry protocol issued by AAPM (1986) was addressed to heavy charged particles in general. As few data were available at that time, this protocol concentrated on a discussion of the different dosimetry methods available and retained Faraday cups and calorimeters as the preferred choice. The subsequent dosimetry protocols for protons issued by the European Clinical Heavy Particle Dosimetry Group, ECCHED (Vynckier et al. 1991, 1994), represented an improvement with regard to the data and practical procedures provided. Although calorimetry and Faraday cups were still the primary dosimetry recommendation in the 1991 protocol, the use of ionisation chamber dosimetry received more attention than in AAPM (1986). This was in parallel with neutron dosimetry, and A-150 was the preferred choice of material both for calorimetry and for the construction of ionisation chamber walls. The 1994 protocol updated proton stopping powers, adopting those from ICRU (1993), and allowed the use of other types of ionisation chambers even if no detailed chamber data were supplied\*.

The ICRU published a report (no.59) on proton dosimetry (ICRU 1999) where, for the first time, the recommended choice of reference dosimeter was a thimble ionisation chamber. The use of water-based calorimeters is, however, encouraged. ICRU Report 59 is the most comprehensive document on proton dosimetry published to date, and includes both the *air-kerma* and *absorbed-dose-to-water* based formalisms for the determination of absorbed

---

\* The user was, instead, referred to IAEA (1987a) and AAPM (1983) to derive chamber-specific factors.

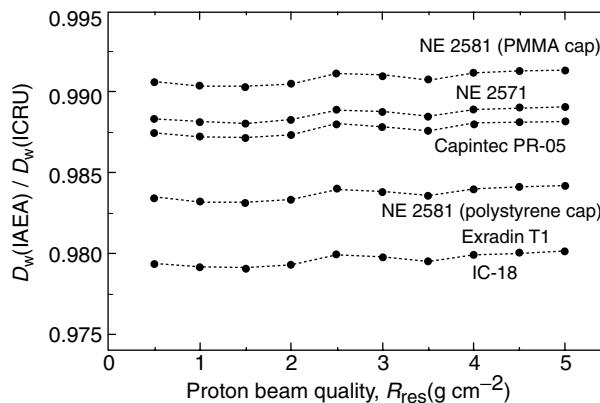

dose to water using ionisation chambers. Unfortunately, instead of providing a unified formalism, this ICRU publication mixes the notation of AAPM (1983), ICRU (1984a) and IAEA (1987), resulting in unnecessary complications for the user.

For all types of heavy charged particles, the *air-karma based formalism* for absorbed dose determination using an ionisation chamber is the same as has been described above (see [Section 18.2](#)) except for the lack of constancy of the mean energy required to produce an ion pair in air,  $W_{\text{air}}$ . When the reference quality  $Q_0$  is cobalt-60  $\gamma$ -rays, the  $N_{D,\text{air}}$  chamber factor, at this quality, is identical to that given in [Equation 18.8](#), but the expression for the absorbed dose to water is modified for the user's heavy charged particle beam quality  $Q$  by the ratio of  $W_{\text{air}}$ -values for this quality  $Q$  and for cobalt-60 according to

$$D_{w,Q}(P_{\text{eff}}) = M_Q N_{D,\text{air},Q_0} \left[ (W_{\text{air}})_Q / (W_{\text{air}})_{Q_0} \right] (s_{w,\text{air}})_Q p_Q \quad (18.31)$$

where, as for electron and photon beams, the factor  $p_Q$  includes the product of different perturbation correction factors of the ionisation chamber at the user's heavy charged particle beam quality  $Q$  (see [Section 18.5.3](#) and [Appendix D, Section D.2](#)). These factors are assumed to be equal to unity for most ionisation chambers used in charged-particle beam dosimetry although the shift of the effective point of measurement for a cylindrical ionisation chamber is still required for heavy ions. As in the dosimetry of all other types of radiation, the values for  $W_{\text{air}}$  and for the stopping-power ratios must be consistent as most determinations of  $W_{\text{air}}$  are based on the knowledge of stopping-power data. [Figure 18.13](#) illustrates the level of consistency achieved in absorbed dose to water determinations based on the IAEA and ICRU  $N_K$  formalisms using different cylindrical ionisation chambers ([Medin et al. 2000](#)).

The IAEA Code of Practice, based on standards of *absorbed dose to water* ([IAEA 2000](#)), has provided recommended procedures and updated data for the dosimetry of proton and heavy-ion beams based on the  $N_{D,w}$ -formalism (see [Section 18.3.2](#)). Because of the lack of standards for this type of radiation, the only current possibility is to use ionisation chambers calibrated in a cobalt-60 beam. The absorbed dose to water in reference conditions is then determined according to [Equation 18.14](#) with  $k_Q$  values determined according to [Equation 18.16](#) ([Medin et al. 1995](#)). The beam quality for protons is defined in terms of the *residual range*,  $R_{\text{res}}$ . This is the difference in a water medium between practical range  $R_p$  (defined as for electrons—see [Appendix D, Section D.3.2](#)) minus the reference depth of measurement (the middle of the spread out Bragg peak, see [Section 46.3.11](#)). Note that for proton and

**FIGURE 18.13**

Ratios of absorbed dose to water as a function of proton beam quality for various cylindrical ionisation chambers determined according to the  $N_K$ -based formalisms of IAEA (1987, 1997a) and ICRU (1999). Note that the data for the Exradin T1 and the IC-18 chambers overlap. The main contributions to the discrepancies shown are the different values adopted for  $W_{\text{air}}$  and  $s_{w,\text{air}}$  and the formalism in ICRU that ignores the influence of the chamber build-up cap. (Reproduced from Medin, J., et al., *Phys. Med. Biol.*, 45, 3195–3212, 2000. With permission.)

heavy-ion beams, the use of the approximate Equation 18.17 is not possible because of the lack of constancy of  $W_{\text{air}}$ .

Whereas the dosimetry of proton beams currently has an acceptable degree of accuracy and only the perturbation factors are still the subject of investigations (c.f. Medin and Andreo 1997; Palmans et al. 1999), considerable effort is required to improve heavy-ion beam dosimetry. The complexity of the physical processes involved, mainly because of projectile and target fragmentation for which detailed cross-sections are not yet available, means that the determination of stopping-powers and  $W_{\text{air}}$ -values relies on rather crude approximations (c.f. IAEA 2000). It is also important to emphasise that in the case of heavy-ion beams, for which the *Relative Biological Effectiveness* (RBE) varies with depth and with the dose delivered to tissue, there is a considerable difference between the so-called *biological dose* and the *physical dose* (c.f. IAEA 2000). Dosimetry protocols are restricted to the determination of the physical dose, ensuring that consistency is achieved in the first step of clinical dosimetry.

---

## 18.8 PHANTOMS FOR DOSE DETERMINATION IN REFERENCE CONDITIONS

### 18.8.1 INTRODUCTION

The quantity to be determined as the basis of a radiotherapy beam calibration is dose to water in reference conditions. All of the above material is based on this assumption, and the formalism presented in the previous sections of this chapter has this objective. Any conversions to dose to other materials are generally undertaken as part of the treatment-planning process, if at all. Therefore, the basic recommendation in dosimetry protocols for all these situations is to use water as the primary reference phantom material. Most ionisation chambers of interest either have built-in waterproofing or can be water-proofed using thin plastic sleeves, ideally no more than 1 mm thick (see Section 15.3.2.2), so this does not generally present any impossible practical demands. Phantoms should be large enough to provide sufficient side-scatter and back-scatter. As a general recommendation, this requires the phantom to be at least 5 cm wider than each field edge at the depth of measurement and to have at least 5 cm of phantom material beyond the maximum depth of measurement (10 cm in the case of medium energy kilovoltage x-ray beams), although, the exact recommendations may vary with beam type and quality and the particular dosimetry protocol. Where possible, the beam should be brought into the phantom directly through the water surface, but where this is not possible, then the phantom wall lying over the chamber position should be made of plastic and should be less than 5 mm thick. The water/equivalent thickness (thickness times density in  $\text{g cm}^{-2}$ ) of this wall should be taken into account when positioning the chamber at the required depth. For very thin windows in the wall, as present on some commercial phantoms, *bowing* can occur because of water pressure. This should be carefully monitored as it can change with time and can therefore alter the depth of water between the surface and the chamber.

Although water is the preferred phantom material, there are situations where using a solid plastic phantom may be more convenient or may provide better positional accuracy, particularly for lower-energy electron beams and for lower-energy kilovoltage x-ray beams. In addition, solid phantoms are more convenient for many relative measurement and routine checks because of the ease of set-up and the reproducibility of chamber depth. Ideally, a solid phantom should be *water-equivalent*, i.e. it should exactly mimic water in all the relevant physical properties over the range of radiation qualities to be met in the particular situation. In practice, no material meets this requirement. Practical phantoms are, at best, an approximation to water. Their use will be limited to the qualities and energies for which they approximate more-or-less to water. In general, each will require the use of some correction factors. However, these correction factors may be close to unity for some materials and for certain

irradiation situations. Various materials are discussed in ICRU (1989). The materials that have been widely used have been acrylic plastic (PMMA, known as perspex or lucite) and polystyrene. More recently, a number of commercial phantom materials, based on epoxy-resin formulations, have become available, specifically designed for dosimetry purposes.

It should be noted that the use of any material other than water will increase the measurement uncertainties (although it may decrease positional uncertainties), and this is why the primary recommendation is to use water wherever possible for beam calibration. Other materials should be tested on purchase to ensure that their density and slab or sheet thicknesses are as expected. They should be checked for flatness as warped sheets can introduce significant air gaps into the radiation path. In addition, the user should demonstrate that the phantom really is *water-equivalent* by comparing the results of measurements made in the phantom material to those made in real water. If necessary, corrections for differences in density may be applied.

### 18.8.2 MEGAVOLTAGE X-RAY AND $^{60}\text{Co}$ $\gamma$ -RAY BEAMS

For these beams, no significant problems arise in the use of water phantoms. Dosimetry protocols all recommend water, and they discuss the waterproofing and positioning requirements needed. The AAPM (1983) protocol allowed the use of polystyrene and acrylic plastics and discussed the depth scaling and transfer correction factors required although this protocol has now been superseded.

Where other materials might be useful for relative or routine measurements, it may be noted that:

- a. Depth-scaling factors can be taken as proportional to electron density
- b. Measurements in the epoxy-resin-based materials are typically within around  $\pm 0.5\%$  of water over the energy range from  $^{60}\text{Co}$   $\gamma$ -rays to 16 MV x-rays (Tello et al. 1995; Allahverdi et al. 1999). Monotonic trends are observed with beam quality, rising for some materials, falling for others. Therefore, dosimetry differences between different phantom materials can be up to 1% in this energy range if no corrections are made
- c. Measurements in polystyrene can show differences from water of up to 3% (Christ 1995), depending on photon beam quality and depth
- d. All the epoxy-resin phantom materials yield reasonably good relative measurements (depth doses, Tissue Phantom Ratio, Tissue Maximum Ratio, etc., generally to within  $\pm 1\%$  of water and Quality Index to within around  $\pm 0.5\%$  of water).

### 18.8.3 ELECTRON BEAMS

Non-water phantom materials are allowed in most dosimetry protocols for lower energy electron beams (generally, less than around 10 MeV) where dose gradients are steeper, depth-dose distributions extend to smaller overall distances and parallel-plate chambers are preferred to cylindrical chambers to minimise the perturbation in the direction of the beam (see [Section 15.3.2.3](#) and [Appendix D, Section D.2](#)). For these chambers, positioning problems can become more significant, and some designs cannot be easily water-proofed. Generally, PMMA and polystyrene (white and/or clear) have been included as allowed phantom materials with epoxy-resin based plastics (White et al. 1977; Constantinou et al. 1982; Ho and Paliwal 1986; Tello et al. 1995) being introduced in more recent protocols (IPEMB 1996a; IAEA 1997b, 2000). The following problems are recognised in the use of non-water phantoms:

- a. Depths must be scaled to the equivalent depth in water such that the spectra are similar, and therefore, the same  $s_{m,air}$  is applicable. Various approaches have been used, e.g. scaling by electron density, by stopping power or range, and by 50% depth. A discussion of these

methods can be found in AAPM (1991) and IPEMB (1996b). Recommended scaling factors can be found in IPEMB (1996b) and IAEA (1997, 2000). Where scaling factors are given in terms of linear dimensions, they require modification if the density of the plastic sample is non-standard (IPEMB 1996b). Similar scaling is required where non-water phantoms are used to determine electron beam quality or to measure electron depth doses.

- b. Even when appropriately depth-scaled, the electron fluence will typically be different to that in water as the scattering powers will not be the same in the two materials. The carbon content in typical plastics (PMMA, clear polystyrene) produces a lower effective atomic number, and therefore, a lower scattering power when the stopping power is matched. This results in a lower electron fluence at an equivalent depth. Plastics with the addition of some higher-Z material partially redress this (e.g. white, or high-impact, polystyrene, having a few percent of  $TiO_2$  added or the epoxy-resin formulations). A fluence-ratio correction,  $b_m$ , generally  $> 1$ , is required to correct for this (Thwaites 1985; Bruinvis et al. 1985; Thomadsen 1995; Tello et al. 1995; Ding et al. 1996; Nisbet and Thwaites 1998b). The specific values depend on beam energy (falling as energy increases), the angular and energy distributions incident on the phantom, and the exact composition of the phantom material. Therefore, there can be significant uncertainties associated with the data. Representative values are given in IPEMB (1996b) and IAEA (1997b, 2000) for depths close to the reference depths. For clear polystyrene, these correction factors can be up to around 1.03 at an effective mean energy below about 3 MeV, falling linearly to unity with increasing energy at a mean energy of around 20 MeV. For white polystyrene, the maximum correction is around 1.02; for a number of commercial epoxy-resin-based plastics (e.g. RMI\* solid water 451, 457; WT1†), it is around 1.01; and for WTe‡ and plastic water§, it is around 1.00, i.e. these two formulations have negligible fluence-ratio corrections to within experimental uncertainties. It is assumed that similar values to those tabulated (e.g. IPEMB 1996) can be applied at greater depths, selecting for the appropriate mean energy at that depth§ and that the values at shallower depths than the depth of maximum dose can be linearly interpolated to unity at the phantom surface. However, this assumes that differences in back-scatter are negligible. There are significant differences in the literature for PMMA. Figure 18.14 shows the spread in  $b_m$  found by different investigators.
- c. For phantoms which are electrical insulators, problems can arise from *charge storage* where the stopped electrons remain in the phantom producing high-strength electric fields that can modify the electron fluence incident on the chamber and the measured ionisation during that irradiation and during subsequent irradiations (Galbraith et al. 1984; Thwaites 1984). These effects can be large, particularly in thick slabs of phantom material (Galbraith et al. 1984; Pitchford and Thwaites 1985). They are unpredictable, depending on the accumulated dose, the time, dose and radiation modality history of the phantom and the specific insulating properties of the material both under normal conditions and under the action of radiation beams. Effects can be large for cylindrical chambers, but they appear to be negligible for parallel-plate chambers\*\*. Effects can be minimised by using thin sheets, no more than 2 cm thick, and sleeves of the same material around the chamber (Thwaites 1984; IPEMB 1996b). The magnitude of these effects can be checked by comparing measurements against those in a conducting phantom, e.g. water. The epoxy-resin-based plastics do not appear to show charge storage effects, implying that their conductivity under the action of radiation beams is sufficiently high to allow the charge to leak away.
- d. Variations in all of the above effects have been observed between different samples of the same nominal material from different manufacturers, mixes, or batches. For example, there are well-

\* Radiation Measurements Incorporated, Wisconsin; solid water mixes 451 and 457.

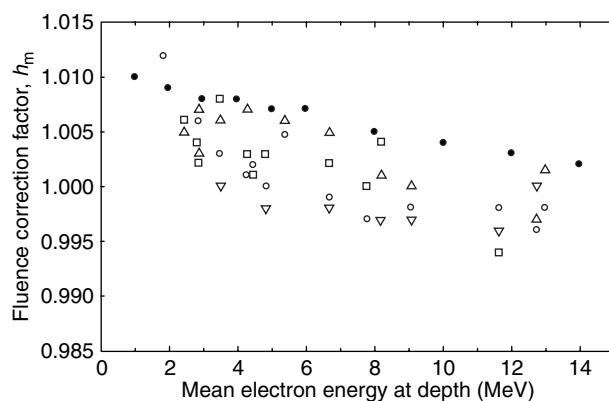

† WT1 is the original White photon formulation, available from Radiation Physics, St Bartholomew's Hospital, London.

‡ WTe is a later electron/photon formulation, also available from Radiation Physics, St Bartholomew's Hospital, London.

§ CIRS, Norfolk, VA.

\*\* Where only single values are given, e.g. IAEA 2000, the reference depth value is assumed to apply to greater depths.

\*\* The use of cylindrical chambers in electron beams to cross-calibrate parallel-plate chambers could introduce problems into parallel-plate chamber calibration factors.

**FIGURE 18.14**

Factor  $h_m$  to correct for the difference in the electron fluence in a PMMA phantom compared to that in water at equivalent depths. The filled circles correspond to the data given in IPEMB (1996) and IAEA (1997). The rest of the data has been measured by participants in an IAEA research project that uses different ionisation chambers: NACP (triangles), Roos (circles), Markus plane-parallel chambers (squares) and a Farmer NE 2571 cylindrical chamber (inverted triangles). (Reproduced from DuSautoy, A., et al., in Review of data and methods recommended, in IAEA TRS-381, *The Use of Plane Parallel Ionisation Chambers in High Energy Electron and Photon Beams*. TECDOC-1173, 1–10, IAEA, Vienna, 2000. With permission.)

established differences between clear and white polystyrene or between different water-substitute plastics from different manufacturers or between different mixes (sometimes with the same commercial name) from the same manufacturer. There can be other, subtler batch differences because of different contaminants, material density, etc. This may explain the differences in  $h_m$ , etc., reported in the literature. In general, it is recommended that, as a minimum, a check of the density should be carried out and a correction \* made if it is different from the generally accepted value. Other checks are also required to ensure that the behaviour of a specific sample of material is as expected (see [Section 18.8.1](#)).

#### 18.8.4 KILOVOLTAGE X-RAY BEAMS

At kilovoltage qualities, small differences between different phantom materials are likely to be magnified as compared to megavoltage beams. For use with parallel-plate chambers in phantom for low or very low energy beams, PMMA and epoxy-resin plastic phantoms have been recommended<sup>†</sup>. However, the measurement in this situation is on the surface, so no correction factors are required for depth. The phantom is intended to provide back-scatter. There is also at least one commercial polyethylene-based material formulated for kilovoltage x-ray beams. For medium energy beams, cylindrical chambers are used, and water phantoms are recommended for beam calibration. For routine and relative measurements where improved positional accuracy or reproducibility is required, epoxy-resin plastic phantoms have been investigated (Nisbet et al. 1998). The comparisons reported indicate that larger differences are observed than for megavoltage x-rays, but that agreement is obtained within a few percent for the photon epoxy-resin plastic formulations. The electron formulations have a greater content of higher-Z material and are expected to yield larger differences.

\* The more straightforward correction consists in scaling depth according to material density provided that the distance from the source to the detector remains unchanged or that its variation is accounted for.

<sup>†</sup> As various protocols recommend in-air measurements for these beams, this depends on dosimetry protocol and approach (see [Section 18.6](#)).

### 18.8.5 PROTONS AND HEAVY CHARGED PARTICLES

For proton and heavy-ion beams, there is little or no information available on the equivalent effects such as  $h_m$  values, and water is recommended for measurements. Any use of non-water phantoms would require careful assessment in the user's own beam relative to water.

---

## 18.9 SUMMARY AND EXPECTED FUTURE DEVELOPMENTS

A fundamental issue pertaining to the development of methods for the determination of the dose in reference conditions is the accuracy that can be currently achieved. The uncertainties attached to the various codes of practice in given conditions are discussed in [Appendix D](#). In general, these are now below 2%. This is the result of considerable efforts made in the last twenty years or so during which the determination of many of the quantities and correction factors used in external-beam dosimetry with ionisation chambers has evolved considerably. The most important changes, of the order of several percent for some of the quantities involved in dose determination as well as a dramatic improvement in current knowledge and interpretation of physical phenomena, occurred during the 1980s as a result of the extended use of Monte-Carlo calculations. The 1990s have been mainly characterised by a refinement of the data at the level of one percent or so.

An important effort to promote the TRS 398 Code of Practice (IAEA 2000), based on absorbed dose to water, has been undertaken by the IAEA. Several concerted projects have been launched to test its implementation and provide guidelines to SSDLs and clinical physicists (IAEA 2005). In the near future, it can be expected that the formalisms involving stopping-power ratios and perturbation correction factors will not be needed for reference dose determination because calibrations in terms of absorbed dose to water and experimental  $k_Q$  factors will be available for most configurations of clinical interest. The uncertainty in dose determination will then all be similar to that available today for a cobalt-60 beam using the  $N_{D,w}$  calibration, which is below the one-percent level.

Some issues remain unsolved, however, such as the difference between the dose determined using the  $N_K - N_{D,\text{air}}$  formalism and with an  $N_{D,w}$  calibration even for a cobalt-60 beam; this is a question to be solved at the level of PSDLs. This has also a direct relation to the differences between primary standards in different countries which cause *1 Gy in one country to be different from 1 Gy in another*. This problem can be of importance in geographical regions where a common dosimetry protocol is used and yet users obtain different calibration factors from different laboratories; the inconsistency may be even greater in countries without a PSDL where it is common practice to purchase instruments calibrated in other countries. This can result in a situation where, within a given country or even within one institution, two instruments may yield slightly different values for the same quantity, and in certain cases, these may even be national secondary standards. Until a kind of averaged mean value is adopted, as proposed by Boutillon and Andreo (1997), international harmonization for the determination of absorbed dose will not have been achieved, and dosimetry will remain one step behind other branches of physics where one metre or one second are the same everywhere in the world.

## 19.1 INTRODUCTION

### 19.1.1 RATIONALE FOR ABSOLUTE AND RELATIVE DOSE MEASUREMENTS

The use of therapy beams for patient treatment requires that the dose can be determined at any point within the patient. Because it is necessary to know beforehand what the dose distribution will be, and it is impossible to perform measurements within the patient's body, one has to predict the dose from calculations. Methods for calculating the patient dose at any point require a good understanding of the properties of clinical beams, and these issues are presented in Part E. The methods for calculating the dose with a computer system and the corresponding dose modelling are presented in Part F. To provide basic data for the necessary dose models, a number of preliminary measurements must be performed on the treatment machine. In practice, it is convenient to make a distinction between *absolute* and *relative* dose measurements.

The *absolute dose* determination in reference conditions is based on published codes of practice discussed in Chapter 18. It is important to stick closely to the recommendations of these codes of practice because they guarantee accuracy and consistency of the dose determination throughout the world. The reference conditions are chosen to provide a point at a depth of clinical interest where electronic equilibrium can be relied on (for photon beams).

However, in practice, the actual treatment situation is different, and it is essential to measure the dose for a wide range of conditions representative of the clinical use. To be able to relate these measurements to absolute dose, they should be normalized to the reference conditions and are called *relative dose* measurements. The detailed procedures for performing these measurements are described in this chapter. Performing these measurements requires an understanding of the properties of clinical beams and of the definition of the corresponding dosimetric parameters presented in Part E. Where appropriate, cross references are provided to the relevant sections.

### 19.1.2 PRE-MEASUREMENT PREPARATION

The period between delivery of a new radiation treatment machine and its release to clinical use is the best, and sometimes only, time that physicists have to characterise the behaviour of the radiation beams and of the various modifiers (such as wedges, blocks, and multi-leaf collimator (MLC)) that will be used with it. It is very important to ensure that measurements taken in this period are accurate and comprehensive. A measure of aforesightedness and preparation will make the task smoother.

This initial period is divided into the acceptance phase and commissioning. *Acceptance* consists of verifying that the performance of the equipment meets the minimum requirements outlined in the purchase contract and in the manufacturer's specifications. *Commissioning* is the process through which all the possible machine characteristics relevant to clinical use are investigated, measured, and recorded. Commissioning of a treatment unit should only start after a thorough acceptance process has established its mechanical and radiation consistency (see Section 38.2 and Section 38.3). In preparation for both the acceptance and commissioning measurements, all in-house dosimetry equipment should be checked for calibration, accuracy, and availability. For example, if a computerised water phantom is to be used, its mechanical motions and the data collection software need to be checked for accuracy; electrometers need to be checked for noise, leakage, and proper polarising voltage; ionisation chambers and diodes need to be checked for leakage and waterproofing if used; a survey should be made of available solid phantoms to establish their slab thicknesses and also of detectors that can be accommodated in them.

The minimum set of measurements needed for commissioning would correspond to the requirements for monitor unit (MU) calculations and the beam data input specifications of the treatment planning system (TPS) to be used at the institution (see Table 19.1).

**TABLE 19.1**

Example of Beam Data Input Required for Different Types of Treatment Planning System (TPS)

Treatment Planning System	XiO	Masterplan	Plato	Pinnacle	Eclipse
Treatment machine name	Y	Y	Y	Y	Y
Modality	Y	Y	Y	Y	Y
Energy	Y	Y	Y	Y	Y
Couch, gantry and collimator limits and direction of rotation	Y	Y	Y	Y	Y
Jaw labelling	Y	Y	Y	Y	Y
Available setups, SSD limits	Y	Y	Y	Y	Y
Source to collimator distance	Y	Y	Y	Y	Y
Source to wedge distance	Y	Y	Y	Y	N
Wedge dimensions	Y	N	Y	N	N
Source to monitor chamber	N	Y	N	N	N
Source to flattening filter	Y	Y	N	Y	N
Source to block tray	Y	Y	Y	Y	N
Primary collimator opening	N	Y	N	N	N
Percent depth dose for a full range of field sizes open and wedge fields	Y	Y	Y	Verification only	Y
Primary axis profiles for a full range of field sizes open and wedge fields	Y	Y	Y	Verification only	Y
In air outputs	Y	Y	Y	Y	Y
In water output	Square/open Y	Square/length Y	Open/wedged Y	Open/wedged Y	Y
SSD and reference depth	Optional	90 cm SSD 10 cm deep 10 cm×10 cm field size	Optional	Optional	Optional
Absolute calibration dose	Y	Y	Y	Y	Y
Wedge factor	Y	Y	Y	Y	Y
Wedge type	Y	Y	Y	Y	Y
Wedge angle(s)	Y	Y	Y	Y	Y
Block/wedge/collimator density and composition	Y	Y	Y	Y	N
Block thickness	Y	Y	Y	Y	N
Collimator transmission	Y	N	Y	N	N

This table is intended to illustrate the type of data needed. Although it has been updated by the editors, it should not be used to determine TPS requirements which may be different for a particular version of software. Data required for the MLC are not listed.

Source: Adapted from Sally Morgan-Fletcher et al., at *Linac commissioning—Changing the Culture*, IPEM meeting, BIR London, 15 November 2001.

However, a much larger range of measurements than these should be performed to check the accuracy of the TPS calculations in widely different situations, to understand the influence of beam modifiers and of asymmetric geometries, and to be able to answer likely clinical questions such as bolusing and skin sparing, which may not be modelled by the TPS (AAPM 1994a; Mayles et al. 1998). A plan of all the measurements to be taken should be created in advance, specifying which equipment would be most suitable for the task and with a thought to the efficient use of the various resources. For example, once a water phantom is properly aligned, the maximum set of measurements should be performed before disturbing its geometry.

### 19.1.3 CHOICE OF PHANTOMS

The choice of phantoms for absolute dose measurements in reference conditions has been discussed in [Section 18.8](#). For relative dose measurements, the main difference is that measurements must be repeated at many points and for many different situations. In addition, the measurements are always relative to some reference situation, which gives more flexibility without loss of accuracy. The alternative is essentially between a remotely controlled water phantom and a solid plastic phantom, and the choice is usually obvious.

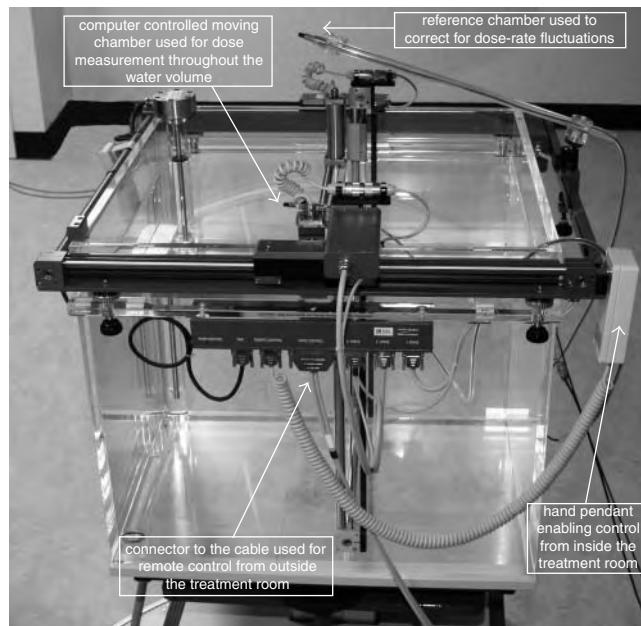

A modern computer-controlled water phantom ([Figure 19.1](#)) can position a detector within a large tank of water to a precision of 1 mm or better, can acquire data at each point with good signal-to-noise ratio in under a second\*, and can adjust its dwell time or step size, or both, depending on the local radiation field properties. Most models can be programmed to acquire specific sets of scans in an appropriate sequence, display the results on a monitor in real-time, and, crucially for transfer to a TPS, store the results in digital form. Some models even offer the option of varying and measuring the water level in the tank during the measurements; however, the water ripples limit the precision of this method.

Water phantoms are ideal for measuring dose distributions varying in space (but not in time) and for fixed source-to-phantom geometry. On the other hand, they are cumbersome and require a large setup time for accurate work. Checks are needed prior to final scanning to ensure that:

- The central axis of the beam (CAX) lies close to the centre of the tank to enable the maximum range of travel in all directions
- The detector's axes of motion are parallel, in depth, to the CAX and, transversally, to the water surface, to a precision of 1 mm over the range of travel
- The origin of the scanning coordinate system (where the CAX intersects the water surface) is correctly identified and recorded to better than 1 mm accuracy, taking into account the effective point of measurement of the detector
- The orientation of the detector is appropriate relative to the direction of scanning
- The required measurement spatial range does not produce collisions between the detector and the tank sides
- The reference detector does not perturb the measured dose distribution
- The gain of the electrometers is appropriate to avoid saturation at all measurement points
- The source-to-surface distance is correct and constant over the time of data collection (mechanical sag of the tank support system and evaporation are the main culprits).

In light of the above, there are many instances when it is preferable to use a solid phantom to a water phantom. If motion of the detector is not required as in relative output measurements at the same depth or even to measure tissue phantom ratios where the detector is at a constant

\* A fast response is especially important if the signal acquisition is performed in continuous mode with a fixed detector used as a reference to correct for dose-rate fluctuations. It is then the ratio of the signal between the moving detector and the reference detector which is used to represent the spatial distribution of the dose.

**FIGURE 19.1**

A remotely controlled water phantom system (Scanditronix-Wellhöfer blue phantom). Detectors can be positioned within the water tank and moved under computer control. The system is most often used with the beam pointing vertically downwards, striking the open water surface; other orientations are possible such as horizontal beams striking the PMMA lateral walls of the tank, which are sometimes equipped with thin entrance windows.

distance from the source and varying amounts of phantom material are added above it, solid phantom slabs are faster, easier, and more reproducible to work with. Relative output measurements are also, usually, better acquired with a high precision, energy independent integrating system such as a Farmer dosimeter (Farmer 1955), and these ionisation chambers are not easy to waterproof. Another example of the preferred use of solid phantoms is in the measurement of doses near the surface that should be performed with a parallel plate (or extrapolation) chamber with a very thin front wall (IAEA 1997). The waterproofing of such a chamber in a water phantom is often difficult, and both water ripples and surface tension so close to the water surface would prevent accurate measurements.

The use of solid phantoms raises the question of their composition and the relationship of the measured dose distributions to those in the universal reference material, water. In the past, materials with effective atomic number and electron density reasonably close to water such as Mix-D™, polymethylmethacrylate (PMMA, also known as Perspex™ or Lucite™), and polystyrene have been used, and correction factors for their effective attenuation relative to water are given in various protocols (IAEA 1987; IPEMB 1996). On the other hand, special plastic compositions specifically designed to have the same linear attenuation as water for various energy ranges have been commercially available\* (White 1977; Constantinou 1982; ICRU 1992) and are recommended for commissioning work. Care must be taken to use the correct material for the radiation under investigation, as different compounds exist for photon and electron water equivalence, and to apply any residual correction factors to the results. When used with electron beams, care should also be taken to avoid accumulating charges in large non-conductive plastic blocks as these will distort the readings (Galbraith et al. 1984; Thwaites 1984) (see also [Section 18.8.3](#)).

\* For example, St. Bartholomew's Hospital, London, U.K., or MRI, Middleton, Wisconsin, U.S.A.

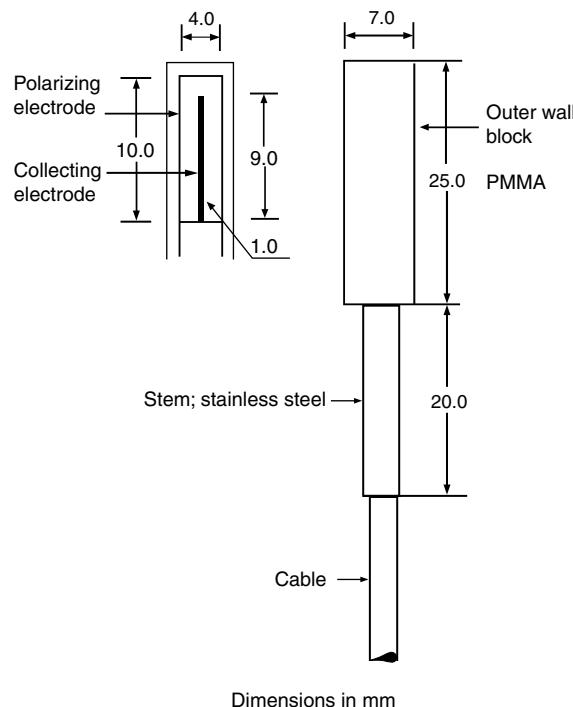

### 19.1.4 CHOICE OF DETECTORS

The radiation detectors used most commonly in commissioning work are air-filled ionisation chambers and semiconductor diodes. Films are also used, especially for radiation leakage measurements of MLC and with electron beams, and thermoluminescent dosimeters (TLD) also play a part in special situations such as whole body dosimetry.

Ion chambers have long-term stability, high sensitivity, and very small energy dependence in response to photon beams. To maximise the advantages of good spatial resolution (Sibata et al. 1991), the logical detectors to use for photons in water phantoms are small volume water-proof ionisation chambers, 0.1 cm<sup>3</sup> thimble for profiles (Figure 19.2 and Figure 19.3), and plane-parallel for depth doses (Figure 19.4). For relative output measurements in solid phantoms, the high precision 0.6 cm<sup>3</sup> Farmer-type chambers (Farmer 1955) are the most popular choice (see Section 15.3.2.2), but plane-parallel chambers with small active diameters are more accurate for small field sizes and close to the surface.

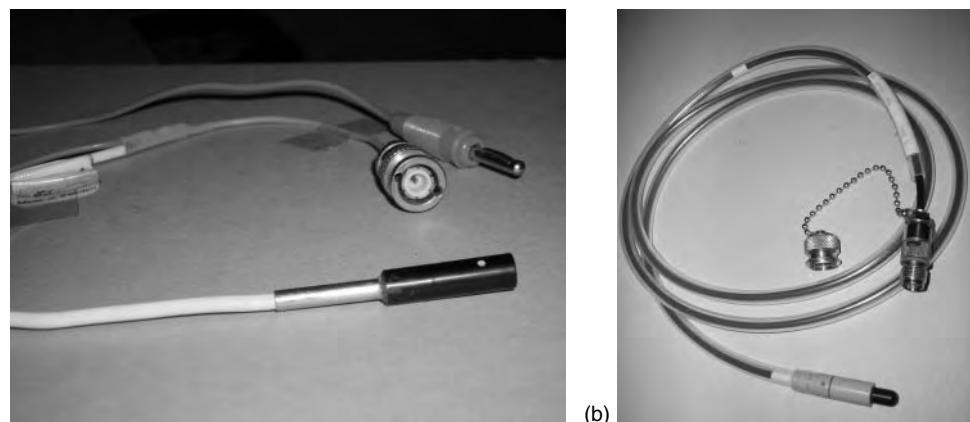

Ionisation chamber response to electron beams, on the other hand, is highly energy-dependent, albeit in a known way, and stopping-power-ratio corrections need to be applied to the readings where the mean electron energy is changing, either with depth or in the penumbra. In addition, the cavity perturbation effects on electron beams can also be significant, and chambers with small volumes and simple geometry such as plane-parallel chambers (Markus 1976; Mattsson et al. 1981; AAPM 1994b; IAEA 1997a, 1997b) are recommended for relative and absolute dosimetry (see also Section 15.3.2.3).

When using an ionisation chamber for dose measurements the cavity displacement effects of ionisation chambers can be corrected for in two ways (see Appendix D, Section D.2.1). The preferred method for air-kerma-based protocols is to define an effective point of measurement  $P_{\text{eff}}$  for the detector that is not coincident with the geometrical centre of the chamber (IAEA 1987; IPEMB 1996). For a cylindrical chamber, this point is taken to be shifted by a certain

**FIGURE 19.2**

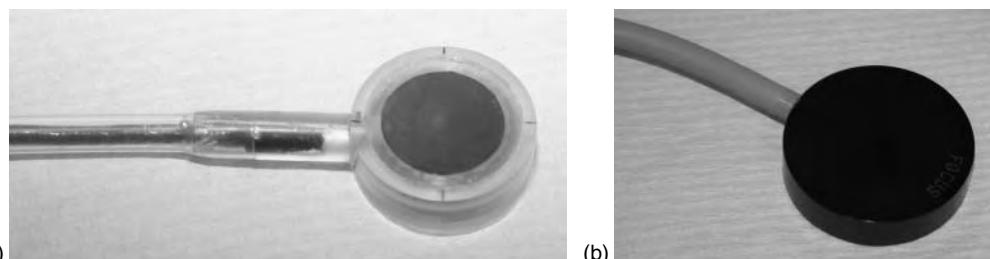

Schematics and dimensions (in mm) of a typical small volume scanning ionisation chamber (0.12 cm<sup>3</sup> RK model from Scanditronix).

**FIGURE 19.3**

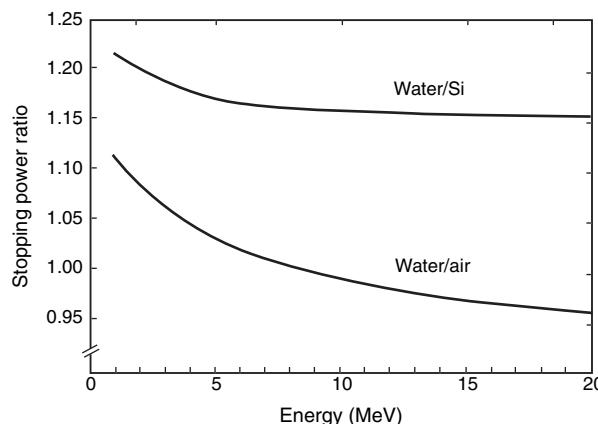

Picture of two waterproof scanning chambers with cables and connectors. (a) the Scanditronix RK chamber depicted in Figure 19.2 equipped with BNC plug for signal and banana plug for high-voltage. (b) the Wellhöfer IC10 chamber shown in Figure 19.1, equipped with a triaxial plug for both signal and high-voltage. These chambers are vented and the communication with ambient air is through the additional waterproof sleeve around the cable.

fraction (0.6 for photons and 0.5 for electrons, IAEA 2000) of its radius towards the radiation source, and for a plane parallel chamber it is defined at the inside surface of its front wall . Alternatively, some photon dosimetry protocols (particularly absorbed-dose-to-water-based codes of practice) take the effective point of measurement as the centre of the chamber. A perturbation correction  $p_{\text{dis}}$  is then applied that depends on the beam energy and the size of the detector. When making *relative* depth dose measurements, whatever code of practice is used for absolute dose measurements, care should always be taken to correct for the effective point of measurement (see Figure D.6). In the build up-region a better accuracy can be achieved if a plane parallel chamber is being used (IAEA 2000). When measuring relative off-axis dose profiles, it is usual to relate the measurement to the geometrical center of the ionisation chamber but one should realize that the size of ionisation the chamber could lead to an overestimation of the penumbra width. It is therefore recommended to use small-volume cylindrical chambers with their axis perpendicular to both the beam axis and the movement direction.

Diodes (see Section 16.3) have much smaller measuring volumes than even the smallest practical ionisation chambers and are ideal candidates for scanning in a water phantom (Sibata et al. 1991). Their sensitivity is not constant, and it depends on their radiation history. Therefore, they are invariably pre-irradiated to ensure some medium term stability.

**FIGURE 19.4**

Two typical waterproof plane-parallel chambers. The  $0.16 \text{ cm}^3$  Scanditronix/Wellhöfer NACP-02 chamber (left figure) has a graphite front window 0.5 mm thick covered with a 0.1 mm thick mylar foil. The  $0.35 \text{ cm}^3$  PTW Roos chamber (right figure) has an acrylic entrance window 1 mm thick. (see also Figure 15.8 and Table 15.4).

**FIGURE 19.5**

Plots of the water to silicon and water to air stopping power ratios as a function of electron energy. (From Berger, M. J. and Seltzer, S. M., *Stopping Powers and Ranges of Electrons and Positrons*, 2nd ed., US Department of Commerce, National Bureau of Standards, Washington, DC, 1983.)

When used for relative dosimetry such as water phantom scanning, this variation in sensitivity is not a problem.

The response of diodes to electron beams above 4 MeV is practically energy independent because of the small variation with energy of the water to silicon stopping power ratio (Berger and Seltzer 1983; Rikner 1985a) (Figure 19.5). The same is not true, however, for photon beams where diodes exhibit an energy dependent response, both at large depths and at the edges of the beam. To overcome these problems, energy-compensated diodes for photon measurements have been designed with a high-density material applied to the back (Rikner 1985b; Rikner and Grüssel 1985) (Figure 19.6). This leads to a directional dependence in response,

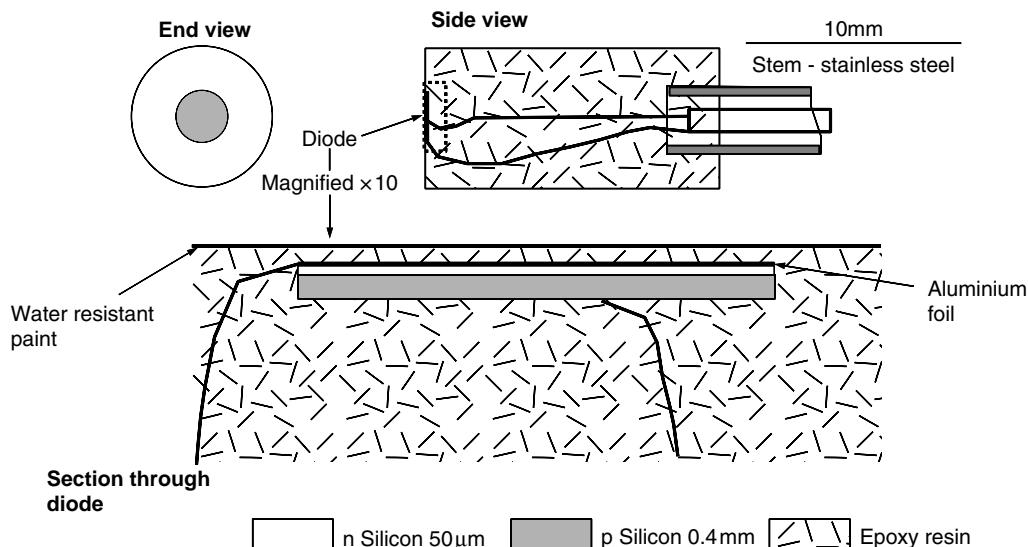

**FIGURE 19.6**

Diagram of an energy-compensated diode suitable for photon measurements. A thin n-Si silicon layer is overlaying a thicker p-Si silicon layer. The aluminium foil provides an energy compensation. The robustness is ensured by the epoxy resin covered with water-resistant paint. (From Rikner, G. and Grusell, E., *Acta Radiol. Oncol.*, 24, 65–69, 1985. With permission.)

making them unsuitable for general dosimetry. When used in a water phantom, however, these diodes are always mounted with the front facing the incident beam, thereby minimising the effect of their directionality.

### 19.1.5 BEAM QUALITY

The quality or energy spectrum of the radiation beams produced by linear accelerators, based on manufacturers' specifications, is checked as part of the initial acceptance procedure. This test is usually performed with a water phantom and looks at certain characteristics of the depth-dose curves for both photon and electron beams. It is highly recommended to check the constancy of the beam quality throughout the long commissioning process and even more so during clinical use. To this end, an easy method of measurement is desirable.

For photon beams, a widely accepted measure of beam quality is the quality index, QI (also known as *ionisation ratio* in the U.S.A.). The QI is presented in [Appendix D.3.1](#). It is defined as the ratio  $TPR_{20,10}$  of doses at two depths in water (20 cm and 10 cm) at the same distance from the source (usually 100 cm) for a standard field ( $10\text{ cm} \times 10\text{ cm}$ ). Various dosimetry protocols base their choice of energy-dependent factors on the value of the QI. Simple water-filled (or water substitute) phantoms can be built to facilitate quick and accurate measurement of this quantity. However, QI is not very sensitive to beam quality changes; 0.3% variation in its value reflects significant changes in energy spectrum.

The beam quality of teletherapy cobalt-60 beams is naturally more stable and predictable than that of accelerator-produced beams. However, it is a good idea to measure the QI even for cobalt units at acceptance and occasionally afterwards to ensure the integrity of the source.

The energy of electron beams is defined by reference to the 50% depth dose  $R_{50}$  and the practical range  $R_p$  (see [Appendix D.3.2](#)). These quantities are derived from depth-dose measurements in a water phantom. For a quick and easy constancy check on the energy, though, an approach similar to the QI can be used for electron beams by recording and checking the ratio of readings at two depths in a small solid phantom. In this case, these depths need to be carefully chosen for each energy; the first should be near the location of dose maximum and the other close to  $R_{50}$ . The values of these ratios then become a very sensitive measure of beam-energy constancy; for example, a shift of 1 mm in the depth of the 50% depth dose can produce a 15% change in this ratio for a 6 MeV electron beam and a 4% change at 20 MeV.

---

## 19.2 PHOTON MEASUREMENTS

### 19.2.1 VIRTUAL SOURCE POSITION

The concept of a virtual source is described in [Section 23.2.1.16](#). The measurement of its position needs to be done in air as only the primary beam is expected to follow the inverse-square law. As with all in-air measurements with high-energy photons, an appropriate build-up cap needs to be added to the detector to achieve electronic equilibrium and to eliminate contaminating electrons. These caps can be made of plastic or high density material, or a mini-phantom can be used (see [Figure 19.8](#)). To establish the position of the virtual source, the dose rate must be measured at several nominal distances from the target. The range of distances should vary from about 80 cm to about 120 cm, and this can be achieved either by moving the couch on which the detector stands (making sure that scatter from the couch is minimal) or by remotely adjusting the depth in an empty water phantom. This test should be repeated for several field sizes, spanning the available range. The resulting variation of dose rate with distance can then be analysed as discussed in [Section 23.2.1.16](#).

### 19.2.2 RELATIVE-DEPTH DOSES

The variation of dose with depth along the central axis (CAX), known as relative or percent depth dose (PDD), is one of the fundamental parameters that characterise a radiation beam (see [Section 22.3.2](#)). PDD should be measured for open fields and for all available physical wedges because of the beam hardening produced by the wedge attenuation. It is best obtained using a remotely controlled water phantom and either a small volume ionisation chamber or a photon-compensated diode. The PDD should be collected for several square field sizes, from the smallest to the largest available, as well as for some rectangular fields and with the water surface at the standard Source to Surface Distance (SSD) (usually 100 cm). Scanning should start with the detector at the deepest possible position and moving toward the surface, possibly overshooting the origin by a few millimetres. This procedure minimises the effect of water ripples and gives an independent check on the position of the surface where the PDD will abruptly change gradient. If the scanning steps can be varied, it is desirable to sample more densely from around 5 cm deep through the depth of maximum dose to the surface and less densely at deeper depths.

### 19.2.3 BUILD-UP REGION

The relative depth dose of a high-energy photon beam increases from the surface to a maximum, at a depth dependent on its energy, before decreasing in a quasi-exponential fashion (see [Section 22.3.1](#)). The layer between the surface and the depth of dose maximum is known as the build-up region, and knowledge of its characteristics is very important in order to estimate the amount of clinical skin sparing or, conversely, the risk of under-dosing a superficial lesion. Although the shape of the dose distribution in this region can be obtained from the relative-depth-dose measurements in water described above (Section 19.2.2), those results can be distorted by the thickness of the ionisation chamber waterproofing and the ripples and surface tension effects caused by the motion of the detector close to the water surface. To obtain a more accurate characterisation of the build-up region, a thin-walled plane-parallel chamber should be used in a solid phantom providing full backscatter. Measurements are performed by adding slabs of well-known thickness and density above the chamber, ranging from zero to just beyond the depth of dose maximum. The set-up geometry for these measurements should correspond to the relative-depth-dose data; that is, a constant SSD should be used. This can be achieved by ensuring that the support on which the phantom is resting is moved every time a build-up slab is added or removed. Alternatively, and more accurately, at the start of the measurement all slabs to be used in the build-up measurements can be placed below the detector as part of the backscattering material. Slabs are then transposed from below the chamber to above it or vice versa, and the source-to-surface distance will stay constant. However, the alternative approach of leaving the chamber at a fixed distance from the source is compatible with tissue maximum ratio (TMR) data, and conversion from one geometry to the other is simple and accurate within the distances involved (see [Section 23.2.2.3](#)). Build-up curves should be obtained for several field sizes, spanning the available range because scatter from the collimators will affect the surface dose. For the same reason, additional measurements should be done with solid wedges in position as these filters will modify the scatter contribution to the surface layers.

The presence of a tray, especially if close to the skin, could also affect the build-up curve and the surface dose. Build-up measurements should be performed with all the available trays to evaluate their effect on skin sparing.

### 19.2.4 OFF-AXIS PROFILES

The variation of dose with distance from the CAX of beam but at the same depth, known as *off-axis profiles* or *off-axis ratios* (OAR), is also a fundamental parameter required to characterise a

radiation beam (see [Section 22.3.3](#) and [Section 23.2.1.15](#)). OARs should be measured for open fields and for all available physical wedges. The shape of the OAR is a function of depth, and profiles at several depths are required. They are best obtained using a remotely controlled water phantom with its surface at the same SSD as for the PDD measurements and either a small volume thimble ionisation chamber or a photon compensated diode. Care should be taken to adjust the electrometer gain to avoid saturation at the thin side of wedged profiles. The depths at which the profiles should be scanned will be determined by the requirements of the treatment planning system, but they should include the depth of maximum dose and the deepest possible position of the detector in the tank. The width of the scans perpendicular to the beam will be a function of both the field size and the depth (because of divergence) and should be large enough to include not only the beam edges but also at least 5 cm beyond the geometrical edge of the beam. For large field sizes, the dimensions of the water phantom may prevent a full scan. As this usually only occurs with unwedged symmetrical fields, the water phantom can be offset to one side and only one half of the beam scanned to the appropriate distance from the CAX.

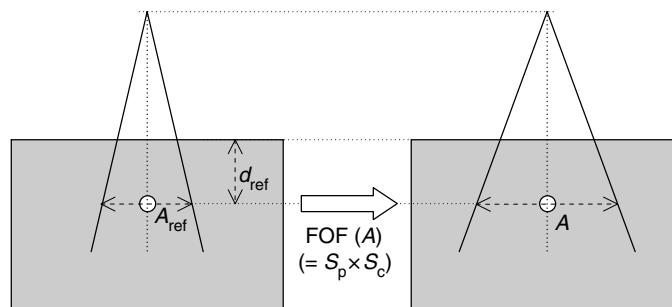

### 19.2.5 OUTPUT FACTORS

Measurements of the dose rate (or dose per MU) in phantom as a function of field size is a necessary step in the commissioning process. A large number of measurements are required because the dose per MU to a fixed point in a phantom depends on the size of the beam at that point, generally increasing monotonically with field size. The measured in-phantom *field output factors* (FOF) are assumed to be the product of two independent effects: *phantom scatter factor* ( $S_p$ ) and *collimator (or head) scatter factor* ( $S_c$ ). That is

$$\text{FOF} = S_p \times S_c \quad (19.1)$$

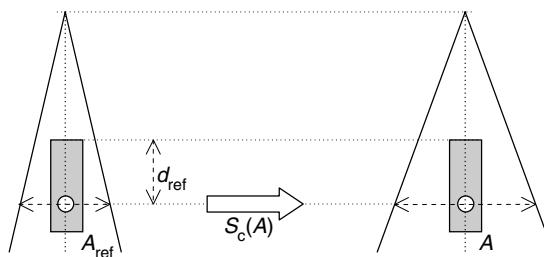

where all three quantities are normalised to unity for the reference field (Khan 1984; van Gasteren et al. 1991). As discussed in [Section 23.2.1.10](#), phantom scatter depends only on the scatter geometry within the phantom or patient; this can be modified by beam shaping, SSD, and patient shape. Collimator (or head) scatter, on the other hand, is independent of the phantom position, but depends on the collimator settings and the presence of additional filters (see [Section 23.2.1.12](#)).  $S_c$  also includes the effect of the monitor chamber response with collimator settings.

Measurements of FOF should be performed with an ionisation chamber, either a Farmer-type or a small area parallel plate, in a water (or water substitute) phantom (see Figure 19.7). The measurements should be at the depth and distance from the source, corresponding to the reference conditions used for calibration (see [Chapter 18](#)). Measurements should never be made at the depth of dose maximum (only a few centimetres below the surface), but instead should be made at a

**FIGURE 19.7**

Diagram illustrating the measurement of the *field output factor* (FOF) in a full scatter phantom.  $A_{\text{ref}}$  is the reference field size at the measurement depth  $d_{\text{ref}}$  and  $A$  is the current field size.

**FIGURE 19.8**

Diagram illustrating the measurement of the *collimator* (or *head*) scatter factor  $S_c$  ( $A$ ) in a mini-phantom.  $A_{ref}$  and  $A$  are the reference and the current set field sizes respectively (see also [Table 23.1](#)). The dimensions of the mini-phantom (and especially its cross-section) must be just large enough to provide electron equilibrium. The depth of measurement  $d_{ref}$ , should be the same as for the measurement of the FOF (see [Figure 19.7](#)).

larger depth such as 5 cm or 10 cm where the influence of electrons scattered from the collimator is negligible. The measured dose rates could then be converted to values at the depth of maximum dose by applying a PDD or TMR correction (see [Section 23.2.2](#)).

Several square and rectangular field sizes should be measured spanning the available range. Rectangles should be measured with both the upper and lower jaws defining the long side to determine the *collimator exchange effect* (see [Section 23.2.1.13](#)). The measured dose rates are normalised to the reference field, usually a 10 cm × 10 cm square.

It is desirable to be able to separate the two contributions to FOF, and several methods have been proposed to achieve this. These approaches can be divided into two categories: those that attempt to measure  $S_c$  separately and those that try to estimate  $S_p$ . In both cases, the total output variation in phantom, FOF, also needs to be measured. The third quantity can then be derived by application of [Equation 19.1](#).

To measure  $S_c$ , an ionisation chamber should be placed at the depth corresponding to the FOF measurements (that could be at 5 cm or 10 cm) but with minimum side scatter contribution. This can be achieved with a mini-phantom\* (van Gasteren et al. 1991; Dutreix et al. 1997) whose cross-section is just large enough for lateral electron equilibrium (Figure 19.8). For energy ranges from 4 MV to 25 MV, a 4 cm × 4 cm cross-section is considered appropriate (Ahnesjö et al. 1987; Dutreix et al. 1997). In this mini-phantom, the scatter contribution to the ionisation chamber is constant for field sizes larger than its cross-section, and values of  $S_c$  can be derived from the measurements. It is preferable to make the measurements with the ionisation chamber at the same distance from the source as in the FOF setup. However, because collimator scatter is assumed to be independent of distance, a larger SSD could be used for the mini-phantom to extend the range of field sizes that totally cover it. Squares and rectangles (in both orientations) should be measured because the collimator exchange effect originates from collimator and head geometry. This method fails for field sizes comparable to or smaller than the mini-phantom cross-section.

On the other hand,  $S_p$  can be calculated from knowledge of the tissue air ratio (as a function of equivalent square) at the reference depth (see [Section 23.2.2.6](#)).

### 19.2.6 WEDGE DOSIMETRY

The availability of wedge filters that attenuate the beam differentially across their width requires additional measurements. The need to collect wedges profiles, relative depth doses, and

\* The symbols  $S_c$  and FOF given here are the most frequently encountered in the literature. In the ESTRO booklet, Dutreix et al. (1997) suggested the use of  $O_0$  instead of  $S_c$  and  $O_R$  instead of FOF. However they kept the symbol  $S_p$  for the *phantom scatter factor*.

build-up curves has already been mentioned. It is also essential to characterise the beam outputs when wedges are present, using the same geometry employed for the FOF measurements and to relate them to the reference condition. The ratio of the dose rate with the wedge present to that without the wedge, for the same beam parameters, is known as the wedge transmission factor (WF). Because of the steep gradients in the beam profiles, particular care needs to be taken to ensure that the detector is aligned with its narrowest dimension along the wedged width and that it is truly on the axis of collimator rotation (CAX). The latter condition can be easily checked by measuring the dose rate through the steepest wedge at two opposite wedge orientations by rotating the collimator by 180°; the readings should vary by less than 1%.

Wedge transmission factors should be obtained for several field sizes spanning the available range because asymmetrical scatter in the phantom will affect the CAX dose. Rectangles as well as squares should be measured to investigate if the variation in wedge outputs can be approximated by a function of field width or of a combination of width and length (e.g. equivalent square see [Section 23.2.1.8](#)). If the formalism separating FOFs in  $S_c$  and  $S_p$  is to be employed, measurements of these quantities should also be performed for all wedges as described in [Section 19.2.5](#).

### 19.2.7 SECONDARY BLOCKING AND ATTENUATORS

Most teletherapy equipment has accessories that enable the positioning of secondary shielding blocks between the machine head and the patient to modify the shape of the radiation field. These blocks are made of lead or high density alloy, and they are held in position by attaching them to a *tray* (usually clear plastic but sometimes metal with a hole pattern) that covers the entire beam. These blocks can be located either on the target side or the patient side of the tray. Several dosimetry issues are raised by the presence of the blocks and tray, and they need to be addressed by appropriate measurements.

First, trays attenuate the radiation, and their transmission needs to be quantified. The transmission factor is the ratio of the doses (at the depth and distance from the source corresponding to the reference condition) with and without the tray in position. This measurement needs to be performed for all available trays and also for any other absorber that could sometimes be in the path of the beam such as head supports, breast boards, or the couch top. For attenuators with uniform thickness across the beam, this factor is not usually a function of field size so that only the reference field need be used.

As previously mentioned, the presence of a tray, especially if close to the skin, could also affect the build-up curve and the surface dose. Build-up measurements should be performed with all the available trays to evaluate their effect on skin sparing.

The introduction of shielding blocks will alter the effective equivalent square of the beam entering the patient and the value of  $S_p$ , and they could also change the value of head scatter factor,  $S_c$ . Additional measurements should be made to evaluate the influence of beam shaping on the dose rate and to check the output factor calculation formalisms.

The beam penumbra, defined by the blocks, could be different from the one measured for the adjustable collimators, especially if the blocks are much farther from the source or if their internal faces are not aligned with the beam divergence. Additional profile measurements to define the beam edges should be taken using typical blocks.

### 19.2.8 ASYMMETRIC INDEPENDENT JAWS

Many modern accelerators offer the option of moving each jaw in a set of collimators independently from the other so as to produce fields asymmetric relative to the beam CAX. Although this facility offers added flexibility in clinical practice, it also increases the possible permutations of field shapes and the amount of data needed to characterise the beams. The variation of output factors and of  $S_c$  and  $S_p$ , separately, needs to be investigated for asymmetric as well as symmetric fields. The shape of the profiles across asymmetric collimators may or may not be predictable by simply splicing two symmetrical half-profiles together. Additional

profiles should be measured to verify this assumption. On the other hand, the penumbra produced by each jaw should not be influenced by whether the opposite jaw is at the same distance from the CAX or not.

In addition to their radiation properties, the mechanical behaviour of asymmetric fields needs to be investigated more carefully than for the simple symmetric version. Their symmetry about the CAX when in symmetrical mode needs to be checked on a routine basis as well as the accuracy and reproducibility of independently repositioning each jaw. Of particular concern in this respect is the accurate positioning at the centre line because asymmetric half-field techniques are sometimes used to abut orthogonal fields at the isocentre.

### 19.2.9 MULTI-LEAF COLLIMATORS

Modern accelerators also offer the option of shaping the beam through the use of adjustable multi-leaf collimators (MLC). These devices consist of several narrow blocks with substantial attenuation along the beam rays that can be positioned independently of each other under computer control to form any desired beam shape (see [Section 11.4.3](#)). MLCs have obvious advantages over custom-made blocks in terms of preparation, handling, and storage, but they require additional mechanical and dosimetry checks, both at commissioning and in a routine quality assurance program (see [Section 38.3](#)).

The conversion of a required manually drawn beam shape into MLC positions or the transfer of MLC shapes from a treatment planning computer needs to be checked for accuracy. The mechanical accuracy and reproducibility of leaf positions need to be verified by extensive operation of the MLC system at regular intervals. Preventive maintenance should be scheduled for the mechanical components of the MLC system.

If the MLC are used as replacements for secondary blocks in conjunction with two orthogonal sets of collimators, the effect of beam shaping on the output needs to be investigated as for blocks. In some accelerator models, the MLC actually replaces one of the sets of jaws. In this case, the position of each leaf will have a significant effect on the overall *head scatter factor*,  $S_c$ , and more extensive measurements will be needed to fully characterise this quantity.

The penumbra, both along and across the MLC leaves, needs to be determined carefully as it will depend on the leaf design and position from the CAX. This information will be needed to determine the required margin between the MLC leaf positions and the planned target volume projection in *beam's-eye-view* (BEV)-based conformal treatment plans.

Radiation leakage within an MLC system is an additional quantity that needs to be evaluated. Leakage can occur though the small gap between two touching opposing leaves. It is worse when they abut on the central plane of the beam because of a lack of divergence, and it decreases as the junction is moved to one side. In clinical use, the position of the junction between *closed* leaves should be forced to be outside the field. Leakage also occurs between adjacent leaves and could also be a function of their distance from the centre line. In practice, this leakage can be minimised by enclosing the MLC shape as tightly as possible with the collimators. These variations in leakage need to be quantified as a function of distance from the centre. They are best studied either with a diode scanned in a water phantom or by exposing a film perpendicular to the beam direction while sandwiched in a solid phantom at the depth of maximum dose.

### 19.2.10 DYNAMIC TREATMENTS

The term *dynamic treatment* refers to several different irradiation modes where some machine parameters vary while the beam is on, from standard arc therapy to full-blown dynamic intensity-modulated radiation therapy (IMRT). Because the dose distribution is changing in time as well as in space, some of the standard measurement techniques previously mentioned need to be modified. Various commonly available modalities will be discussed in detail with some general guidelines on the more esoteric developments.

### 19.2.10.1 Arc Therapy

Most teletherapy units equipped with an isocentric gantry can deliver radiation while the gantry rotates around the isocentre. The equipment's ability to deliver the required MUs within the specified arc range needs to be validated. To check the TPS predictions, output measurements should be performed within cylindrical or anthropomorphic phantoms of known density that should be introduced into the TPS through CT scanning. These checks are best carried out with Farmer-type chambers in integration mode, located at pre-drilled holes in the phantom at the isocentre and other points of interest.

### 19.2.10.2 Dynamic Wedges

Some accelerators can produce wedge-shaped profiles by moving one independent jaw across the field while the beam is on. In this case, there is no beam hardening to worry about, so there is no pressing need to measure relative depth doses under those conditions. Many treatment planning systems can model the wedge shape directly using a knowledge of the jaw movements. In this case it is only necessary to make a few verification measurements. However, if this facility is not available, profiles need to be collected at several field sizes for each wedge angle - more than for fixed wedges. This was also necessary with early Varian implementations of the dynamic wedge where jaw motion was field size dependent.

These requirements are made even more time-consuming because of the difficulties posed by the time-varying nature of the exposure. The use of a remotely controlled water phantom moving a single detector to measure profiles becomes problematical. One solution consists of using an array of large numbers of detectors in integration mode suspended in the water phantom (Sidhu 1999; Martens et al. 2001). To extend the range and resolution of this array, it can be shifted using the water phantom controls with the full programmed exposure repeated several times. Alternatively, a large number of films need to be exposed and carefully scanned, taking into account the nonlinearity of the film's response over the large range of doses produced by a steep wedge.

Another consequence of the custom programming of the motion pattern for each field size mentioned above is that the output on the CAX (i.e. the effective WF) could be a strong and unpredictable function of the field dimension along the jaw motion (width). In that case, measurements of effective WF need to be made at every programmable field width so that there is no need to rely on interpolation.

Considering the large number of measurements required for dynamic wedges, alternative solutions have been investigated where the dynamic data are obtained from calculated superposition of static beam data (Papatheodorou et al. 1999). However, even in this case, an experimental verification for a limited number of conditions covering the whole range of clinical situations is required.

### 19.2.10.3 Other Dynamic Treatment Modalities

With the advent of fully three-dimensional (3D) planning systems incorporating BEV facilities and inverse planning, a large variety of complex dynamic treatments can be planned and delivered on modern accelerators (see [Section 43.3](#)). Examples include dynamic arc therapy where the MLC shape is adjusted to the BEV projection of the target every few degrees of rotation without pause in the irradiation; sequential IMRT that is obtained by a programmed succession of differently shaped fixed fields at each beam orientation; and dynamic IMRT where the shape of the field is varied while the beam is on, moving each MLC leaf at a programmed differential speed.

The basic commissioning of such treatment modalities as far as the dosimetry of each of its separate static components is concerned, is not different in principle to that for normal MLC treatments. The difficulty arises in attempting to verify that the complex sequence of configurations that constitute the complete treatment is being correctly performed as planned. Measuring

the integrated dose at the centre of the treated volume with an ionisation chamber is an obvious minimum requirement. However, as the aim of these techniques is the delivery of a very specific dose distribution in three dimensions, checking the dose at only one point is not a sufficient check. Films (see [Section 17.2](#)) or multidetector-arrays (Letourneau et al. 2004) are of great value to assess the 2D fluence pattern for each beam individually. In addition, the task of validating dynamic treatments will be facilitated by the development of truly 3D and tissue-equivalent dosimeters such as Fricke or BANG gels that can be scanned in an MR imager to yield a 3D picture of absorbed dose (see [Section 17.3](#)).

## 19.3 ELECTRON MEASUREMENTS

### 19.3.1 VIRTUAL SOURCE POSITION AND ANGULAR SPREAD

The *effective* source position for electron beams depends somewhat on how this information is intended to be used. To estimate the dose rate at extended distances, a value for the virtual source position derived from inverse square analysis of output at different distances as described for photons is appropriate (see [Section 19.2.1](#) and [Section 23.2.1.16](#)). In contrast to the latter, measurements should be performed at the depth of maximum dose in a water phantom\*. In addition, the virtual source position for electrons is a strong function of the beam energy, jaw settings, field size of the applicator and endframe area, and extensive data need to be collected.

Some implementations of the *pencil beam* approach to calculating electron dose distributions (Hogstrom et al. 1981) require the input of an effective source position as well as an initial angular spread  $\sigma_{\theta x}$  (see also [Section 27.2.4.4](#)). Both these quantities as well as the effective collimator position can be extracted from measurements of several beam profiles in air at different distances from the source. These measurements can be performed using a small ionisation chamber or a diode in a remotely controlled water phantom by scanning profiles at different distances but without filling the tank with water. Alternatively, films exposed in air perpendicular to the beam direction, supported by expanded polystyrene blocks at various distances, can be scanned to obtain the profile and penumbra information. A plot of the beam width (that is, the distance between the two points that receive 50% of the CAX dose) against the nominal distance from the source will extrapolate back to zero width at the *virtual* source position. A similar plot of the distance between the 90% and 10% penumbra levels against the nominal distance from the source will extrapolate back to zero penumbra at the *effective* collimator position. The slope of this regression line will be proportional to the initial angular spread (see [Section 27.2.4.4](#)).

### 19.3.2 RELATIVE DEPTH DOSES AND OFF-AXIS PROFILES

The same procedures for photon measurements described above should be followed for electron depth doses and profiles. If an ionisation chamber is employed to measure relative depth doses, the readings will have to be converted from ionisation to dose by applying energy-dependent corrections at each depth in the scan. In contrast to photons, electron depth doses have definite ranges beyond which only a bremsstrahlung contamination dose will be present (see [Section 24.2.2](#)). Depth scans need not reach much deeper than about 5 to 10 cm beyond the range of each electron energy. This depth can be estimated by the well-known rule of thumb that the range in water, in centimetres, is half the nominal energy in MeV.

\* Such measurements are not trivial since the depth of maximum dose varies with field size and slightly with distance (see [Section 24.2.4](#) and [Section 24.2.6](#)). However, in practice, the measuring depth could be kept constant for a large range of situations and be adjusted only for smaller field sizes or extreme SSDs.

Another consequence of the finite range of electron beams is that the depths for profiles need to be carefully chosen at each energy, restricting them to values smaller than the practical range. A possible profile measurement scheme would be to scan at depths beyond the maximum corresponding to the 100%, 90%, 70%, 50%, 30%, and 10% relative depth dose values as well as at one depth relatively close to the surface, for instance 0.5 cm. The shape of the profiles and the width of the penumbra in electron beams are strongly dependent on the distance from the end of the applicators to the surface. Depth doses and profiles should be measured at several source-to-surface distances covering the expected clinical range.

### 19.3.3 OUTPUT FACTORS

The measurement and behaviour of output factors for electron beams differ greatly from those of photon beams.

Because of the sharp fall-off of the electron depth-dose curves, measurements at depths larger than the depth of maximum dose ( $d_{\max}$ ) would introduce unacceptable uncertainties with even small variations in detector position. The point of output measurement is invariably at the depth of  $d_{\max}$ . For the same reason, care must be taken to determine this depth for all measured field sizes, as it can change for smaller fields, and reposition the detector accordingly. Alternatively, if the same depth of measurement corresponding to the depth of maximum for the reference field is used for all field sizes, the value at each  $d_{\max}$  needs to be calculated using the corresponding depth dose curve. The optimal detector for electron output factors is a small volume plane-parallel chamber, both because of the unambiguity of its effective position (at the inside surface of its front wall) and the virtual absence of perturbation corrections. However, as previously mentioned, the ionisation-to-dose conversion factors depend on the effective electron energy and on the depth of measurement. These corrections need to be applied before normalisation to the reference field. Measurement of output factors for very small fields where the field size is comparable to the chamber size need special consideration.

The variation of output dose rate with field size for electron beams depends on accelerator design. For units with a single variable electron applicator consisting of four *trimmers* attached to the photon jaws, the output is a smooth function of applicator size. More often, field shaping is achieved by separate *applicators* for different field size ranges with the provision to add *endframes* to achieve intermediate or irregular fields. These applicators often have additional scattering rings within them to improve the beam flatness near the edge of the beam. These scattered electrons also contribute to the dose rate at the centre of the beam. As a consequence, the variation of output with applicator size and with endframe area is not obviously predictable just on the basis of the beam shape at the surface. Therefore, dose rates need to be measured for each applicator and for a range of endframe shapes within each applicator to be able to determine the dosimetric characteristics of such electron beams. For some accelerators, the position of the photon jaws is adjusted to achieve a preliminary collimation upstream from the applicator. Therefore, the field size delimited by the photon jaws is both dependent on the size of the applicator and on the beam energy. Because the opening of these jaws has a significant influence on the beam output, care should be taken to ensure that commissioning measurements and clinical use are performed in a consistent way.

Because a large number of measurements at different depths for different energies and field sizes are required, it can take a long time. The careful use of a remotely controlled water phantom can speed up the acquisition of output factors at different depths of maximum dose, as an alternative to measurements at a fixed depth in solid phantoms corrected to the individual  $d_{\max}$  through use of previously acquired depth dose curves.

This appendix is intended to provide supplementary information on the codes of practice for absolute dose determination which are described in [Chapter 18](#). The origin of the various factors involved in dose determination and the questions which are still to be resolved are discussed. Only megavoltage photon and electron beams are dealt with. The proper choice for stopping-power ratios and perturbation factors are dealt with in [Section D.1](#) and [Section D.2](#), respectively. [Section D.3](#) is dedicated to the specification of the beam quality. [Section D.4](#) considers the issue of humidity correction for ionisation chambers. Finally, [Section D.5](#) contains an estimation of the overall uncertainties in absolute dose determination in reference conditions. For a better understanding of the concepts discussed in this appendix, it is recommended that the reader familiarise her/himself with the codes of practice presented in Chapter 18 and with the general characteristics of photon and electron beams presented in [Chapter 20](#), [Chapter 22](#) and [Chapter 24](#).

## D.1 STOPPING-POWER RATIOS

### D.1.1 THEORY

The determination of the absorbed dose in a medium using an ionisation chamber is based on the Bragg–Gray principle, which relates the absorbed dose at a point in the medium (water),  $D_w$ , to the mean absorbed dose in the detector (air),  $\bar{D}_{\text{air}}$ , through a proportionality factor that has been classically identified as the ratio of the mass (collision) stopping powers, water/air:

$$D_w = \bar{D}_{\text{air}} s_{w,\text{air}} \quad (\text{D.1})$$

The key Bragg–Gray assumption is that the electron fluence present in the detector is identical to that in the (undisturbed) medium at the position of interest. The gas-filled ionisation chamber in a high-energy photon or electron beam behaves to a good approximation as a Bragg–Gray detector. Any deviations from perfect Bragg–Gray behaviour are taken care of by perturbation factors which are dealt with in [Section D.2](#).

Thus the stopping-power ratio applies to the electron spectrum at the point of interest in the undisturbed medium and is thus independent of the detector (except for the minor influence of the Spencer–Attix cutoff—see below). The determination of this stopping-power ratio is the task of cavity theory (see [Section 6.7.3](#) for a derivation of the Bragg–Gray result) and will now be described.

To understand the reasons for the existence of some of the theories and approximations described below, ones needs to be aware of the calculation limitations some decades ago, when the determination of the so-called *slowing-down spectrum* (which today is called the *electron fluence spectrum*) by numerical methods was a considerable undertaking (see, for instance, the review given in NCRP [1961]). Approximations had to be developed to make the analytical calculations feasible, and some of these approximations have persisted for many years. Today, it is actually more straightforward to carry out accurate calculations using Monte Carlo simulation, as will be seen. In what follows, the terminology and formulation given by ICRU (1984a) will be used.

For an ideal detector that does not perturb the fluence of electrons in the medium, and assuming that electrons lose their energy *continuously* and *locally*, the *Bragg–Gray stopping-power ratio* is given by

$$s_{w,\text{air}}^{\text{BG}} = \frac{\int_0^{E_{\max}} (\Phi_{E,w})_p (S/\rho)_{\text{col},w} dE}{\int_0^{E_{\max}} (\Phi_{E,w})_p (S/\rho)_{\text{col},\text{air}} dE} \quad (\text{D.2})$$

where  $(\Phi_{E,w})_p$  is the fluence of primary electrons in water, differential in energy, at the point of measurement, and  $(S/\rho)_{col}$  is the unrestricted mass collision stopping-power of an electron with kinetic energy  $E$  in water or air\*. In this context, *primary* electrons are either *incident electrons* or *photon-generated electrons*, e.g. Compton electrons; subsequent generations of electrons, i.e.  $\delta$ -rays, are termed *secondaries*. The assumption of continuous and local energy loss ignores the finite ranges of  $\delta$ -rays whose energy is assumed to be deposited at their site of production. Thus these  $\delta$ -rays do not contribute to the primary electron fluence,  $(\Phi_{E,w})_p$ . Note that the numerator and denominator of Equation D.2 can be identified with the quantity *cema*, defined by ICRU (1998). The use of the *Bragg–Gray* (i.e. unrestricted) stopping-power ratio can only strictly be justified when  $\delta$ -ray equilibrium conditions are realised due to a complete build-up of the  $\delta$ -ray electron spectrum, which in practice never exists. However, approximate  $\delta$ -ray equilibrium can be achieved through the use of a detector wall (or a thin lining on the inner side of the wall, e.g. graphite dag) which is approximately equivalent (in the sense of radiation interaction coefficients) to the cavity material itself (air). Bragg–Gray stopping-power ratios were used in ICRU Report 14 for photon dosimetry (ICRU 1969); they were evaluated using a primary electron fluence estimated from the reciprocal of the total stopping-power. Such methods are discussed in Johns and Cunningham (1983).

The *Spencer–Attix* stopping-power ratio (Spencer and Attix 1955) takes approximate account of the finite ranges of  $\delta$ -rays with regard to energy deposition *in* the detector by  $\delta$ -rays generated *outside* the cavity (however, the detector walls are assumed equivalent to the surrounding medium). Quoting NCRP (1961), “the Spencer–Attix theory is the only higher approximation that has been developed to the point where comparison with experiment is generally possible. The theory is not a rigorous one. At the risk of oversimplifying the physical picture, rigor was reduced to the point where numerical calculations became feasible.” Nahum (1976, 1978) recast the original Spencer–Attix formulation into a more practical one involving (depth-dependent) electron fluence spectra.

The Spencer–Attix stopping-power ratio is given by (Nahum 1978; ICRU 1984a)

$$s_{w,air}^{SA} = \frac{\int_{\Delta}^{E_{max}} \Phi_{E,w}(L/\rho)_{\Delta,w} dE + \Phi_E(\Delta)_w (S(\Delta)/\rho)_w \Delta}{\int_{\Delta}^{E_{max}} \Phi_{E,w}(L/\rho)_{\Delta,air} dE + \Phi_E(\Delta)_w (S(\Delta)/\rho)_{air} \Delta} \quad (D.3)$$

where  $\Phi_{E,w}$  is the total fluence of electrons in water, differential in energy (at the point of interest), and  $(L/\rho)_{\Delta}$  is the mass collision stopping-power in water or air *restricted to energy losses less than  $\Delta$* . In analogy with Equation D.2, the integrals in the numerator and denominator can be identified with the quantity *restricted cema*, defined by ICRU (1998). The quantities  $\Phi_E(\Delta)_w$  and  $(S(\Delta)/\rho)_w$  are, respectively, the total electron spectrum and *unrestricted* collision stopping-power evaluated at energy  $\Delta$ ; the product of these two gives approximately the number of electrons falling below  $\Delta$  in energy which, when multiplied by energy  $\Delta$ , is equal to the total energy dissipated by the so-called *track-ends*. The energy cut-off,  $\Delta$ , is related to the dimensions of the cavity, being equal to the energy of an electron whose range is equal to the mean chord

\* A simple approximation for the *Bragg–Gray* stopping-power ratio has been given by Harder (1965a):

$$s_{w,air}^H = \frac{(S(\bar{E})/\rho)_{col,w}}{(S(\bar{E})/\rho)_{col,air}}$$

where the unrestricted mass collision stopping-powers are evaluated at the mean energy  $\bar{E}$  of the primary electron spectrum at the point of measurement. This approximation for  $s_{w,air}^{BG}$  is only acceptable when  $(S(E)/\rho)_{col,w}/(S(E)/\rho)_{col,air}$  varies *linearly* with energy over the range of energies in the primary electron spectrum, as is the case when the detector and the medium are similar materials, and presupposes that the mean energy  $\bar{E}$  is correctly estimated. For electron beams Nahum (1976, 1978) found discrepancies of up to 3.5% between the Harder approximation using a very crude expression for  $\bar{E}$  and a rigorous evaluation of  $s_{w,air}^{BG}$  using Monte-Carlo generated  $\Phi(z)_{E,w}$ .

length across the cavity. Electrons with energy greater than  $\Delta$  are assumed to originate *outside* the cavity and to deposit their energy locally *inside* the cavity. It can be mentioned that some early determinations of Spencer–Attix stopping-power ratios omitted the track-end term (see, for example, Nahum [1976, 1978]).

The expression for  $s_{w,\text{air}}^{\text{SA}}$  given in Equation D.3, with a cut-off,  $\Delta$ , of 10 keV (approximately valid for most ionisation chambers in clinical use), has been used for the determination of practically all stopping-power ratio data available today for electron and photon beam dosimetry. The calculation of electron energy spectra in different media produced by photon and electron beams has relied extensively on the use of the Monte-Carlo method\*. An alternative procedure to that of first calculating electron energy spectra and then using this to evaluate the cavity integrals is to compute *directly* the stopping-power-ratios at all depths during a Monte Carlo simulation. During the transport of charged particles in a medium, the product of the electron step-length (see [Section 5.4](#)) and the (restricted) stopping-power for any medium, evaluated at the mean energy of the step-length, yields the energy deposition in the material where the transport is simulated. There are two main advantages in this procedure, namely, it is independent of the number and size of the energy bins (as opposed to the calculation of electron spectra differential in energy) and it allows a straightforward determination of the statistical uncertainty of the calculated stopping-power ratios. This *on-the-fly* procedure for the computation of stopping-power ratios has been used for photon, electron and proton beams (see, for example, Andreo [1991, 1994], Malamut et al. [1991], and Medin and Andreo [1997]).

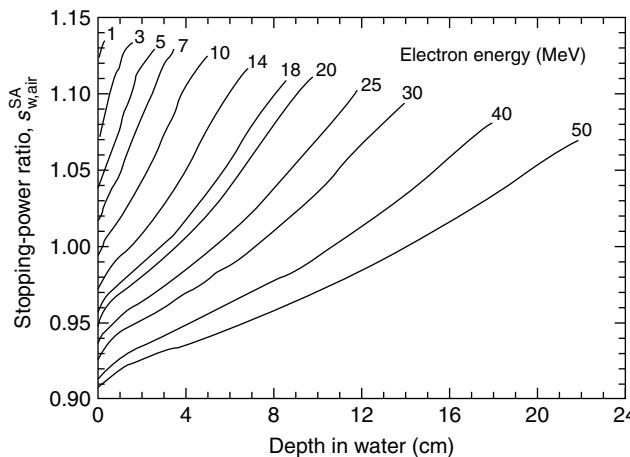

### D.1.2 STOPPING-POWER RATIOS FOR ELECTRON BEAMS

Berger and Seltzer (1969) were the pioneers in using Monte Carlo simulation to derive electron fluence spectra as a function of depth in monoenergetic electron beams; subsequently they applied this to computing  $s_{w,\text{air}}^{\text{SA}}$  (Berger et al. 1975; see also ICRU 1984a). This was improved upon by Nahum (1976, 1978) who included the track-ends in the evaluation of  $s_{w,\text{air}}^{\text{SA}}$ , as mentioned above. Andreo (1990a) calculated a comprehensive set of ICRU-37 (ICRU 1984b) based stopping-power ratios for monoenergetic electrons with different Monte Carlo codes, finding a level of agreement that provided confidence in the data used for clinical dosimetry. The most important characteristic of electron stopping-power ratios is their strong dependence on energy and depth (see [Figure D.1](#)), mainly resulting from the considerable differences in energy spectra at the various depths.

Until recently, the selection of stopping-power ratios,  $s_{w,\text{air}}$ , for the user's beam in electron dosimetry protocols was based on monoenergetic-beam data, using a procedure based on the characterization of the electron beam via the mean electron energy *at the phantom surface*,  $\bar{E}_o$ , together with the depth of measurement,  $z$  (IAEA 1987; IPEMB 1996a; IAEA 1997b);<sup>†</sup>. Clinical beams are, however, far from monoenergetic and monodirectional at the phantom surface. The validity of the  $s_{w,\text{air}}(\bar{E}_o, z)$  selection procedure has been reviewed in detail in the IAEA Code of Practice for plane-parallel ionisation chambers (IAEA 1997b); it was concluded that even for beams with large energy and angular spread the maximum error produced by such a procedure was always within 1%. For most beams used in clinical practice, even for those with a certain degree of photon contamination, the agreement was within the estimated uncertainty of the calculated stopping-power ratios, which is of the order of 0.6%. As illustrated in [Figure D.2](#), differences can be greater at small depths for beams with considerable energy and angular spread. It is worth emphasizing that curves of  $s_{w,\text{air}}$  vs. depth for clinical and for monoenergetic beams have different slopes, crossing at a depth (greater than the depth of maximum absorbed dose,  $d_{\max}$ ) which varies with the contamination of the incident electron

\* See Andreo (1988) for a review of this technique applied to the determination of stopping-power ratios.

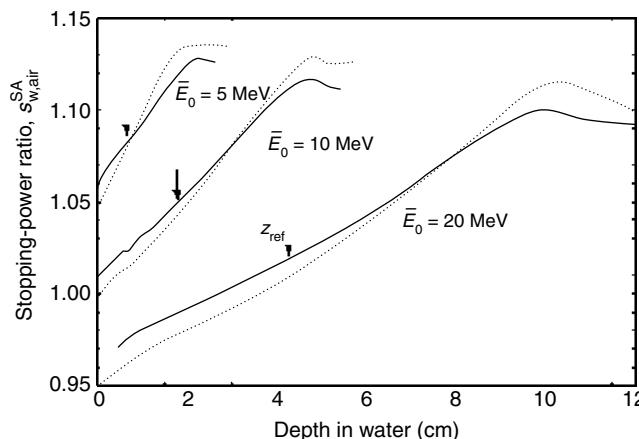

<sup>†</sup> See [Section D.3.2](#) for a discussion on electron beam quality specification.

**FIGURE D.1**

Depth variation of the Spencer–Attix water/air stopping-power ratio,  $S_{w,air}^SA$ , for  $\Delta = 10$  keV, derived from Monte-Carlo generated electron spectra for monoenergetic, plane-parallel, broad electron beams. (From Andreo (1990a); IAEA (International Atomic Energy Agency), *The use of plane-parallel ionisation chambers in high-energy electron and photon beams. An International Code of Practice for Dosimetry*, Technical Report Series no. 381, IAEA, Vienna, 1997.)

beam. This supports the recommendation of the use of a depth greater than  $d_{\max}$  as the reference depth for electron beams (ICRU 1984a; IAEA 1987, 1997b).

The work by Andreo and Fransson (1989), including stopping-power ratios for the *realistic* electron beams obtained by Udale (1988), who simulated in detail the treatment head of some clinical accelerators, has been extended by Ding et al. (1995) to other accelerators using the Monte-Carlo code BEAM (c.f. Rogers et al. 1995). Their results have confirmed the conclusions given above; thus no dramatic changes are expected in electron-beam dosimetry solely due to this improvement in the calculation of stopping-power ratios. The new stopping-power ratio data have been fitted empirically by Burns et al. (1996) to a ratio of polynomials,

**FIGURE D.2**

Water/air stopping-power ratios of highly *contaminated* electron beams calculated directly with the Monte Carlo method (solid lines), compared with the  $S_{w,air}^SA(\bar{E}_0 = 2.33 R_{50}, z)$  method used in most  $N_K$ -based dosimetry protocols (dashed lines). The *contaminated* beams, with initial energies of 5, 10, and 20 MeV, include the energy and angular spread of electrons and contaminant photons produced in single scattering lead foils, the beam defining system, air, and water; their contamination is stronger than that existing in most clinical accelerators. The arrows indicate the reference depths recommended for beam calibration, usually different from the depth of maximum dose. (From IAEA (International Atomic Energy Agency), *The use of plane-parallel ionisation chambers in high-energy electron and photon beams. An International Code of Practice for Dosimetry*, Technical Report Series no. 381, IAEA, Vienna, 1997.)

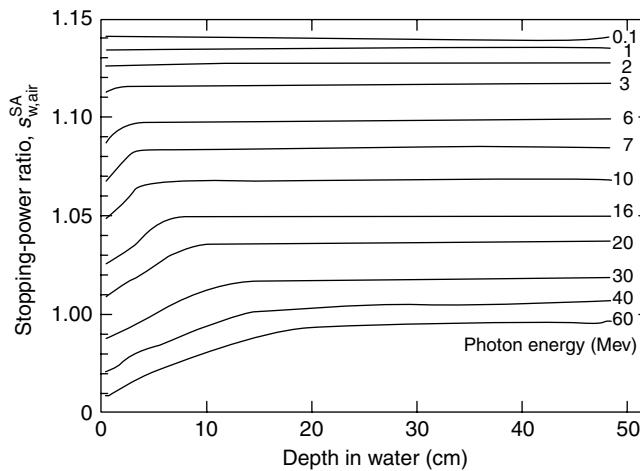

constituting the set of data in common use today in the AAPM (1999) and IAEA (2000) dosimetry protocols based on standards of absorbed dose to water.

### D.1.3 STOPPING-POWER RATIOS FOR PHOTON BEAMS

For high-energy photon beams, Nahum (1976, 1978) first performed calculations of stopping-power ratios based on Monte Carlo derived electron slowing-down or fluence spectra at different depths. The technique has been used by Andreo and Nahum (1985) to compute  $s_{w,air}$  values for a set of monoenergetic photon beams and then weight these to obtain stopping-power ratios for bremsstrahlung, i.e. polyenergetic spectra. This technique has been used also by Kosunen and Rogers (1993), who found exceptionally good agreement in the calculated stopping-power ratio data (at the 0.1% level), even when the Monte Carlo codes were different. As in the case of electron beams, agreement between different Monte Carlo calculations provides confidence in the data used for photon-beam dosimetry.

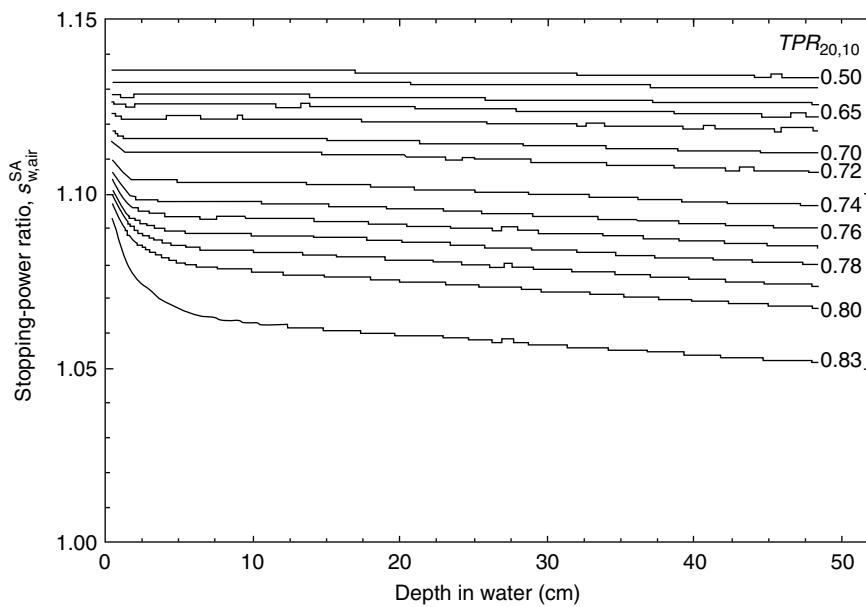

The most important characteristic of the depth variation of the stopping-power ratios of monoenergetic photons is that they are almost constant beyond the depth of transient electronic equilibrium, as Figure D.3 clearly shows. The range of variation of the stopping-power ratio data with energy is also much smaller than in the case of electrons with similar energies. In the case of bremsstrahlung spectra, interesting phenomena can be observed (see Figure D.4 and Figure D.5). The constancy of the stopping-power ratio is reached at shallower depths due to the presence of low-energy photons in the spectrum; furthermore, due to the higher values of the stopping-power ratio at lower energies, there is a *build-down* of the final stopping-power ratio, instead of the build-up shown for monoenergetic photon beams (Nahum 1982). This typical build-down pattern at small depths in a pure bremsstrahlung photon beam almost disappears in practice (except at very high energies) due to the presence of electron contamination (Figure D.5); the stopping-power of these electrons is usually lower than that of the photons. Thus, the two effects tend to cancel each other out and the constancy of the stopping-power ratio in a real photon beam is thus reached at smaller depths than in the case of a *clean* photon beam (Figure D.5).

Stopping-power ratios correlated in a consistent manner with the quality of clinical photon beams were calculated by Andreo and Brahme (1986) for a large number of bremsstrahlung spectra, including also the effect on  $s_{w,air}$  of the electron contamination in photon beams and their dependence with depth and field size. These results have been used to calculate stopping-power

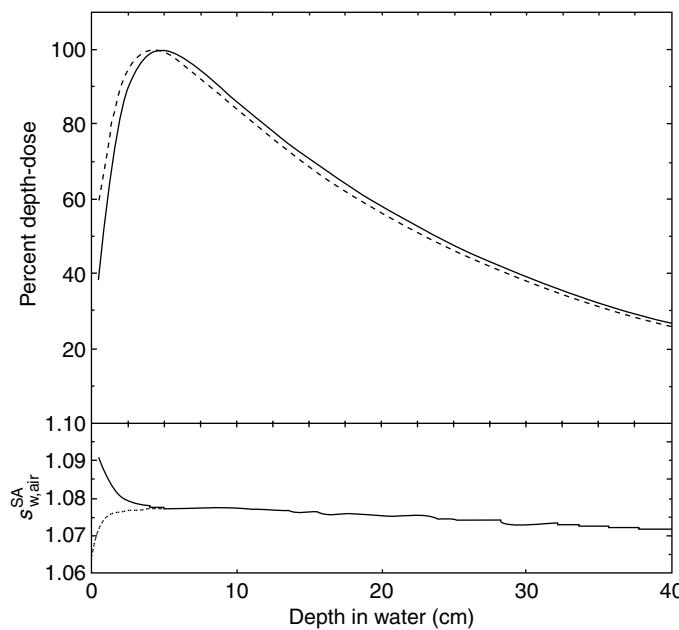

**FIGURE D.3**

Depth variation of the Spencer-Attix water/air stopping-power ratio,  $s_{w,air}^{SA}$ , for  $\Delta = 10$  keV, derived from Monte Carlo generated electron spectra for monoenergetic, plane-parallel photon beams. (Adapted from Andreo, P. and Nahum, A. E., *Phys. Med. Biol.*, 30, 1055–1065, 1985.)

**FIGURE D.4**

Depth dependence of the water/air stopping-power ratios for uncontaminated plane-parallel (i.e. non-divergent) bremsstrahlung x-ray spectra as a function of the quality of the beams,  $TPR_{20,10}$  (defined in Section D.3.1). The range of values for  $s_{w,air}^{SA}$  should be compared with that for monoenergetic photons in Figure D.3. (Adapted from Andreo, P. and Brahme, A., *Phys. Med. Biol.*, 31, 839–858, 1986.)

**FIGURE D.5**

The influence of electron contamination in depth-dose and water/air stopping-power ratio for a 25 MV linac spectrum. The solid lines show distributions for the *pure* photon bremsstrahlung beams, and the dashed lines show the final distributions when electron contamination is taken into account. (Adapted from Andreo, P. and Brahme, A., *Phys. Med. Biol.*, 31, 839–858, 1986.)

ratios for different materials and derive the ionisation-chamber correction factors used today in the majority of dosimetry protocols (Andreco et al. 1986). Improved calculations of stopping-power ratios using different Monte Carlo codes, and their correlation to the quality of photon beams based on the convolution of Monte Carlo calculated kernels, have also been made (Andreco 1991, 1994) but in most cases differences found were negligible, thus providing a firm consensus and lending reliability to the existing set of data. These have also been included in the IAEA (2000) dosimetry protocol based on standards of absorbed dose to water. The set of data calculated by Kosunen and Rogers (1993) have been used by the AAPM (1999) protocol but, as already mentioned, these stopping-power ratios are practically identical to those used by other protocols, the only difference residing in the use of a different photon-beam quality specifier to select stopping-power ratios. This aspect will be discussed in [Section D.3.1](#).

## D.2 PERTURBATION FACTORS

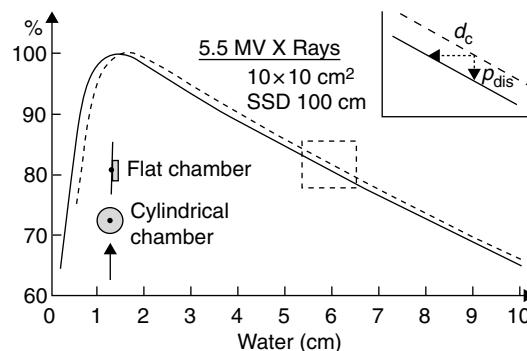

The perturbation factors are related to all the corrections which are required to take into account the fact that the Bragg–Gray conditions are not fulfilled when a real ionisation chamber is introduced into the medium. In what follows there is no further subdivision into photon and electron beams, though some of the effects are much more important for one modality than the other. In the case of kilovoltage x-ray beams, the formalism in the codes of practice is not based on Bragg–Gray behaviour and therefore the correction factors involved, such as  $k_{ch}$ , are not strictly perturbations and are not discussed here. In fact, one cannot logically talk about *perturbation* unless there is a quantity to be *perturbed*. Detailed treatments on perturbation have been given by Andreo (1991) and Nahum (1994, 1996). The emphasis here is on the *physics* of these correction factors; again, it is stressed that numerical values for the particular chamber and radiation quality of interest should be taken from the particular *code of practice* being followed.

### D.2.1 THE DISPLACEMENT EFFECT ( $P_{eff}$ OR $P_{dis}$ )

When an ionisation chamber measurement is performed, a certain volume of the medium is *displaced* by the detector. Even if it is assumed that the wall is medium-equivalent, one still has the volume occupied by the air cavity. In general, for cylindrical chambers, the dimensions of this volume are not negligible compared to any gradients in the radiation field and hence in the dose distribution, e.g. the dose may change by a few percent over a distance equal to the diameter of the chamber. Clearly the chamber reading will then be affected by this *missing* medium. In simple terms one can expect that the reduced attenuation, in the case of photon beams, will result in a higher chamber reading, compared to that in a vanishingly small *air bubble* situated at the centre of the detector. However, there is another effect: the missing material means that there is less scatter. This will counterbalance the first effect. The net result is still generally an *increase* in the signal and a factor known as the displacement factor is required, usually denoted by  $p_{dis}$ , which will therefore be less than unity.

The value of  $p_{dis}$  will in general depend on both the radiation quality and the physical dimensions of the air cavity in the direction of the beam, as well as on the depth of measurement. In photon beams,  $p_{dis}$  will be practically constant beyond the depth of dose maximum, due to the exponential fall-off in dose. However, in the buildup region, it will vary in a complicated fashion with depth. For a Farmer chamber, which has an internal radius of 2.95 mm, the value is close to 0.988 in a  $^{60}\text{Co}$  beam beyond  $d_{max}$  (Johansson et al. 1978).

The correction for displacement can be viewed in an alternative way. Instead of applying a factor to correct the chamber reading, assumed to be positioned so that its centre is at the depth of interest, a *shift* in the position of the chamber can be made. For a cylindrical chamber the electrons enter the wall at various depths, generally upstream of its centre, and hence the electron fluence in the air cavity is representative of that existing at some point in the uniform

**FIGURE D.6**

Depth-ionisation curves measured at 100 cm Source to Surface Distance (SSD) with a cylindrical chamber (dashed line) or with a parallel-plate chamber (solid line). The depths are referred to the geometrical centre of the cylindrical chamber and to the inner surface of the front window of the parallel-plate chamber. Coincidence between the two curves can be achieved by translating the dashed line upstream by a constant shift,  $d$ . (From Dutreix, A. and Bridier, A., in *The Dosimetry of Ionizing Radiation*, Vol. 1, Kase, K. R., Bjärngård, B. E., Attix F. H., Eds., Academic Press, Orlando, FL, 163–228, 1985.)

medium shifted upstream of the chamber centre. In fact, it was found (Dutreix 1976; Johansson et al. 1978) that the (relative) readings of different chambers could be brought into coincidence with one another by performing shifts depending on the chamber dimensions. Thus the concept of the *effective point of measurement*,  $P_{\text{eff}}$ , was developed. This is illustrated in Figure D.6.

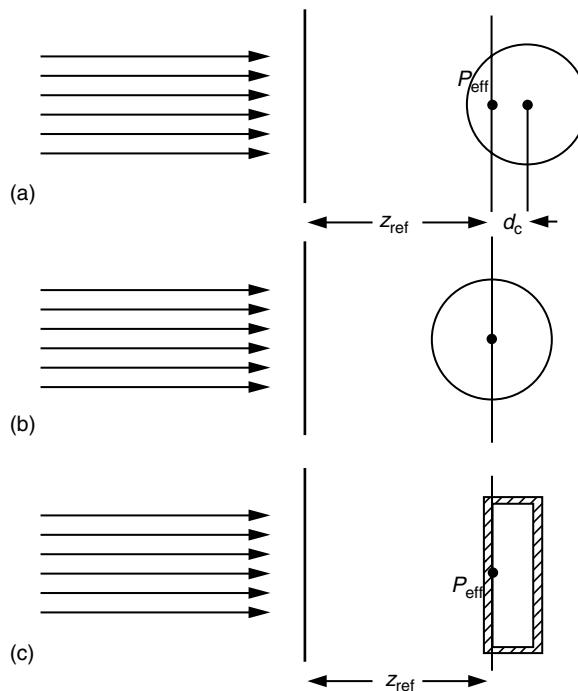

Assuming that the secondary electrons travel in the *forward*, i.e. beam direction, and that the number of ion pairs created is proportional to the chord length of the electrons in the cavity, it can be shown that the shift is  $8r/3\pi (=0.85r)$  for a cylindrical cavity and  $3r/4$  for a spherical cavity, both of radius  $r$  (Dutreix and Bridier 1985). More detailed treatments have been attempted, which take into account backscatter and the angular distribution of the secondary electrons (Svensson and Brahme 1986) but still fall well short of an exact theoretical analysis. Various experimental determinations of the *upstream* shift of  $P_{\text{eff}}$  from the cavity centre have been carried out (e.g. Hettinger et al. 1967; Dutreix 1976; Johansson et al. 1978); the readings of cylindrical chambers with different radii were generally compared with those of a plane-parallel chamber (cf. Figure D.6).

The newer absorbed-dose-to-water-based codes of practice favour the  $p_{\text{dis}}$  approach for the reference calibration point\*. However, air-kerma-based codes of practice utilise the  $P_{\text{eff}}$  concept in preference to  $p_{\text{dis}}$ <sup>†</sup>. IAEA (1987) recommended a shift of  $0.5r$  for  ${}^{60}\text{Co}$   $\gamma$ -rays, increasing to  $0.75r$  for all higher energy photon beams; this is the quantity  $d_c$  in Figure D.7. More recent reviews of the experimental evidence on the magnitude of the shift (Andreo 1993; IAEA 1996) led the IAEA to recommend a single value of  $0.6r$  for all high-energy photon beams (IAEA 1997a, 1997b).

In electron beams the use of  $p_{\text{dis}}$  is impractical as the depth-dose curve is very irregular in shape in total contrast to the quasi-exponential decrease in photon beams at depths beyond the buildup region, i.e.  $p_{\text{dis}}$  would vary rapidly and in an irregular way with depth in an electron beam. Thus in this case the  $P_{\text{eff}}$  concept is universally employed. For cylindrical chambers the recommended shift is  $0.5r$  (IAEA 1987, 1997a, 1997b). For plane-parallel chambers  $P_{\text{eff}}$  is assumed to be situated at the centre of the inside face of the front wall, as illustrated in Figure D.7 (IAEA 1987, 1997b);

\* It must be stressed that, although both approaches are possible and yield equivalent results for the absolute beam calibration at the reference point, the relative dose measurements (e.g. depth dose variation) must always be based on the  $P_{\text{eff}}$  concept, i.e. assigning the measured dose to the effective point of measurement.

<sup>†</sup> In the case where a  $p_{\text{dis}}$  coefficient is used at the PSDL to obtain a calibration factor at the *centre* of the ionisation chamber, the same factor is strictly valid only if the user's beam falls off at approximately the same rate as the calibration beam.

**FIGURE D.7**

In most  $N_K$ -based dosimetry protocols the effective point of measurement of a cylindrical ionisation chamber is positioned at the reference depth,  $z_{\text{ref}}$ , where the absorbed dose is required; the chamber centre is deeper than  $z_{\text{ref}}$  a distance  $d_c$  equal to the shift of  $P_{\text{eff}}$  (for example  $0.6 r_{\text{cyl}}$  for photon beams in TRS-277 IAEA 1987/1997a) (a). Except in electron and heavy-ion beams, in  $N_{D,w}$ -based protocols, the centre of a cylindrical chamber is positioned at the reference depth,  $z_{\text{ref}}$ , and the absorbed dose is determined at this position (b). For plane-parallel chambers all protocols position the effective point of measurement (front of the air cavity) at the reference depth,  $z_{\text{ref}}$  (c).

IPEMB 1996a); this is logical as, in a well-guarded chamber, it can be assumed that all the electrons entering the sensitive air volume do so through the front window.

### D.2.2 THE EFFECT OF THE CHAMBER WALL ( $\rho_{\text{wall}}$ )

Bragg–Gray behaviour implies that the electron fluence in the sensitive volume of the detector is identical (strictly both in magnitude and in energy and angular distribution) to that present in the undisturbed medium at the position of interest. However, an ionisation chamber has a wall which in general is not made of medium-equivalent material. In the case of *photon beams*, the electron fluence in the air cavity in an ionisation chamber, assumed cylindrical, with a wall of a typical thickness, will consist partly of electrons generated in the (uniform) medium surrounding the wall and which have travelled through the wall, and partly of electrons generated by photon interactions in the wall material. Quite clearly, the number and energy distribution of these wall-generated secondary electrons will be characteristic of photon interactions with the material of the wall and not of the medium as demanded by Bragg–Gray conditions.

It can be shown (e.g. Attix 1986; Bielajew 1986) for the case of an (air-filled) ionisation chamber with a so-called *thick* wall, i.e. of a thickness equal to the buildup depth in the wall material, and where this material is a single substance, e.g. graphite or aluminium, that the relationship between the (mean) dose to air and the (mean) dose to medium is given, to a good approximation, by

$$D_{\text{med}} = \bar{D}_{\text{air}} \left( \frac{\bar{\mu}_{\text{en}}}{\rho} \right)_{\text{wall}}^{\text{med}} s_{\text{wall,air}} \quad (\text{D.4})$$

This expression is based on assuming that there is charged particle equilibrium in the wall at the position of the air cavity, i.e. using the *large detector* result [ $D_{\text{wall}} = \psi(\mu_{\text{en}}/\rho)_{\text{wall}}$ ], and then the Bragg–Gray result to relate  $\bar{D}_{\text{air}}$  to  $D_{\text{wall}}$ . By comparing it to

$$D_{\text{med}} = \bar{D}_{\text{air}} s_{\text{med,air}} p_{\text{wall}} \quad (\text{D.5})$$

the perturbation factor  $p_{\text{thick-wall}}$  can be written as

$$p_{\text{thick-wall}} = \left( \frac{\bar{\mu}_{\text{en}}}{\rho} \right)_{\text{wall}}^{\text{med}} s_{\text{wall,med}} \quad (\text{D.6})$$

For a graphite wall in a water medium,  $p_{\text{thick-wall}}$  is practically constant at approximately 0.982 over the megavoltage range, and only begins to increase at the high-energy end,  $TPR_{20,10} > 0.70^*$ , where pair-production becomes important; for a nylon wall, the corresponding value of  $p_{\text{thick-wall}} \approx 1.022$ . Nahum (1994) has shown that over the broad (megavoltage) energy range where the Compton effect dominates, the material dependence of  $p_{\text{thick-wall}}$  is essentially proportional to the difference between the mean excitation energies ( $I_{\text{med}} - I_{\text{wall}}$ ).

For ionisation chambers in practical use in radiotherapy the wall thicknesses are much less than the buildup depths, and thus the above expression is not valid. Almond and Svensson (1977) wrote down an approximate two-component expression for the case of a wall of intermediate thickness, which is equivalent to:

$$p_{\text{wall}} = \frac{\alpha s_{\text{wall,air}}(\mu_{\text{en}}/\rho)_{\text{med,wall}} + (1 - \alpha)s_{\text{water,air}}}{s_{\text{water,air}}} \quad (\text{D.7})$$

where  $\alpha$  is the fraction of the dose to the air in the cavity due to electrons generated in the chamber wall; thus if this is zero then  $p_{\text{wall}}$  reduces to unity, as expected. In Equation D.7 the medium is water; this is the expression given in some air-kerma-based codes of practice such as IAEA (1987).

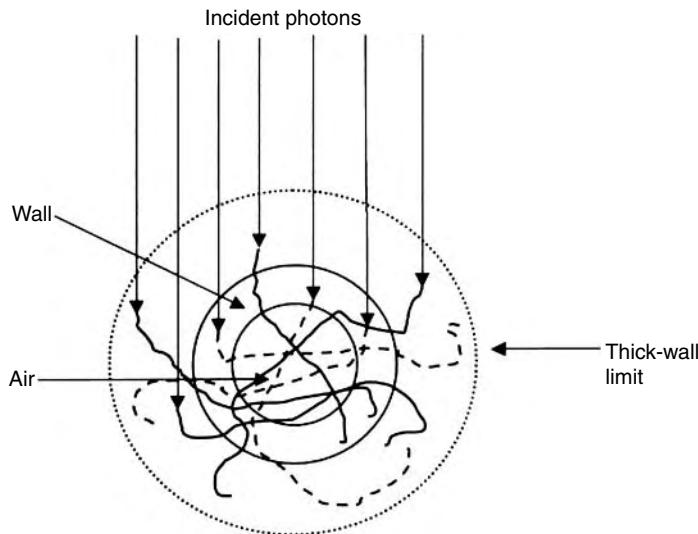

The very simple Equation D.7 cannot in any sense be *derived* for the practically important intermediate-wall-thickness case; it is a purely empirical approach to an extremely complex problem. [Figure D.8](#) illustrates schematically the origins of the different contributions to the dose in the air cavity:

- The spectrum of the water- or more generally, medium-generated electrons will be modified by their passage through the wall material, thus modifying the effective stopping-power ratio,  $s_{\text{med,air}}$ , for these electrons
- The  $\delta$ -rays generated in the wall by the electrons originating in the medium will also affect  $s_{\text{med,air}}$
- The  $\mu_{\text{en}}/\rho$  ratio in Equation D.7 applies only to wall thicknesses sufficient for charged particle equilibrium which does not exist in the intermediate wall case
- The stopping-power ratio for the wall-generated electrons,  $s_{\text{wall,air}}$ , should reflect the fact that this spectrum is only partially *built-up*, i.e. similar to that existing in the buildup region in a high-energy photon beam (Andreo and Nahum 1985)

In a more complete analytical treatment all of the above factors would need to be taken into account. Only Monte-Carlo simulation can yield reliable theoretical values for  $p_{\text{wall}}$ .

To evaluate  $p_{\text{wall}}$  from Equation D.7, the wall-generated fraction of the ionisation,  $\alpha$ , must be estimated. Lempert et al. (1983) measured  $\alpha$  by adding successively thicker sheaths to a thin-walled chamber until full build-up was achieved at a number of different qualities. Codes of practice such as IAEA (1987, 1997a) give graphs of  $\alpha$  as a function of beam quality,  $TPR_{20,10}^*$ , for different wall thicknesses, expressed in units of  $\text{g cm}^{-2}$  and it is

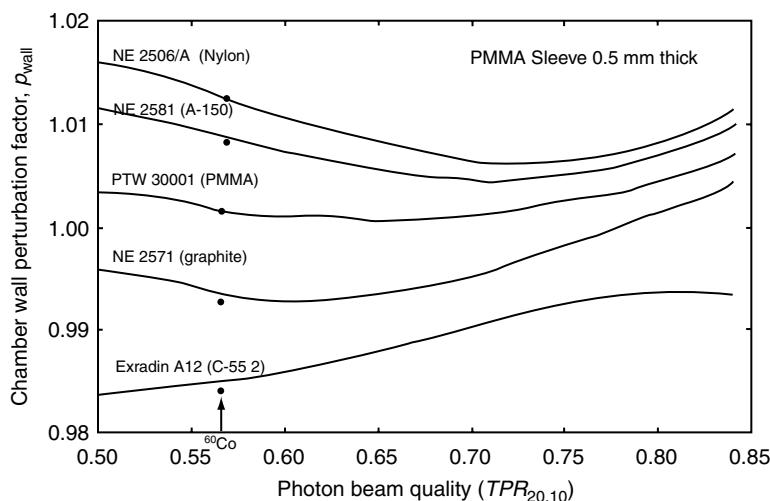

\*  $TPR_{20,10}$  is an index representative of beam quality of a megavoltage photon beam; it is defined in [Section D.3.1](#) and increases with beam energy.

**FIGURE D.8**

The influence of the chamber wall on the secondary electron fluence in the air cavity; the dashed tracks are wall-generated electrons, the full lines are medium-generated.

then assumed that these  $\alpha$  values are valid for any low-Z wall material. Values of  $s_{\text{wall,air}}$  and  $(\mu_{\text{en}}/\rho)_{\text{water,wall}}$  as a function of  $TPR_{20,10}$  are also given in the IAEA code. Figure D.9 shows the values of  $p_{\text{wall}}$  using Equation D.7 for a range of commonly used chamber-wall materials, of thickness 0.5 mm. An additional small correction has been made for a 0.5 mm thick waterproofing sleeve of PMMA, using the extension of Equation D.7 to a three-component model, with a third term  $\tau s_{\text{sheath,air}}(\mu_{\text{en}}/\rho)_{\text{water,sheath}}$  where  $\tau s_{\text{sheath,air}}$  is the fraction of the ionisation due to electrons generated in the sheath (Gillin et al. 1985; Hanson and Dominguez-Tinoco 1985).

Experimental determinations of  $p_{\text{wall}}$  have been made by assuming that, for two chambers of different wall materials, the ratio of their air volumes is given by the ratio of the signals in an

**FIGURE D.9**

The chamber wall perturbation factor,  $p_{\text{wall}}$ , as a function of the quality of photon beams for different ionisation chambers (wall materials). It is assumed that all the chambers are used in a water phantom with a waterproofing sleeve of PMMA 0.5 mm thick. (Adapted from Andreo, P., Nahum, A. E., and Brahme, A., *Phys. Med. Biol.*, 31, 1189–1199, 1986.)

electron beam, i.e. that the wall effects are negligible in an electron beam (see below). Using this method, Johansson et al. (1978) and Mattsson (1984) obtained values for Farmer-like chambers which were reasonably consistent with the Almond–Svensson two-component theory (Equation D.7); Nahum (1994) should be consulted for a more detailed discussion. A more direct test of Equation D.7 was carried out by Nahum et al. (1985) using a Farmer chamber, irradiated in a  $^{60}\text{Co}$   $\gamma$ -ray beam, with a wall of aluminium coated on the inside with successively thicker layers of dag, which is essentially graphite. Clear deviations from the simple two-component model were found, though aluminium represents an extreme test, having an atomic number more different from water than the wall materials used in practical chambers.

The formalism for evaluating  $p_{\text{wall}}$  described above was developed for cylindrical chambers, e.g. the Farmer chamber. However, plane-parallel chambers, which are specifically recommended for use in electron beams, especially at energies below about 10 MeV, are sometimes also used in photon beams. One particular instance of this is to determine the  $N_{D,\text{air}}$  factor for a plane-parallel chamber by cross-calibrating it against a cylindrical chamber in a  $^{60}\text{Co}$  beam (NACP 1981; IAEA 1997b). In this case,  $p_{\text{wall}}$  for the plane-parallel chamber must be known. However, it has been found that Equation D.7 gives values that are inconsistent with experiment for a number of plane-parallel designs (Mattsson 1984; Wittkämper et al. 1992; Nyström and Karlsson 1993). This is almost certainly due to the fact that several different materials are generally used in their construction. A Monte-Carlo simulation of plane-parallel chamber response (Rogers 1992b) showed that the energy deposition in the air cavity depends strongly on the material *behind* the cavity, probably due to electron backscattering. Such effects cannot be accounted for by the simple two- or three-component model. Consequently, it is no longer recommended that plane-parallel chambers be used in photon beams except for *relative* dose measurements (IAEA 1997b); however even here there can be perturbation effects in the buildup region unless there is a wide guard ring (Nilsson and Montelius 1986).

In the case of *electron beams*, it is generally assumed that the effect of the chamber wall is negligible. Certainly the physics here is different from the photon-beam case because there is no counterpart to the generation of secondary electrons characteristic of the wall material which can provide a large fraction of the chamber signal (through the factor  $\alpha$  in Equation D.7). However,  $\delta$ -rays are generated in the chamber wall which could, in principle, affect the chamber signal. Nahum (1988) developed an approximate theory to take this into account; this predicts that for walls of practical thicknesses and materials (graphite, A-150, C-552 plastic) the effect is always less than 0.5% and virtually independent of electron energy. Nahum (1996) should be consulted for a more detailed treatment.

### D.2.3 THE EFFECT OF THE CENTRAL ELECTRODE ( $p_{\text{cel}}$ )

Cylindrical chambers have a central electrode which is usually made of aluminium but can be made of graphite. A correction for the lack of air-equivalence of this is in principle necessary and is denoted by  $p_{\text{cel}}$ , though in some cases it has been included in  $p_{\text{wall}}$ . Mattsson (1984) measured the ratio of signals of cylindrical chambers with aluminum and graphite central electrodes at different photon beam qualities; he found a 0.9% effect at cobalt-60 on the assumption that there was no effect in the high-energy electron beam used to derive the ratio of the chamber volumes; Kristensen (1983) obtained 0.8% using a more direct method, without involving any assumptions in electron beams. Ma and Nahum (1993) carried out Monte-Carlo simulations of the effect of the electrode compared to a chamber with no electrode and their values are now the generally accepted ones: in photon beams,  $p_{\text{cel}}$  for a 1 mm diameter graphite electrode is negligibly different from unity at all qualities investigated (cobalt-60 to  $TPR_{20,10}=0.80$ ) but decreases from 1.008 to 1.004 for a 1 mm diameter aluminium electrode. Ma and Nahum

(1993) showed that the effect was negligible for graphite in electron beams, and never greater than 0.2% at any energy (5 MeV to 20 MeV) or depth for a 1 mm diameter aluminium electrode.

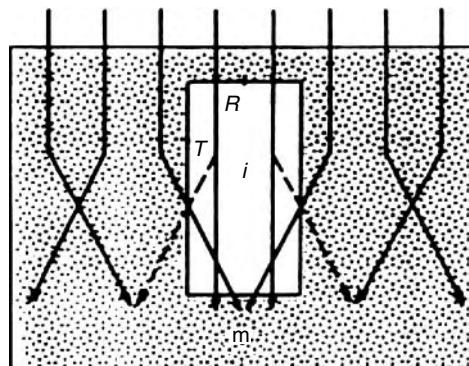

#### D.2.4 THE ELECTRON FLUENCE (IN-)SCATTERING EFFECT ( $p_{\text{cav}}$ )

An ionisation chamber introduces a low-density heterogeneity into a medium. In principle this is no different from the general problem of the influence of heterogeneities on the dose distribution in treatment planning. In an *electron beam*, density changes can cause *hot* or *cold* spots as a result of electron scattering. Harder (1968) analysed the problem of the effect of small air cavities on the electron fluence and produced an approximate theory using small-angle scattering which predicted an increase in the chamber signal. The reason for this is clear from the elegant figure due to Harder (see Figure D.10). As a result of (elastic nuclear) scattering, in an electron beam the angular distribution of electrons broadens with depth in the wall (or phantom material) whereas this broadening will be negligible in a gas cavity due to the very low density. Consequently, more electrons are scattered *into* a low-density cavity than are scattered *out*, resulting in an *increase* in the electron fluence towards the *downstream* end of the cavity, compared to the fluence in a uniform medium at that depth.

The magnitude of this *in-scattering* effect must be referred to a particular depth in the undisturbed medium. Thus a perturbation factor,  $p_{\text{cav}}$ , which corrects for the effect of the air cavity is defined as

$$\Phi_{\text{med}}(P_{\text{eff}}) = \bar{\Phi}_{\text{cav}} p_{\text{cav}} \quad (\text{D.8})$$

where  $\Phi_{\text{med}}(P_{\text{eff}})$  and  $\bar{\Phi}_{\text{cav}}$  refer to the primary electron fluence in the undisturbed medium (at the depth of the effective point of measurement  $P_{\text{eff}}$ ) and in the cavity (averaged over the volume), respectively. It can be noted that this definition of the perturbation correction factor is only consistent with the expression for the absorbed dose to water (Equation D.4) if the energy distribution of the electron fluence in the cavity is very similar to that at  $P_{\text{eff}}$  in the uniform medium. This makes it possible to use the standard computations

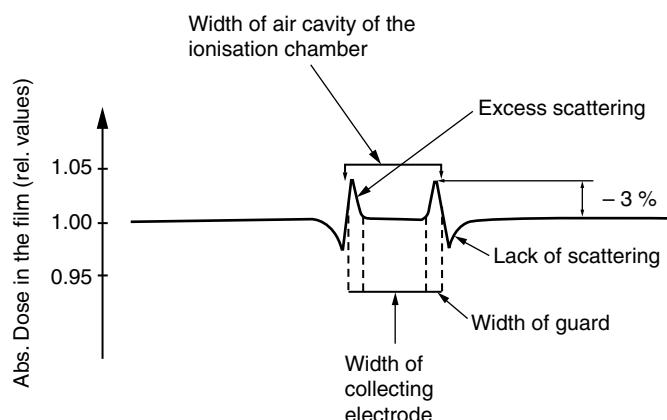

**FIGURE D.10**

Perturbation of the electron fluence caused by a gas-filled cavity in a solid or liquid phantom irradiated by an electron beam. Electron tracks are idealized to emphasize the effects being shown. The dashed lines represent tracks which would exist if the cavity was not present. The dominance of in-scattering over out-scattering gives rise to an increase in the fluence towards the back of the cavity and hence an increase in the chamber signal. (From Harder, D., Fano's theorem and the multiple scatter correction, in *Proceedings of the 4th Symposium on Microdosimetry*, Booz, H. G. E. J., Eickel, R., Waker, A., Eds., Euratom, Brussels, 677–693, 1974.)

of the stopping-power ratio, which are based on the Bragg–Gray requirements of identical fluences, differential in energy, in the medium and in the detector material.

The in-scattering effect has been experimentally demonstrated for cylindrical chambers by several workers (Harder 1968; Johansson et al. 1978). Johansson et al. (1978) used PMMA-walled chambers of diameters 3, 5, and 7 mm. The ratios of the sensitive air volumes in the chambers were assumed to be given by the signal ratios at  $d_{\max}$  in photon beams. The measurements in the electron beams were all made in a PMMA phantom at the peak of the depth-ionisation curves to eliminate any displacement effects (see Section D.2.1). The energy at this depth  $z$ ,  $E_z$ , varied between 2.5 and 22 MeV. For Farmer-type chambers (by interpolation)  $p_{\text{cav}} = 0.995$  at  $E_z = 20$  MeV, but decreases to 0.970 at 6 MeV. Johansson et al. (1978) found a linear relation between  $p_{\text{cav}}$  and cavity radius in contrast to the non-linear dependence on radius predicted by the Harder (1968) theory. All modern air-kerma-based dosimetry protocols (IAEA 1987; NCS 1989; IPEMB 1996a) include values of the perturbation factor determined experimentally by Johansson et al. (1978). Palm and Mattsson (2000) made another experimental investigation of  $p_{\text{cav}}$  using the same PMMA phantom and PMMA-walled cylindrical chambers as had been originally used by Johansson et al. (1978). Only minor deviations from the 1978 values were found. Additionally, Palm and Mattsson measured  $p_{\text{cav}}$  for graphite-walled Farmer-like chambers and found values at the lowest energies ( $E_z$  between 5 and 10 MeV) about 1% higher than those given in IAEA (1997b). In all cases, the linear relationship between  $p_{\text{cav}}$  and cavity radius was confirmed. Nahum (1994, 1996) and IAEA (1997b) should be consulted for a more detailed treatment of the *in-scattering* effect.

The magnitude of the in-scattering perturbation exceeds 3% for Farmer-type chambers for  $E_z$  below 8 MeV. This is one of the principal reasons why plane-parallel (or parallel-plate) chambers are recommended in low-energy electron beams (NACP 1981; AAPM 1994b; IPEMB 1996a; IAEA 1997b). A plane-parallel chamber has a completely different geometry to a cylindrical or thimble chamber. The diameter of the air cavity (typically between 13 and 20 mm) is deliberately made much greater than its thickness (the electrode spacing), which is 2 mm in almost all commercial designs. Thus most of the electrons enter the air cavity through the front face of the chamber and only a small fraction through the side walls. Furthermore, well-designed plane-parallel chambers have a relatively wide guard ring—3 mm or more—which ensures that almost no electrons entering through the short side walls can contribute to the chamber signal. Consequently, *in-scattering* is virtually

**FIGURE D.11**

Film measurements across the front surface of an air cavity in a PMMA phantom at the depth of maximum dose in a 6 MeV electron beam; the effect of the guard ring in eliminating the perturbation is clearly demonstrated (From Mattsson, L. O., Johansson, K.-A., Svensson, H., *Acta Radiol. Oncol.*, 20, 385–399, 1981.)

eliminated. [Figure D.11](#) shows how any perturbation of the dose distribution is confined to the guard-ring region. The electron fluence in the sensitive volume of such a chamber is therefore that existing in the uniform medium at the depth of the inside face of the front window, which is the position of the effective point of measurement  $P_{\text{eff}}$  as illustrated in [Figure D.7c](#).

There is a substantial body of experimental evidence that in-scattering perturbation is negligible for well-designed parallel-plate chambers such as the NACP and Roos chambers (e.g. Mattsson et al. 1981; Wittkämper et al. 1991; IAEA 1997b). A good example of this evidence is the study by Roos (1993) who compared the response of chambers with different guard-ring widths, each with a 2-mm cavity depth, in a 6-MeV electron beam. He showed that for guard-ring widths greater than 3 mm there was no change in the chamber responses compared to a chamber with an ultrabroad (8 mm) guard ring (IAEA 1997b). However, for one commercial parallel-plate design in particularly widespread use, the *Markus chamber*, several series of measurements have demonstrated a perturbation effect of the order of 1% at  $E_z = 5$  MeV, increasing to 2% at 3 MeV (this is summarized in IAEA 1997b). This was to be expected given that the Markus chamber has a collecting electrode diameter of only 5.3 mm, a cavity depth of 2 mm, and a guard ring of only 0.2 mm.

When investigating the response of an ionisation chamber, the perturbation factor obtained experimentally is naturally an *overall* factor and may well include contributions from effects other than the primary one that is believed to dominate, e.g. in-scattering in electron beams. An example of a possible secondary effect in plane-parallel chambers is differences in electron backscattering from the material behind the air cavity compared to that of the (uniform) medium (Hunt et al. 1988; Klevenhagen 1991; Nilsson et al. 1996). The back wall of the Roos chamber is PMMA and is only 1.3 mm thick, whereas the NACP chamber has about 7 mm of graphite. And yet the NACP/Roos response ratio has been shown to be independent of electron energy (Roos 1993) and given that the designs of these two chambers almost certainly ensure that there is a negligible in-scattering effect, this strongly suggests that backscattering effects are also negligible (IAEA 1997b).

In *photon beams*, should a perturbation of the electron fluence in the air cavity due to the in-scattering effect also be expected? The effect in electron beams is due to the change in the *angular* distribution of the electron fluence with *depth*. However, in photon beams there is generally charged particle equilibrium (or a very good approximation to it), and there will therefore be no (or negligible) change in either the energy or angular distribution of the secondary electrons with position in the irradiated medium. Harder (1974) also reasoned that any such effect would be inconsistent with Fano's theorem (Attix 1986). Johansson et al. (1978) tried to detect such an effect by measuring the response ratios of cylindrical chambers with radii of 3, 5, and 7 mm at photon qualities from  $^{60}\text{Co}$   $\gamma$ -radiation to 42 MV x-rays with the chamber centres at  $d_{\text{max}}$  to eliminate the displacement effect (see [Appendix D.2.1](#)). A constant ratio of the readings was obtained despite the very different secondary electron energies over the photon quality range; it was thus concluded that the effect was negligible in photon beams. However, in the buildup region in photon beams, where there is incomplete charged particle equilibrium, perturbation effects have been demonstrated (Velkley et al. 1975; Nilsson and Montelius 1986).

## D.2.5 CONCLUDING REMARKS

Experimental determinations of perturbation factors often involve questionable assumptions, e.g. that a particular effect is negligible in the beam quality used to normalise the responses of the different chambers, and none of the analytical treatments for any of these effects is wholly satisfactory. Only Monte-Carlo simulation of chamber response can be expected to yield highly accurate values of the different perturbation factors in the various chamber types (Rogers 1992b, 1993; Nahum 1999a; Kawrakow 2000; Verhaegen et al. 2006).

## D.3 BEAM-QUALITY SPECIFICATION

### D.3.1 PHOTON BEAM QUALITY SPECIFIERS

Prior to the use of modern practices for specifying photon beam quality, the nominal accelerator potential was the parameter most commonly used in photon-beam dosimetry. Measured absorbed-dose or ionisation ratios were first used as a beam-quality index in the dosimetry recommendations of the Nordic Association of Clinical Physicists (NACP, 1972; NACP, 1980). The measured dose ratio was, however, associated with the nominal accelerating potential, which was then used for the selection of conversion factors. A first attempt at improving the NACP procedure was made in the AAPM TG-21 protocol (AAPM 1983) where stopping-power and mass energy-absorption coefficient ratios, were associated in graphical form with measured ionisation ratios. However, these data were still given numerically as a function of the nominal MV, which involved a unique correspondence between MV and ionisation ratios, similar to the drawback pointed out for the NACP recommendations. Andreo and Brahme (1986) showed that the use of only the nominal accelerator potential, ignoring the actual penetration properties of a clinical beam, could yield variations of up to 1.5% in the stopping-power ratio. It is mainly for this reason that the use of a quantity representative of the beam attenuation in water and derived from the Tissue Phantom Ratio (TPR defined in [Section 23.2.1.6](#)),  $TPR_{20,10}$  was considered to be a more appropriate choice for radiotherapy beams than the nominal accelerating potential. Most dosimetry protocols, based on standards of air kerma and on standards of absorbed dose to water, have recommended  $TPR_{20,10}$ , as the specifier of the quality of high-energy photon beams (AAPM 1983; SEFM 1984, 1987; NCS 1986; IAEA 1987; AIFB 1988; IPSM 1990; DIN 1997).  $TPR_{20,10}$  is defined as the ratio of water absorbed doses on the beam axis at the depths of 20 cm and 10 cm in a water phantom, obtained with a constant source-detector distance (e.g. 100 cm) and a 10 cm  $\times$  10 cm field size at the position of the detector. The parameter  $TPR_{20,10}$  is a measure of the effective attenuation coefficient, and describes the approximately exponential decrease of a photon depth-dose curve beyond the depth of maximum dose\*; more importantly, it is independent of the electron contamination in the incident beam.

Other beam-quality specifiers have been proposed for photon-beam dosimetry which are, in most cases, related to the depth of maximum absorbed dose and can, therefore, be affected by

\* A photon depth dose distribution can be described by the functional form (c.f. Brahme and Svensson 1979; Greening 1981; Brahme and Andreo 1986):

$$D(z) \approx D_0(e^{-\mu_p z} - \nu e^{-\mu_e z})$$

where  $\mu_p$  is the effective attenuation coefficient of the photon spectrum and  $\mu_e$  is the effective attenuation coefficient of photon-produced electrons plus contaminant electrons ( $\nu$  is an adjusting parameter). At large depths, where the electron component can be ignored, the ratio of dose at two depths,  $z_1$  and  $z_2$ , is given by,

$$\frac{D(z_2)}{D(z_1)} \approx e^{-\mu_p(z_2-z_1)}$$

from where

$$\mu_p \approx \frac{1}{z_2 - z_1} \ln \frac{D(z_2)}{D(z_1)}$$

Thus, the ratio of absorbed dose at two depths is related to the effective attenuation coefficient of the photon spectrum. This relationship of the dose ratio with the effective attenuation coefficient is valid both for Tissue-Phantom Ratio and for Percent Depth Dose distributions although the  $\mu_p$  will be of a different kind (for a parallel or for a divergent beam). The relationship is not valid when the dose is specified at one depth only, referred to  $d_{max}$ , where the distribution has a shoulder and it is not exponential.

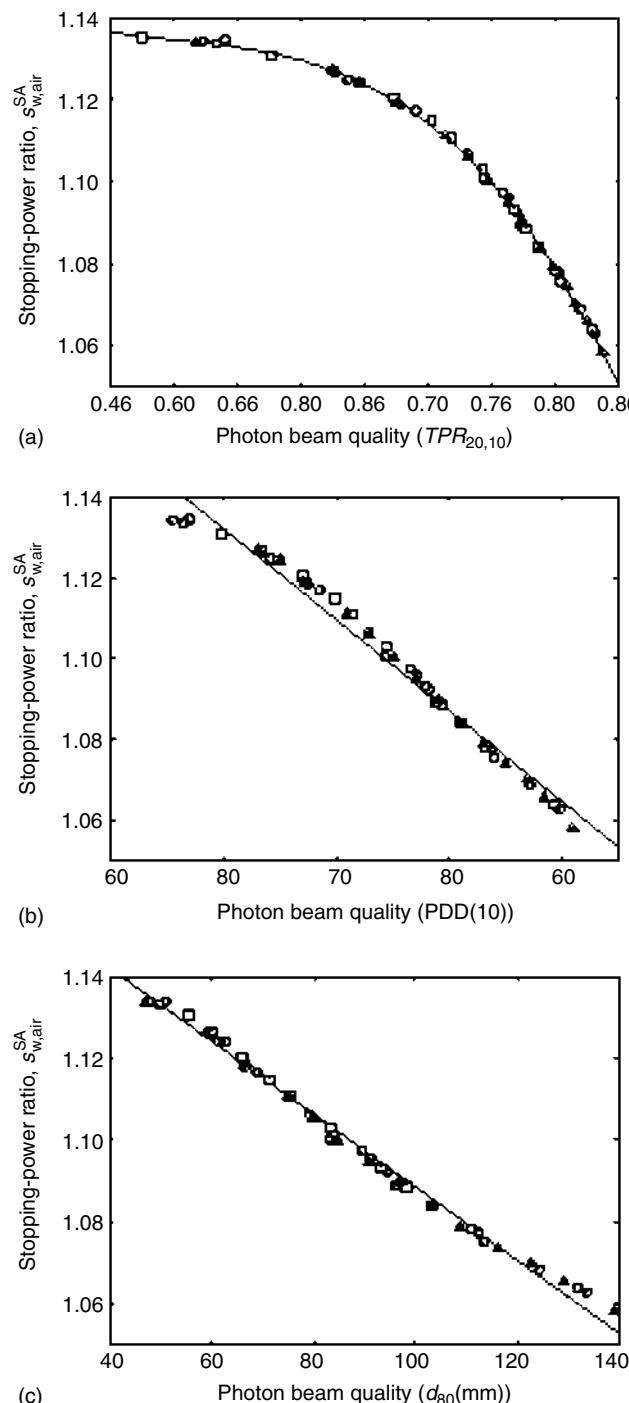

the electron contamination at this depth\*. Based on percentage depth-dose distributions, a widely disseminated recommendation for specifying the quality of high-energy photon beams was made in Supplement 17 of the British Journal of Radiology (British Institute of Radiology 1983); the parameter  $d_{80}$  was defined as the depth of the 80% depth dose (i.e. 80% of the dose maximum) for a 10 cm × 10 cm field size at a Source to Surface Distance (SSD) of 100 cm. In this supplement it was pointed out that electron contamination should be considered as a practical shortcoming of the method. The use of  $d_{80}$  as a photon beam quality index has also been endorsed in Supplement 25 of the *British Journal of Radiology* (British Institute of Radiology 1996), although other beam quality specifiers, like the Percent Depth Dose (PDD defined in [Section 23.2.1.1](#)) at a given reference depth, are also considered. In its conclusions, Supplement 25 also referred to contaminating electrons as the greatest problem for normalization at  $d_{\max}$ , as by changing the dose at this depth electron contamination can alter the apparent beam quality†.

The parameter PDD(10), the percentage depth-dose at 10 cm depth, determined under the same conditions of field size and source to surface distance (SSD) as  $d_{80}$ , has the same limitation with regard to the effect of electron contamination as  $d_{80}$  (see [Section 23.2](#)). This parameter has been commonly used by accelerator manufacturers, associating it with an effective accelerator potential. The work by LaRiviere (1989), proposing a relation between the beam quality specified in terms of MV and PDD(10), has been used by manufacturers to justify the use of this parameter. This has, however, produced the paradoxical situation where an accelerator could have an effective MV larger than the accelerator electron energy (see [Section 22.2.2](#)). LaRiviere also proposed a relation between PDD(10) and the dose-weighted mean energy of the photon spectrum, which was suggested as an alternative beam quality index. That proposal led Kosunen and Rogers (1993) to investigate the relation of PDD(10)<sub>x</sub> in a *pure photon beam* (i.e. without electron contamination) to stopping-power ratios. Based on the linearity of the relation obtained, they proposed extending the use of PDD(10)<sub>x</sub> to specify the quality of photon beams and to select conversion and correction factors. Kosunen and Rogers referred to the problem of the difference between absorbed-dose and ionisation measurements with cylindrical ionisation chambers due to the use of a displacement (or replacement) factor, and also emphasized that electron contamination should be removed from the photon beam for measuring PDD(10)<sub>x</sub>. According to these authors the latter can be achieved using a thin lead foil as filter, which has become the method recommended by the AAPM TG-51 dosimetry protocol (AAPM 1999). Limitations of this attempt to remove contaminant electrons have been stressed by Andreo (2000).

It is important to emphasize that, in principle, stopping-power ratios and  $k_Q$  values can be related to any parameter indicating the penetration characteristics of photon beams, as both stopping-power ratios and dose distributions are usually determined in a correlated manner using a Monte Carlo calculation. [Figure D.12](#) illustrates the variation of water/air stopping-power ratios with different photon beam quality specifiers,  $TPR_{20,10}$ , PDD(10) and  $d_{80}$ , using the beam quality parameters given in Table 5.iii of Supplement 25 of the *British Journal of Radiology* (British Institute of Radiology 1996) for the latter two specifiers. However,

\* Stopping-power ratios at the depth of  $d_{\max}$  are usually affected by electron contamination, but this occurs in a way such that the depth-variation of  $s_{w,air}$  is practically constant after shallow depths (c.f. Andreo and Brahme 1986); pure photon beams have a build-up effect that makes  $s_{w,air}$  different at shallow and at large depths. In addition, the use of ionisation distributions measured with thimble-type ion chambers is problematic, since the displacement perturbation factor has to be taken into account in converting ionisation into dose at depths other than the maximum. The alternative concept of the effective point of measurement is to be preferred. Plane-parallel ion chambers solve this problem, although they are not commonly used in photon beam dosimetry.

† It is worth noting that ever since the publication of BJR-11 (BJR 1972), the problem of electron contamination and the need to normalize dose-distributions at depths greater than  $d_{\max}$  has been addressed by different BJR Supplements, but alternatives for a specifier independent of electron contamination have not been recommended in this series of publications.

**FIGURE D.12**

Spencer-Attix ( $\Delta = 10$  keV) water/air stopping-power ratios,  $s_{w,\text{air}}^{\text{SA}}$ , at the reference depth for clinical photon beams versus different photon beam quality specifiers: (a)  $TPR_{20,10}$ ; (b) PDD(10); and (c)  $d_{80}$ . Circles correspond to spectra published by different authors (c.f., Table 2 in Andreo and Brahme 1986) and squares represent the calculated spectra in the same reference. The triangles correspond to the qualities given in the *British Journal of Radiology*, Suppl. 25, 1996. The solid lines represent fits of the stopping-power ratios to each beam quality specifier; note that the left-most data point of (a) has not been included in the linear fits of (b) and (c). (Adapted from Andreo, P., *Med. Phys.*, 27, 434–440, 2000.)

calculating stopping-power ratios directly as a function of PDD(10) or  $d_{80}$  for realistic beams is not possible due to the lack of information on the spectra of contaminant electrons, which would be required as input to the calculations. Instead, the parameter PDD(10)<sub>x</sub>, i.e. PDD(10) for *pure photon beams*, has been recommended to select stopping-power ratios (Kosunen and Rogers 1993; Rogers 1996). The problem is that in reality *pure photon beams* do not exist. Therefore, beam quality specification must rely either on a simple practical parameter which is truly related to the intrinsic physics of photon interactions (such as the practical attenuation coefficient discussed in relation with  $TPR_{20,10}$ ) or the problems associated with electron contamination and attempts to remove it will outweigh any possible theoretical advantage in the use of an apparently more attractive simple linear fit.

Advantages and limitations of the different photon-beam quality specifiers have been discussed by Andreo (2000). The general conclusion is that there is no unique beam-quality specifier that works satisfactorily in all possible conditions for the entire range of photon energies used in radiotherapy and all possible accelerators used in hospitals and in standards laboratories. Most recent dosimetry protocols or codes of practice, based on the calibration of ionisation chambers in terms of absorbed dose to water, use a photon beam quality specifier in terms of  $TPR_{20,10}$  (IPSM 1990; DIN 1997; IAEA 2000); the AAPM TG-51 protocol (AAPM 1999) uses PDD(10). Although both sets of data, PDD and TPR, are generally available for routine clinical use, there are more practical problems in measuring PDD(10)<sub>x</sub> than  $TPR_{20,10}$ , and errors in determining the beam quality index may have in general more serious consequences with PDD(10)<sub>x</sub> than with  $TPR_{20,10}$ . The overall impact on clinical photon-beam dosimetry resulting from the use of different photon-beam quality specifiers to select  $k_Q$  values is that they are not expected to yield a significant change (i.e. 0.5% at most and in most cases within 0.2%, c.f. Huq et al. [1999]) in the value of the absorbed dose to water in reference conditions for most clinical beams. This difference is considerably smaller than the combined uncertainty of the different factors and coefficients used in photon dosimetry and it is also less than the uncertainties quoted by standard dosimetry laboratories for calibrations in terms of absorbed dose to water (typically around 0.6%).

### D.3.2 ELECTRON-BEAM QUALITY SPECIFIERS

For more than two decades, following the early recommendations of NACP (1980), the quality of electron beams has been specified in practically all dosimetry protocols by the mean electron energy,  $\bar{E}_o$ , of the incident spectrum at the phantom surface. This specifier was derived from the measurement of the half-value depth,  $R_{50}$ , defined as the depth at which the absorbed dose has decreased to 50% of its maximum value (ICRU 1984a). An empirical relationship between  $\bar{E}_o$  and  $R_{50}$ , derived by Brahme and Svensson (1976), is

$$\bar{E}_o[\text{MeV}] = CR_{50} \quad (\text{D.9})$$

where  $C=2.33 \text{ MeV cm}^{-1}$  and  $R_{50}$  is in cm. This approximate relationship was derived from measurements on clinical accelerators in common use during the seventies. Strictly speaking, it is valid only for large field sizes (*broad beams*), energies between 5 and 30 MeV, and for  $R_{50}$  determined from depth-dose distributions measured in water with a constant source-chamber distance (i.e. equivalent to a plane-parallel beam) (Brahme and Svensson 1976; ICRU 1984a). The criterion for a *broad beam* is when the depth-dose distribution can be considered to be relatively independent of the field size, which is approximately achieved with at least 12 cm  $\times$  12 cm for energies up to about 15 MeV, and at least 20 cm  $\times$  20 cm for higher energies.

When the dose distribution has been obtained with a constant source-surface distance this relation is not valid. As an alternative, IAEA (1997b) has provided the relations

$$\bar{E}_o[\text{MeV}] = 0.818 + 1.935R_{50}^J + 0.040(R_{50}^J)^2 \quad (\text{D.10})$$

for  $R_{50}^I$  determined from a depth-ionisation curve, and

$$\bar{E}_o[\text{MeV}] = 0.656 + 2.059R_{50}^D + 0.022(R_{50}^D)^2 \quad (\text{D.11})$$

for the case of an  $R_{50}^D$  determined from a depth-dose curve.

There has been much controversy around the use of Equation D.9 and consequently new energy-range relationships between  $\bar{E}_o$  and  $R_{50}$ , based on Monte-Carlo calculations for mono-energetic electron beams, have been developed (see for instance Rogers and Bielajew 1986; Andreo 1993; Ding et al. 1996); all yield  $\bar{E}_o$  values higher than those obtained using Equation D.9. This would result in *lower* stopping-power ratios at the reference depth compared to those obtained with the  $s_{w,\text{air}}(\bar{E}_o, z)$  method and  $\bar{E}_o$  from Equation D.9. It has been shown (see IAEA 1997a) that accurate determinations of  $s_{w,\text{air}}$  based on beam quality derived from detailed Monte Carlo simulations of accelerator treatment heads yield values of  $s_{w,\text{air}}$  at the reference depth which are closer to those derived from Equation D.9 than from the use of new energy-range relationships. Further details on the energy-range relationship in connection with the selection of  $s_{w,\text{air}}$  have been given in an appendix of IAEA (1997). It should be stressed that accurate experimental determinations of the mean energy at the surface are extremely difficult. Energy determinations based on spectrometric measurements have been reported (André et al. 1985; Sorcini and Rosander 1993) in which detailed straggling distributions around the most probable energy have been obtained. However, precise measurements of the low-energy tail of a straggling distribution are inherently limited by the experimental procedure, and therefore experimental determinations of the mean energy of the spectrum will in general overestimate the true value.

The mean energy at depth,  $\bar{E}_z$  is a related quantity in widespread use in electron-beam dosimetry. An empirical relation, originally developed by Harder (1965b), for the most probable energy of an electron spectrum has been recommended by many dosimetry protocols for estimating  $\bar{E}_z$ :

$$\bar{E}_z = \bar{E}_o(1 - z/R_p) \quad (\text{D.12})$$

where  $R_p$  is the practical range defined as the depth where the tangent at the steepest point (the inflection point) on the almost straight, descending portion of the depth-dose curve meets the extrapolated bremsstrahlung background (ICRU 1984a) (see Figure 24.1). Other expressions for the calculation of  $\bar{E}_z$ , based on the continuous-slowing-down approximation, have been given in ICRU (1984a). Using the Monte Carlo method it has been shown by various authors that Equation D.12 is an acceptable approximation of the mean energy at depth only for electron beams with incident energies less than 10 MeV or for small depths at higher energies (Andreo and Brahme 1981; Ding et al. 1996; Fernandez-Varea et al. 1996). Much of the available data for electron dosimetry, which were originally given in terms of  $\bar{E}_z$  determined according to Equation D.12, have been recast to Monte-Carlo determined  $\bar{E}_z$  in recent dosimetry protocols (IPSM 1996; IAEA 1997b, 2000).

It must be emphasized that the use of  $\bar{E}_o$  and  $\bar{E}_z$  in electron-beam dosimetry is only an approximation for the practical purpose of selecting dosimetric quantities and correction factors, and is not intended to be an accurate statement of the energy parameters of an electron beam. This misunderstanding has resulted in numerous publications questioning the validity of the available relations and data, but the reality is that electron-beam dosimetry has not been improved by more than 1%–2% due to the more accurate determination of these beam parameters. Whereas the scientific interest of the new calculations is unquestionable, on the practical side the real improvements have been due to the availability of more accurate stopping-power data and perturbation correction factors included in recent dosimetry protocols, as well as the improved understanding of the physical processes involved.

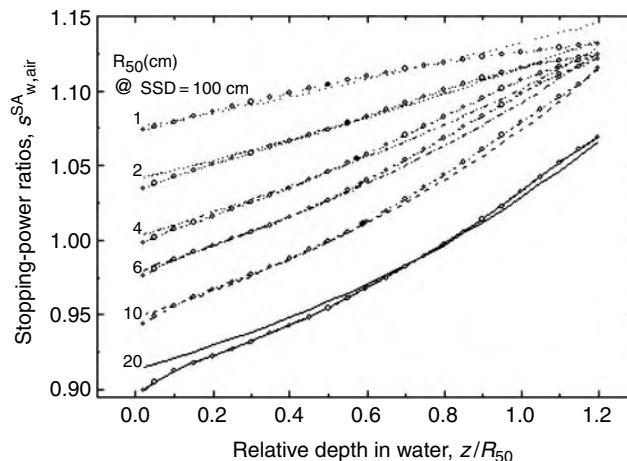

A recent suggestion for electron beam quality specification effectively puts an end to the controversy of energy-based relationships. The proposal by Burns et al. (1996) for directly using  $R_{50}$  as a beam-quality specifier for selecting stopping-power ratios (and reference depths) parallels the longstanding practice in photon dosimetry where beam qualities are expressed in terms of the penetration of the beam. The choice of  $R_{50}$  as the beam quality index is a change from the current practice of specifying beam quality in terms of the mean energy at the phantom surface; because  $\bar{E}_o$  is normally derived from  $R_{50}$ , this change in beam quality index is merely a simplification which avoids the need for a conversion to energy. The recent dosimetry protocols based on standards of absorbed dose to water, AAPM (1999) and IAEA (2000), have endorsed this approach and all data are expressed in terms of  $R_{50}$ , measured with a constant SSD of 100 cm and a field size at the phantom surface of at least 10 cm  $\times$  10 cm for  $R_{50} \leq 7$  cm ( $\bar{E}_o < 16$  MeV) and at least 20 cm  $\times$  20 cm for  $R_{50} > 7$  cm ( $\bar{E}_o > 16$  MeV). Stopping-power ratios for electron beams as a function of  $R_{50}$  are given in Figure D.13, which shows a comparison between the values in IAEA (2000) which include the effect of the clinical accelerator head on the beam quality and those in IAEA (1997b) for monoenergetic electrons, recast in terms of  $R_{50}$ .

When the half-value depth is determined from a depth-ionisation distribution in water,  $R_{50,ion}$ , the half-value of the depth-dose distribution in water  $R_{50}$  is obtained using

$$\begin{aligned} R_{50} &= 1.029R_{50,ion} - 0.06 \text{ cm } (R_{50,ion} \leq 10 \text{ cm}) \\ R_{50} &= 1.059R_{50,ion} - 0.37 \text{ cm } (R_{50,ion} > 10 \text{ cm}) \end{aligned} \quad (\text{D.13})$$

The reference depth for beam calibration is also expressed in terms of  $R_{50}$  as

$$z_{\text{ref}} = 0.6R_{50} - 0.1 \text{ cm } (R_{50} \text{ in cm}) \quad (\text{D.14})$$

**FIGURE D.13**

A comparison between the water/air stopping-power ratios,  $s_{w,air}^{SA}$ , for electron beams given in IAEA (1997) (open circles) and those recommended in IAEA (2000) (lines without symbols). The latter set of data originate from Monte Carlo simulations which included details of the accelerator heads of clinical accelerators for a variety of accelerator types (Ding et al. 1995; Burns et al. 1996). The values in IAEA (1997), for monoenergetic electrons, have been recast to electron beam quality specified in terms of  $R_{50}$  and depths scaled according to  $R_{50}$ . The filled circles correspond to  $s_{w,air}$  values at the reference depth. The agreement is very good except at large depths, which is consistent with the discussion on beam contamination. Note that an unexplained large difference occurs for an energy close to 50 MeV ( $R_{50} = 20$  cm approximately), even if in both cases the beams are practically monoenergetic. (Reproduced from Dusautoy, et al., in *The Use of Plane Parallel Ionisation Chambers in High Energy Electron and Photon Beams*. TECDOC-1173 IAEA, Vienna, 1–10, 2000.)

This depth is close to the depth of the absorbed-dose maximum  $d_{\max}$  at beam qualities  $R_{50} < 4$  cm ( $E_0 < 10$  MeV), but at higher beam qualities is greater than  $d_{\max}$ . It has been recognized that this choice of reference depth may be less convenient than that recommended in previous dosimetry protocols because, for a given accelerator, no two reference beams will have the same reference depth. However, the new depth has been shown to significantly reduce machine-to-machine variations in chamber calibration factors (c.f. Burns et al. 1996) and the accuracy gained justifies its use. For completeness, and to allow the re-casting of existing dosimetry data, an expression for the mean energy at the reference depth in terms of  $R_{50}$  has been given in IAEA (2000):

$$\bar{E}_{z_{\text{ref}}} = 0.07 + 1.027 R_{50} - 0.0048(R_{50})^2 \quad (\text{D.15})$$

which is a fit to the Monte-Carlo data used in previous IAEA Codes of Practice (IAEA 1987, 1997) at the reference depths given by Equation D.14.

## D.4 HUMIDITY CORRECTIONS FOR IONISATION CHAMBERS

It is known that the  $W_{\text{air}}/e$  value for air at 20°C, 101.325 kPa and 50% relative humidity is 0.6% lower than that for dry air at the same temperature and pressure. That is, it has a value of  $33.77 \text{ J C}^{-1}$  instead of  $33.97 \text{ J C}^{-1}$  (c.f. Figure 5.15 in ICRU 1979). Thus, for the same amount of energy available for creating charge, 0.6% more charge will be created in air at 50% relative humidity than in dry air (at 20°C and 101.325 kPa). However, the response of a cavity ionisation chamber will also depend on the degree to which the incident charged particles deposit energy, i.e. on the stopping power, which is different for ambient air than for dry air. For the secondary electrons generated in a  $^{60}\text{Co}$  beam, for example, the combined effect is that 0.3% more charge is created in air at 20°C, 101.325 kPa and 50% relative humidity than in dry air at this temperature and pressure. Thus for  $^{60}\text{Co}$ , the humidity correction factor,  $k_h$ , which corrects the ambient-air charge,  $Q_h$ , to the dry-air charge,  $Q_{\text{dry}}$ , is 0.997 (c.f. Figure 5.14 in ICRU (1979).

By definition, the air kerma is independent of air temperature, pressure, and humidity. However, all primary standards for air kerma are based on ionisation in air and the measured charge depends on these parameters. The air-kerma calibration factor,  $N_K$ , is defined as

$$N_{K,h} = \frac{K_{\text{air}}}{Q_h} \quad (\text{D.16})$$

where  $K_{\text{air}}$  is the air kerma, free in air (and independent of humidity), and  $Q_h$  is the chamber charge measured at 50% relative humidity, corrected to 20°C and to 101.325 kPa. The subscript  $h$  has been added to  $N_K$  to indicate the charge is measured at 50% relative humidity. When the  $N_K - N_{D,\text{air}}$  formalism is used, one derives the chamber factor  $N_{D,\text{air}}$ , which strictly should be written as

$$N_{D,\text{air}} = N_{K,h}(1-g)k_{\text{att}} k_m k_{\text{cel}} \frac{1}{k_h} \quad (\text{D.17})$$

This equation does two things. First, it converts  $K_{\text{air}}$  into the mean absorbed dose to the air in the cavity,  $\bar{D}_{\text{air}}$ . If, as is usual, the electron stopping power ratios and mass energy-absorption coefficient ratios entering into  $k_m$  are the dry-air values, then  $\bar{D}_{\text{air}}$  is also the dry-air value. Secondly, by including  $k_h$  in the denominator, Equation D.17 converts the air charge at 50% relative humidity  $Q_h$  to the dry-air value  $Q_{\text{dry}}$ . Clearly then the chamber

factor can be written unambiguously as  $N_{D,\text{dry air}}^*$ . The absorbed dose to water in the user's beam  $\mu$  is then derived using

$$D_{w,u} = Q_{\text{dry},u} N_{D,\text{dry air}} (s_{w,\text{dry air}})_u \mu_u \quad (\text{D.18})$$

Note here that the dry-air value  $(s_{w,\text{dry air}})_u$  must be used for consistency with the dry air electron stopping powers used in  $k_m$  in Equation D.17. Note also that the charge,  $Q_{\text{dry},u}$ , must be the dry-air value. Thus the measured value for ambient air,  $Q_{h,u}$  must be corrected for the effect of humidity. Combining Equation D.17 and Equation D.18 yields the final equation for the determination of absorbed dose to water using  $N_K$  referred to air at 50% relative humidity,

$$D_{w,u} = Q_{h,u} k_{h,u} N_{K,h} (1 - \vartheta) k_{\text{att}} k_m k_{\text{cel}} \frac{1}{k_h} (s_{w,\text{dry air}})_u \mu_u \quad (\text{D.19})$$

where all the physical constants are referred to dry air, and the humidity correction  $k_{h,u}$  in the user's beam cancels, at least to first order, with the  $^{60}\text{Co}$ - value  $k_h$ . The importance of consistency in the use (or omission) of  $k_h$  becomes obvious from this expression. The approximate cancellation of  $k_{h,u}$  and  $k_h$  in Equation D.19 is the reason why dosimetry protocols do not include a humidity correction in the expressions for  $N_{D,\text{air}}$  and  $D_{w,u}$  when  $N_K$  refers to air at 50% relative humidity. When  $N_K$  is referred to dry air, as already stated,  $k_h$  in the denominator is omitted and the remaining humidity correction to the charge measured must be applied.

## D.5 UNCERTAINTIES IN REFERENCE DOSIMETRY

Uncertainties are generally evaluated following the recommendations given by ISO (1995). They are expressed as relative standard uncertainties classified into type A and type B. The method of evaluation of a type-A standard uncertainty is by statistical analysis of a series of observations, whereas the method of evaluation of a type-B standard uncertainty is based on means other than statistical analysis of a series of observations. It is emphasized that the classification rests exclusively on the procedure used to evaluate the uncertainty, and does not relate to the origin of the uncertainty. It is therefore incorrect to identify type-A and type-B uncertainties as systematic and random uncertainties, respectively; the use of the latter terms is discouraged. Type-A and type-B uncertainties are combined in quadrature to yield the combined standard uncertainty,  $u_c$ , and an expanded uncertainty (previously called *overall uncertainty*) can be built by multiplying  $u_c$  by a factor, which must always be stated; this *coverage factor*,  $k$ , is typically in the range 2 to 3.

Whereas uncertainties of type A are evaluated in a straightforward manner as the standard deviation of the mean value, uncertainties of type B are in many cases difficult to estimate and the ISO guide has provided examples to help in the determination of this type of uncertainty. A good example of an application to dosimetry is the case when there is no specific knowledge about the possible values of a variable  $X_i$  within an interval; then one can only assume that the variable  $X_i$  lies within a uniform rectangular distribution with an expected value  $x_i$  at the midpoint of the interval and an associated type-B uncertainty,  $u_B = a/\sqrt{3}$ , where  $a$  is the half-width of the interval. This should be compared to the common *overestimation* made when, for example, two different values are available for a given quantity or correction factor and the uncertainty is taken to be equal to the difference of the values ( $u_B = 2a$ ). A common mistake made for the expanded uncertainty is to ignore the coverage factor used and

\* It should be noted that if the reference conditions for the air-kerma calibration factor include dry air (that is,  $N_{K,\text{dry}}$  is supplied rather than  $N_{K,h}$ ), then the factor  $k_h$  has already been applied at the standards laboratory and so must be removed from Equation D.17.

compare, for instance, the standard uncertainty ( $k=1$ ) for one value of a quantity, with the 95% confidence limit ( $k=2$ ) for another. It is for this reason that the comparison of uncertainty estimates becomes particularly problematic and requires extreme care; in any case, subjective type-B evaluations are always the largest source of discrepancy between different estimates.

Uncertainties in external-beam radiotherapy dosimetry can be classified into four major groups according to:

- Absolute dose determination at the reference point in a water phantom (beam calibration), performed with a calibrated ionisation chamber according to a code of practice or dosimetry protocol (see [Chapter 18](#))
- Procedures involving relative beam dosimetry (field size output dependence, influence of beam modifiers like wedges, secondary collimation and blocks, etc.), performed with any type of detector suitable for measurements in water or in a plastic phantom (see [Chapter 19](#))
- The calculation of the dose delivered to the patient (monitor units or irradiation time to deliver the prescribed dose) and its distribution, usually performed with a computerized treatment planning system (see [Chapter 23](#) and [Part F](#))
- The process of treatment delivery throughout a complete treatment, which accounts for daily variations both in patient and machine setup, patient movements and machine instability during several weeks of treatment (see [Part H](#))

The first of these uncertainties is of concern here. Following the work by Loevinger and Loftus (1977), estimates of the combined standard uncertainty of the dose distribution in the different steps of a treatment with external photon and electron beams have been given, for example, by Brahme et al. (1988). These provided the basis for the uncertainty estimates included in IAEA (1987) for the dose determination in reference conditions. Updates have been given by Andreo (1990b, 1992) and Thwaites (1994) showing that the uncertainty component due to basic physical quantities is considerably smaller than previously estimated. A comprehensive new estimate of the uncertainties in dose determination with all types of beams has been made in IAEA (2000) to which the reader is referred for details; IAEA(2000) takes into account the issues raised above on the evaluation of type-B uncertainties, as well as the cancellation of common terms in some contributing factors. These estimates are considered to be an update of the more conservative estimates given in Andreo (1992) and IAEA (1997b) for photon and electron beams, respectively.

A summary of the estimated uncertainties for the calibration of photon and electron beams using the  $N_K - N_{D,\text{air}}$  and  $N_{D,w}$  formalisms is presented in what follows; it focuses only on aspects related to measurements in the user's beam or factors selected by the user. The values provided are intended only to be a guide and refer only to some of the cases found in clinical use. Dose determinations in low-energy electron beams made in plastic phantoms, for example, are not considered even if these determinations are considered to be one of the biggest problems in dosimetry, but any uncertainty estimation would be too approximate. Because different alternatives are available for the calibration of the user's reference detector, it will be assumed here, except when stated otherwise, that calibrations are made at a secondary standards laboratory with a typical average uncertainty for the relevant calibrations\*.

\* It is of interest to mention that the uncertainty of an  $N_K$  or  $N_{D,w}$  calibration factor for the user's chamber does not change significantly (i.e. more than a linearly added 0.2% or so) if the calibration is carried out at a primary or at a secondary standards laboratory. This is because the largest part of this uncertainty is directly associated with the primary standards used to realize the relevant quantity. The dissemination of this quantity to a secondary standard and then to the user's chamber does not involve any appreciable increase of the final uncertainty after the uncertainties of the different steps at a secondary standards laboratory (mainly related to reproducing the reference conditions) have been combined in quadrature.

### D.5.1 AIR-KERMA BASED FORMALISM

For the  $N_K - N_{D,\text{air}}$  formalism, the first step made by the user is the determination of the chamber factor  $N_{D,\text{air}}$  based on an  $N_K$  calibration. Table D.1 shows the estimated relative uncertainties for the various contributing factors, as well as the relative combined standard uncertainty for  $N_{D,\text{air}}$  which is close to 1% and thus approximately double that of the uncertainty in the  $N_K$  calibration factor. The largest contribution is due to the factor  $k_m$ , which is mainly caused by the uncertainty of the stopping-power ratios and of the approximate theoretical model used in the calculation of  $k_m$ . No attempt is made to include the contribution due to assuming generic values of  $k_m$  and  $k_{\text{att}}$  for all chambers of a specific type by a given manufacturer, as information on manufacturing tolerances (dimensions and thicknesses) is in general rather scarce.

At this point it is of interest to refer to the uncertainty of stopping-power ratios, which also enters in later steps of the dose-determination process. This estimate has been the subject of numerous studies and controversy. Uncertainties in the calculated stopping-power ratios are almost entirely type-B uncertainties because type-A uncertainties can be easily reduced to 0.1% or less, usually by a Monte-Carlo calculation. The uncertainty quoted by ICRU (1984b) for the basic electron stopping-power data is 1% to 2% at the level of two standard deviations, but it is difficult to estimate the uncertainty in the *ratios* of stopping powers, for which some components cancel out due to correlation. At the level of one standard deviation, Berger et al. (1975) estimated an uncertainty in the *ratios* of 0.6%, and more recently Berger (1988) reduced this to 0.25% to 0.5%. Andreo and Fransson (1989, 1992) used statistical procedures to argue that the uncertainty of stopping-power ratios is 0.4% to 0.6%. Any comparison among the estimations given in different references becomes even more problematic because uncertainties are usually given using different probability coverage factors, and these are not always clearly stated. Changes in the electron stopping-power data in the past typically led to changes in the stopping-power ratios of about the same amount, and the entire variation has sometimes been used as an estimate of the uncertainty (see the comment given above on the overestimation of type B uncertainties). Table D.2 reproduces a survey of estimations made by different authors which provides support to the figures used in this section.

The second step to be considered is that of the measurements carried out by the user in the clinical beam, and these estimates are the same for either type of formalism, i.e.  $N_{D,\text{air}}$  or  $N_{D,w}$ . The estimations can be considered to be typical when modern and reliable equipment is used. The components in this step, in addition to the long-term stability of the user's dosimeter, are

**TABLE D.1**

Estimated Relative Standard Uncertainty of the Chamber Factor  $N_{D,\text{air}}$  and of the Various Factors Entering in Its Definition

Factors in $N_{D,\text{air}}$	Standard Uncertainty	Factors in $k_m$	Standard Uncertainty
$N_k$	0.4%	$\alpha$	0.1%
$g$	0.02%	$s_{\text{med},\text{air}}^a$	0.5%
$k_m$	0.7%	$(\mu_{\text{en}}/\rho)_{\text{med},\text{air}}$	0.2%
$k_{\text{att}}$	0.2%	$k_m$ empirical model	0.4%
Combined uncertainty in $N_{D,\text{air}}$	0.8%		

<sup>a</sup> med refers to the wall and build-up cap of the ionisation chamber.

**TABLE D.2**

Survey of Estimates of the Uncertainties of Stopping-Power Ratios for Photon and Electron Beam Dosimetry

Reference	Uncertainty Quoted as	Standard Combined Uncertainty, $u_c$
ICRU-14 (1969)	2% (95% confidence limit)	1%
Berger et al. (1975)	0.55% (1std dev)	0.55%
Loevinger and Loftus (1977)	1.5% (95% confidence limit)	0.55% <sup>a</sup>
ICRU-35 (1984a)	1.5% (3 std dev)	0.5%
Boutillon and Perroche (1987, 1991)		0.2%–0.3%
Berger (1988)	0.5%–1% (2 std dev)	0.25%–0.5%
Brahme et al. (1988)		1.5%
Andreо (1990b)		0.4%–0.6%
Rogers (1991)		1% or larger
ICRU-37 (1984b)	1%–2% (2 std dev)	0.5%–1%

The middle column shows the statement of uncertainties quoted or inferred from the corresponding reference. The uncertainties given in the last row are those quoted by ICRU report 37 (1984b) for the collision stopping-powers of electrons above 10 keV, rather than for stopping-power ratios. The values in the last column should be considered as standard combined uncertainties,  $u_c$ , according to ISO (1993).

<sup>a</sup> The original statement of 1.5% (95% confidence limit) in this reference, or 0.75% (1 std dev), included also a component resulting from the uncertainty in the specification of the quality of the beam, approximately equal to 0.5% (1 std dev), which has been subtracted in quadrature here.

Source: Adapted from Andreо, P., The status of high-energy photon and electron beam dosimetry five years after the publication of the IAEA code of practice in the Nordic countries, *Acta Oncologica*, 32, 483–500, 1993.

the establishment of the experimental set-up in the clinical conditions, the uncertainty of the readings of the dosimeter relative to a timer or beam monitor, and the necessary corrections for the *influence quantities*. The latter include polarity effect, temperature and pressure, humidity, stem effect, and recombination. The combined uncertainty varies with the type of beam and ionisation chamber, being typically between 0.6% for the use of a cylindrical chamber in a  $^{60}\text{Co}$  beam and 1% for a plane-parallel chamber in a low-energy electron beam. For completeness, the details on these uncertainty values have been included in step 2 of Tables D.3 and D.4, which summarize the uncertainty estimates for the entire beam calibration process performed with the two formalisms.

The third step in the uncertainty estimate of the dose determination corresponds to the values of quantities and perturbation correction factors selected by the user for the dosimeter-beam combination. This is without any doubt the most controversial step and here type-B uncertainties play the major role. Especially for the perturbation correction factors, in some cases there exist experimental values determined by multiple authors without a clear uncertainty estimate. In others these are calculated using very approximate empirical equations; yet others are simply assumed based on some theory, etc. Table D.3, step 3, gives the most up-to-date estimates available for the factors entering into the  $N_{\text{K}}-N_{\text{D},\text{air}}$  formalism. In the case of a plane-parallel chamber cross-calibrated in a high-energy electron beam against a cylindrical chamber (calibrated in a  $^{60}\text{Co}$  beam), due to the uncertainties of the different perturbation factors for cylindrical and plane-parallel chambers, the uncertainty in the  $N_{\text{D},\text{air}}$  factor (step 1) increases considerably with respect to the  $N_{\text{D},\text{air}}$  of the reference cylindrical chamber. Quoting every single reference used for the uncertainty estimates of all the factors in step 3 would result in a considerable list and the interested reader is referred to IAEA (2000) and references therein for details. The combined uncertainty of the product of all quantities and perturbation correction factors ranges from 0.8% for a cylindrical chamber in a  $^{60}\text{Co}$  beam to 1.0% for a cylindrical chamber in an electron beam.

When the three steps are combined, the relative standard uncertainty in the determination of the absorbed dose to water at the reference depth in  $^{60}\text{Co}$  gamma and high-energy photon

**TABLE D.3**

Combined uncertainty in $D_w$	<b>1.3</b>	<b>1.5</b>	<b>1.6</b>	<b>1.9</b>

<sup>a</sup> The plane-parallel chamber is cross-calibrated in a high-energy electron beam against a cylindrical chamber calibrated in a  $^{60}\text{Co}$  beam.

and electron beams using the  $N_K - N_{D,\text{air}}$  formalism ranges between 1.3% and 1.9% for the cases discussed here. Note that these values are considerably smaller than the figures given for example in IAEA (1987), which vary between 2.5% and 3.7%. As already mentioned, the changes are justified not only in terms of the more accurate values for some physical quantities and perturbation correction factors available today, and more up-to-date uncertainty estimates, but also in the way in which many of the uncertainty components have been estimated and combined. It is emphasized that many of the new values used in this analysis are not included in any of the  $N_K - N_{D,\text{air}}$  protocols currently in use.

### D.5.2 ABSORBED-DOSE-TO-WATER FORMALISM

For the  $N_{D,w}$  formalism there are multiple options available for the calibration of the user's reference dosimeter, and for simplicity only the most common cases of cylindrical chambers calibrated in  $^{60}\text{Co}$  beams and plane-parallel chambers cross-calibrated in high-energy electrons will be included in the discussion.

For the first step, the  $N_{D,w}$  calibration factor, typical uncertainties are around 0.6% for cylindrical chambers and 1.4% for cross-calibrated plane-parallel chambers. Uncertainties associated with the measurements in the user's beam, the second step, are identical to those quoted above for the  $N_K - N_{D,\text{air}}$  formalism. The only component in step 3 is that of the beam-quality correction factor,  $k_Q$ , which is not relevant in the case of  $^{60}\text{Co}$  beams. It has already been mentioned that the most common approach available today is based on the use of

**TABLE D.4**

Estimated Relative Standard Uncertainty (%) in the Determination of Absorbed Dose to Water at the Reference Depth in  $^{60}\text{Co}$  and High-Energy Photon and Electron Beams Using the  $N_{D,w}$  Formalism, Based on a Cylindrical Chamber Calibration in a  $^{60}\text{Co}$  Beam

Type of Ionisation Chamber	$^{60}\text{Co}$ Beams	Megavoltage Photon Beams	Electrons with $R_{50} > 4 \text{ g cm}^{-2}$ ( $\bar{E}_o > 10 \text{ MeV}$ )	Electron Beams of Any Energy
	Cylindrical			Plane-Parallel <sup>a</sup>
<i>Step 1: User chamber calibration factor</i>				
Combined uncertainty in $N_{D,w}$	0.6	0.6	0.6	1.4
<i>Step 2: User beam measurements</i>				
Long-term stability of user dosimeter	0.3	0.3	0.3	0.4
Establishment of reference conditions	0.5	0.4	0.4	0.6
Dosimeter reading relative to timer or beam monitor	0.1	0.6	0.6	0.6
Correction for influence quantities	0.3	0.4	0.4	0.5
Combined uncertainty in dosimeter reading	0.6	0.9	0.9	1.1
<i>Step 3: Beam quality correction</i>				
3a $k_{Q,Q_o}$ (calculated)		0.9	1.1	0.6 <sup>b</sup>
3b $k_{Q,Q_o}$ (measured at a standards laboratory)		0.7	0.7	0.8
Combined uncertainty in $D_w$ (calculated $k_{Q,Q_o}$ )	<b>0.9</b>	<b>1.4</b>	<b>1.6</b>	<b>1.9</b>
Combined uncertainty in $D_w$ (measured $k_{Q,Q_o}$ )	<b>0.9</b>	<b>1.3</b>	<b>1.3</b>	<b>1.9</b>

<sup>a</sup> The plane-parallel chamber is cross-calibrated in a high-energy electron beam against a cylindrical chamber calibrated in a  $^{60}\text{Co}$  beam. If the plane-parallel chamber is calibrated directly in an electron beam at a standards laboratory, then  $u_c(N_{D,w})=0.7\%$ , yielding  $u_c(D_w)=1.4\%$ .

<sup>b</sup> The  $k_{Q,Q_o}$  factor is in this case calculated for a reference electron beam, whereas for the other two cases the reference beam is  $^{60}\text{Co}$ . Using  $^{60}\text{Co}$  as reference quality for the calculation of  $k_{Q,Q_o}$  for plane-parallel chambers would increase its uncertainty up to 1.7%.

theoretically determined  $k_Q$  factors, which include ratios, at the user's quality  $Q$  and at  $^{60}\text{Co}$  of water/air stopping-power ratios,  $s_{w,\text{air}}$ , the mean energy expended in air per ion pair formed,  $W_{\text{air}}$ , and the perturbation factors  $p_Q$ . The uncertainty of calculated  $k_Q$  factors is, therefore, obtained by a combination of the uncertainties of these quantities and perturbation factors given in Table D.3, but correlations between the ratios of various parameters must be taken into account. The estimates made in IAEA (2000), which should be consulted for the details, are reproduced in Table D.4, step 3. The uncertainties for a cylindrical chamber are 0.9% for megavoltage photons and 1.1% for high-energy electron beams; for a plane-parallel chamber the uncertainty with reference to an electron beam is 0.6% (this value increases to 1.7% if  $^{60}\text{Co}$  is used as reference). These uncertainties are larger than the corresponding values in step 3 for the  $N_K - N_{D,\text{air}}$  case, but they are lower than that which would result from a simple combination in quadrature of the different ratios.

The relative standard uncertainty in the determination of the absorbed dose to water at the reference depth in  $^{60}\text{Co}$  and high-energy photon and electron beams using the  $N_{D,w}$  formalism, based on a cylindrical chamber calibrated in  $^{60}\text{Co}$  and a plane-parallel chamber cross-calibrated in high-energy electrons, is, upon the combination of the uncertainties in the different steps, smaller for photon beams and about the same for electrons compared to the corresponding values for the  $N_K - N_{D,\text{air}}$  formalism, ranging between 0.9% for  $^{60}\text{Co}$  and 1.9% for low-energy electron beams. Note that, for  $^{60}\text{Co}$  beams in particular, it is the first

time that the uncertainty in dose determination has been brought below 1%. It is also worth pointing out that, even if the uncertainty for low-energy electrons is about the same as for the  $N_K - N_{D,\text{air}}$  formalism, this value would reduce to 1.4% if the plane-parallel chamber were calibrated directly in an electron beam (see footnote *a* in the table). The case when  $k_Q$  factors are directly measured for the user's chamber in high-energy photon and electron beams at standards laboratories has also been included in [Table D.4](#) for completeness (see step 3b). In the case of electron beams this is a situation of reduced application at present because of the limited availability of such experimental determinations (McEwen et al. 1998).

## INTRODUCTION

The equipment used to deliver the correct amount of dose to the patient has been introduced in [Part C](#). The methods by which absolute dose and relative dose distributions are measured have been dealt with in [Part D](#). It is then necessary to devise a methodology where these measurements are used to make accurate predictions of the dose distribution delivered to the patients, taking into account the beam characteristics as well as the patient characteristics.

The main issues related to this methodology are addressed in [Chapter 20](#), where it is demonstrated that a detailed knowledge of the beam properties is required. The characteristics of photon beams adapted to clinical needs and generated either from kilovoltage or from megavoltage equipment (consisting both of cobalt units and linear accelerators) are presented in [Chapter 21](#) and [Chapter 22](#) respectively. The quantities and the methods used to calculate the dose using a spreadsheet or pocket calculator (often referred to as *manual calculations*) at a specified depth for a patient treated with photon beams are presented in [Chapter 23](#). Finally [Chapter 24](#) covers the case of clinical electron beams.

## 20.1 CONTROL OF DOSE DELIVERY

Whatever the method employed for a particular type of equipment, there is a need to convert an elapsed time or a reading on a dose meter into the absolute dose delivered. For modern x-ray treatment machines, it is usual to have an ionisation chamber situated in the beam close to the x-ray source (see [Section 11.7.3.1](#)). This produces a reading proportional to the dose delivered by the beam. By its nature, the reading will generally have a relationship to the dose delivered that is dependent on various beam parameters. For this reason, the term *Monitor Unit* (MU) has been introduced. In principle, it is not necessary that there is a one-to-one correspondence between monitor units and dose, but it is usual to calibrate the machine

so that a MU corresponds to 1 cGy at a specified point in a phantom and with a specified field size.

### 20.1.1 KILOVOLTAGE X-RAY UNITS

The dose rate delivered by a kilovoltage x-ray unit is likely to be fairly constant for a given combination of kilovoltage and filtration, but will change significantly if either the kilovoltage or the filter is changed. Older units were controlled by a timer, and the absolute dose could then be calculated using a dose rate chart. Modern units mostly have a transmission ionisation chamber. The relationship between the reading of this chamber and the dose delivered to the patient will depend on the applicator in use (especially the distance from the source to the end of the applicator) and the quality of the beam. It is usual to choose a standard applicator such as a 10 cm circle and to relate the doses for other applicators to this. Because of the rapid fall off in dose with depth, it is usually the dose at the surface of the phantom that is used for reference; although, the method of calibration may involve dose measurements in air or at a depth in the phantom (see [Section 18.6](#)).

### 20.1.2 LINEAR ACCELERATORS

For linear accelerators, the standard practice is to choose a 10 cm square field, but the position of the specified point and the set-up of the phantom can be different. The most common definitions of the MU are

- (a) The monitor chamber reads 1 MU when 1 cGy is delivered to a point at the depth of dose maximum in a water equivalent phantom whose surface is at the isocentre of the machine (i.e. usually at 100 cm from the source) with a field size at the surface of 10 cm × 10 cm.
- (b) The monitor chamber reads 1 MU when 1 cGy is delivered to a point at a given depth in the phantom with the surface of the phantom positioned so that the specified point is at the isocentre of the machine and the field size is 10 cm × 10 cm at the isocentre.

Whether definition (a) or definition (b) is used in a particular department is largely historical, but definition (a) is most appropriate for percentage depth dose based calculations and method (b) for tissue phantom based calculations (see [Section 23.3](#)). Many linear accelerators can be used at different energies, and the treatment beam can be either photons or electrons. It is usually possible to establish a different monitor chamber calibration factor for each energy and modality so that the relationship between the monitor unit and the absolute dose in the standard conditions is not dependent on modality or energy.

The calibration procedure must be carefully performed following one of the protocols described in [Chapter 18](#). It is essential to maintain the stability of the calibration throughout the clinical use of the accelerator. Therefore, the stability of the monitor response must be ensured by setting up a Quality Assurance programme that guarantees that there is no drift beyond acceptable limits (see [Section 38.8](#)).

### 20.1.3 COBALT UNITS

Cobalt teletherapy units are usually controlled by a timer. Calibration of the unit involves measuring the dose rate with a standard setup as for linear accelerators. The mechanical nature of the source transfer mechanism means that the dose delivered in one minute will generally be greater than the dose rate measured with the source fully exposed. Timers are often set to measure the time for which the source is fully exposed, and a timer end correction will be necessary to compensate for the dose delivered while the source is in transit at the beginning

and end of the exposure. Unlike for kilovoltage equipment or linear accelerators, there is no risk that the dose rate fluctuates during irradiation. Provided that the timer is accurate and that an appropriate correction is performed for the decay of the source activity, the calibration is accurately maintained over a long period of time with a minimal quality assurance program. Apart from this singularity, the treatment time is not conceptually different from the MU, and in what follows, no distinction will be drawn. The term *dose rate* (or sometimes, simply, *dose*) will be used to refer to the absorbed dose at a specific point in specific conditions for one monitor unit. *Absolute dose rate* will be used when it is expressed, for instance, in cGy/MU, or *relative dose rate* will be used when it is expressed as a percentage and normalized to an arbitrary reference point in some reference conditions.

---

## 20.2 RELATIVE DOSE DISTRIBUTIONS

The methods for measuring relative dose distributions, as part of the commissioning of a new treatment machine or as a supplementary procedure for a machine already in use, have been described in [Chapter 19](#). In the present chapter the emphasis is on the link between absolute and relative dose measurements and some factors that are necessary to an understanding of the application of clinical beams are considered. Detailed definitions and relationships between the quantities briefly mentioned here will be found in [Chapter 23](#).

Having established the relationship between the monitor unit and the absolute dose delivered to a reference point under specific conditions, doses at all other points and in all other circumstances can be calculated by making measurements relative to this standard situation. However, the range of different situations for patient treatment is very wide, and it is necessary to establish a system of measurements that will allow the relationship between absolute dose and monitor units to be calculated for any treatment situation. For a given beam energy, the dose delivered to the patient will be affected by:

- The distance of the skin surface from the source of radiation
- The depth inside the patient
- The field size and shape (and the method of shaping)
- The distance of the point of interest from the centre of the beam
- The composition of the patient tissue and, particularly, its density
- Oblique incidence of the beam on the skin surface
- Any accessories used such as wedge filters and other beam attenuators.

The system of measurements must allow all these factors to be considered. The details of the methods used to apply the necessary corrections depend on the quality and type of radiation being used, but some of the broad principles are common to all radiation beams. Allowance for the effect of all these factors can be carried out with a pocket calculator or a spreadsheet based on these broad principles, although some of the calculations are more appropriately carried out with a treatment planning computer. These basic principles will be considered in the following sections.

### 20.2.1 VARIATION OF DOSE WITH DISTANCE FROM THE SOURCE

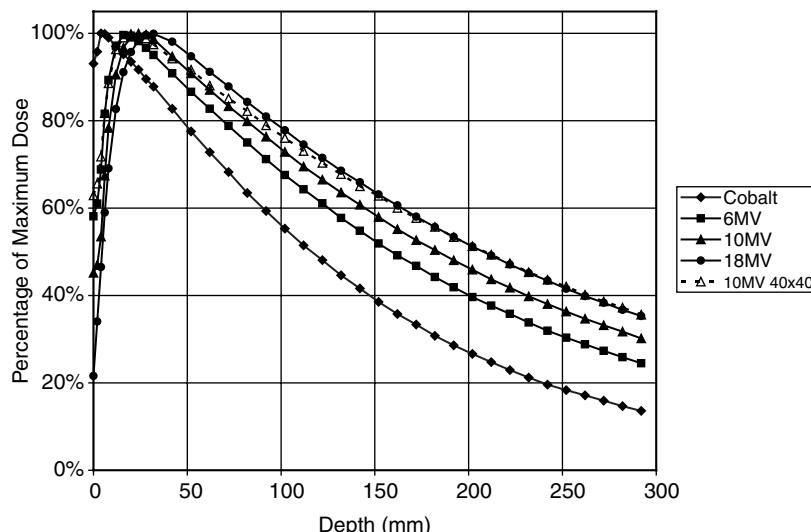

Unattenuated dose rates at a distance from a point source of radiation vary as the inverse square of the distance from the source. This is a direct consequence of the fact that if radiation is emitted isotropically from a point source, the total number of particles crossing the surface of a sphere of radius  $r$  centred on the source, is independent of  $r$ . Therefore the particle fluence at a distance  $r$ , obtained by dividing this number of particles by the area of the surface of the sphere,

varies proportionally to  $r^{-2}$ . Since the dose is proportional to the particle fluence (see [Section 6.4](#) and [Section 6.6](#)), it varies also as a function of the inverse square of  $r$ . This variation is generally referred to as the *inverse square law*. It is useful to bear this in mind when determining if the inverse square law is likely to be obeyed in particular circumstances. For example, in situations where a beam is scattered, the inverse square law will not be followed exactly in proportion to the amount of scatter. It may also be deduced that on the beam axis of a radiation treatment unit, the dose rate fall-off in air will follow closely the inverse square law if the energy is such that the attenuation and scattering in air may be neglected (in practice, photon energies above some tens of kV and electron energies above some MeV) and if the distance from the scattering materials (treatment head, room walls, and floor) is large enough.

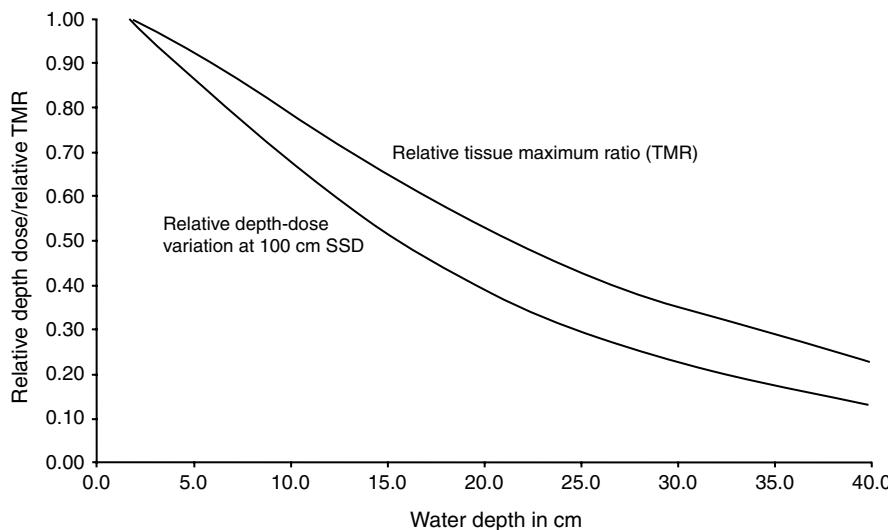

### 20.2.2 VARIATION OF DOSE WITH DEPTH WITHIN THE PATIENT

In a solid medium, the effect of the inverse square law will be added to that of the absorption and scattering of radiation in the material. For a polyenergetic photon beam the primary component would be exponentially attenuated (see [Section 4.4.1](#)) if it were not for the fact that the low energy components of the beam will be attenuated more than the high energy components, making the primary beam progressively more penetrating. However, the scattered radiation is not lost to the beam, and so with increasing depth, there is an increasing scatter contribution. Examples of depth-dose curves for photon beams are shown in Figure 20.1. Depth-dose curves are easily measured in a water tank with a remotely controlled detector (see [Section 19.1.3](#)). Using the depth dose curve, it is easy to calculate the dose at a depth if the dose at the normalisation point is known. However, with megavoltage equipment where the source-skin distance (SSD) is not fixed, it is necessary to make a correction to the depth dose curve measured at another SSD. An alternative approach is to measure the variation of the Tissue Maximum Ratio (TMR) or Tissue Phantom Ratio (TPR) (see [Section 23.2.1.6](#)) with depth. The TMR or TPR are measured by keeping the source to detector distance constant and varying the depth of the detector in the phantom (by adding water).

Because the TMR and TPR are almost independent of SSD, they effectively allow a separation of the effect of distance from the source from the effect of attenuation and scatter. [Figure 20.2](#) shows the variation of TMR with depth. The difference between the

**FIGURE 20.1**  
Percentage depth dose curves in water for a cobalt-60 beam, 6 MV, 10 MV, and 25 MV x-ray beams for a 10 cm square field. Also shown is the depth dose curve for a 10 MV beam with a 40 cm square field.

**FIGURE 20.2**

Comparison of the variation of percentage depth dose ( $\times 0.01$ ), at 100 cm SSD and tissue maximum ratio with depth for a 6 MV x-ray beam with a 10 cm square field. Graph drawn from data given in British Journal of Radiology, Supplement 25. (From BIR, Br. J. Radiol., Suppl. 25, 1996.)

depth-dose curve and the depth TMR curve shows the contribution of the inverse square law to the depth dose curve. The details of calculations using TMRs will be dealt with in Chapter 23. In practice, making direct measurements of TMR or TPR in water is not easy because the water level must be accurately controlled (i.e. using a pump and a depth sensor) while the detector is kept in fixed position. It is much easier to change the position of the detector by moving it with a computer controlled system. Alternatively, TMR or TPR can be measured in solid phantoms. On the other hand, in spite of their outstanding advantages for dose calculation, TMR or TPR do not exactly reflect the depth dose variation that occurs within the patient. For these reasons, it is common practice to measure depth-dose curves at a fixed SSD and to use the formalism in Chapter 23 to calculate the TMR or TPR.

### 20.2.3 EFFECT OF FIELD SIZE AND SHAPE

As the field size increases, the amount of scatter generated within the patient and reaching a point on the central axis of the beam increases, and consequently, the dose increases, especially at larger depths. In addition, the amount of radiation reaching the patient from the machine head components also increases because of scatter from the collimators. With photon beams from linear accelerators, an additional (and more significant) factor comes into play; more of the radiation scattered out of the primary beam in the flattening filter is able to reach the patient (Chaney et al. 1994). Where customized shielding is used to shape the radiation beam, this will have a different effect depending on where the shielding is placed in relation to the flattening filter. For this reason, it is usual for photon beams to separate the effect of field size into phantom scatter and collimator scatter factors. The collimator scatter factor may be measured using relative measurements made in air. The phantom scatter is indirectly measured by measuring the variation in dose per monitor unit for different field sizes to obtain an output factor and using the relationship

$$\text{Output factor} = \text{Collimator Scatter Factor} \times \text{Phantom Scatter Factor}$$

When the TMR/TPR approach is used, the output factor is often measured at a depth beyond the depth of dose maximum. This depth is taken as the *reference depth*. Even when depth dose-

based calculation methods are used, it is better to make the relative output measurements at a depth and make appropriate corrections to calculate the output factor at the depth of dose maximum in air or in a Mini-phantom (see also [Section 19.2.5](#) and [Chapter 23](#)).

#### 20.2.4 EFFECT OF DISTANCE FROM THE CENTRAL AXIS

As the distance of the point of interest from the central axis of the beam increases, the dose rate compared to that on the central axis will change. The dose rate is usually (but not always) highest on the central axis. In order to account for this in dose calculations, an *off-axis factor*, defined as the ratio of the dose at the appropriate distance from the axis to the dose on the central axis at the same depth, can be measured. The off-axis dose distributions for megavoltage photon beams are discussed in [Section 22.3.3](#). Further details of the use of off-axis factors in dose calculation are presented in [Section 23.2.1.15](#), and examples of off-axis curves (also called *dose profiles*) are shown in [Figure 23.9](#). For a given field size, dose profiles are essentially determined by the depth and the distance from the source. Because the beam diverges from a small source, the value of the off-axis factor is found to vary least if a fan-beam geometry is assumed. This means that the off-axis factors along a ray line directed back to the source are approximately constant. This forms the basis of the Bentley–Milan model of a photon radiation beam that is described in more detail in [Section 26.2.1.1](#).

#### 20.2.5 COMPOSITION OF PATIENT TISSUE

The effect of the composition of patient tissue depends on the nature and energy of the beam. At orthovoltage energies, the principal method of interaction with tissue is through the photoelectric effect that has a dependence on the atomic number of the tissue according to  $Z^4$ , and this gives rise to differential absorption in bone (see [Section 4.3.1](#)). In megavoltage beams, the effect is less because it is primarily the density of the tissue that affects the amount of attenuation. However, lung tissue has a major effect on the attenuation of the beam, and methods of calculating the effect of this are needed. The effect of inhomogeneities is even larger for electron beams due to their influence on the electron scattering processes. Only a rough calculation is possible with pocket calculator-based methods, and more sophisticated computer calculations are required (see Part F).

---

### 20.3 REPRESENTATION OF DOSE DISTRIBUTIONS: ISODOSE CURVES AND SURFACES

Although depth-dose curves and beam profiles can be used to calculate the dose at any point in the beam, it is useful to have a representation of the effect of the radiation beam as a whole. For this purpose, it is helpful to represent dose distributions in the form of isodose curves. In a given plane, the isodose curves (or, simply, *isodoses*) represent lines of equal dose rather like the isobars on a weather map. The isodose lines can be relative isodoses that are normalised to some point (e.g. the point of maximum dose on the beam axis) within the plane of interest, or they can be absolute isodoses that are lines representing a particular dose value for a given machine setting. Examples of isodose curves are shown in [Figure 21.8](#) for a kilovoltage x-ray machine, in [Figure 22.11](#) for a cobalt machine and a linear accelerator and in [Figure 24.7](#) for electron beams. In three dimensions, isodose lines become isodose surfaces.

### 21.1 INTRODUCTION

Kilovoltage x-rays were the first form of external beam therapy to be used. Because of their inadequate penetrative qualities it was necessary to use multiple overlapping beams to deliver a high dose to the tumour while keeping within tissue tolerance. At kilovoltage energies the photoelectric effect makes a significant contribution to the absorbed dose especially in higher atomic number materials such as bone. The soft tissue within trabecular bone receives an enhanced dose (see [Section 6.7.3](#)), which is normally undesirable. Kilovoltage x-rays are used mostly for superficial lesions and for palliative treatments. In modern radiotherapy many superficial lesions could also be treated with electrons. However there are some

disadvantages in using electrons for superficial lesions. For instance, with low energy electrons it is difficult to obtain an accurate and uniform dose for small fields or for an irregular patient surface (see [Chapter 24](#) and [Chapter 34](#)) and they may not be ideal for eye treatments (see [Section 21.5](#)).

---

## 21.2 BEAM QUALITY

### 21.2.1 ENERGY SPECTRUM AND ROLE OF FILTRATION

The penetrative quality of an x-ray beam will depend on the peak kilovoltage used to generate it and the filtration applied. As discussed in [Section 10.2.2](#), the spectrum of an x-ray beam is the bremsstrahlung spectrum arising from electrons used to produce it. The resulting x-ray energies typically range from the energy of the electrons reaching the anode down to a minimum energy determined by the filtration of the x-ray tube. X-ray tubes can be either glass walled with an equivalent inherent filtration of between 0.6 mm and 1 mm of aluminium or have a beryllium window between 1 mm and 2 mm thick. The mean energy of the beam is typically one third of the maximum x-ray energy. A typical medium energy spectrum is shown in [Figure 21.1](#).

The energy fluence shown in [Figure 21.1](#) must be multiplied by the mass energy-transfer coefficient in air to obtain the resulting air kerma in order to approximate the variation with energy of the dose that will be delivered. When this is done the spectrum shown in [Figure 21.2](#) is obtained. Without filtration a very high dose would be delivered to the skin with very little penetration and the lower energies must be filtered out in order to produce a more penetrating beam\*. Filtration aims to reduce the low energy radiation while allowing high energy radiation to pass through. This result can be achieved because the photoelectric effect has a higher cross section for low energies than for high energies. As can be seen from the two figures very different penetration characteristics can be expected depending on the combination of generating potential and filtration. The effect on the depth-dose curve is shown in [Figure 21.3](#).

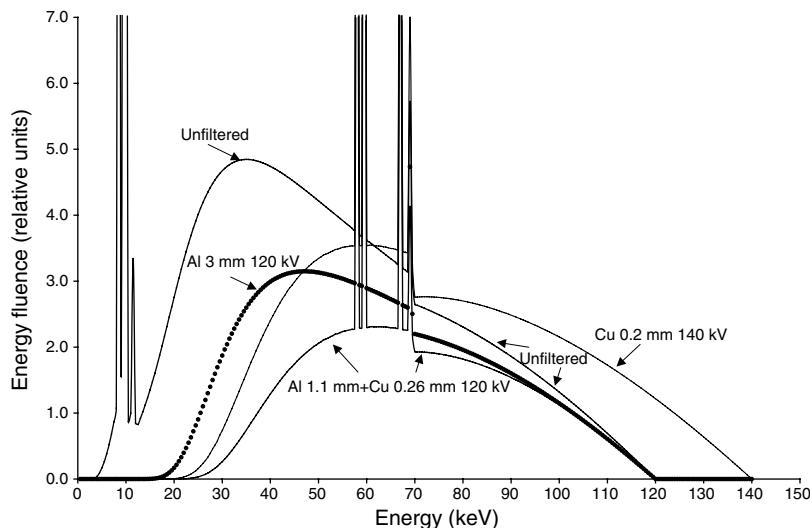

For energies up to 100 kV a simple aluminium filter is used. At higher energies, to maximise the photoelectric cross section, a high atomic number material may need to be used. However, there is then the problem that the attenuation of the material will be sharply reduced below the K-absorption edge, and additionally the photoelectric effect will produce radiation at this characteristic energy. For this reason, at higher energies it is common to use a combination of metals so that the lower atomic number material will remove the radiation below the K-absorption edge. A much-used combination is the Thoraeus filter in which tin, copper and aluminium are combined (the K-absorption edge for tin occurring at 29 keV, while that of copper is at 9 keV). The original Thoraeus filter was composed of 0.4 mm of tin, 0.25 mm of copper and 1.0 mm of aluminium, but different combinations of these materials have been used since to produce different spectra. Care must be taken to ensure that the correct filter is in place. Ideally machines should be used for one beam quality only, but where multiple energies are used, a system of filter interlocks must be provided to ensure that the appropriate filter is selected.

### 21.2.2 HALF VALUE LAYER

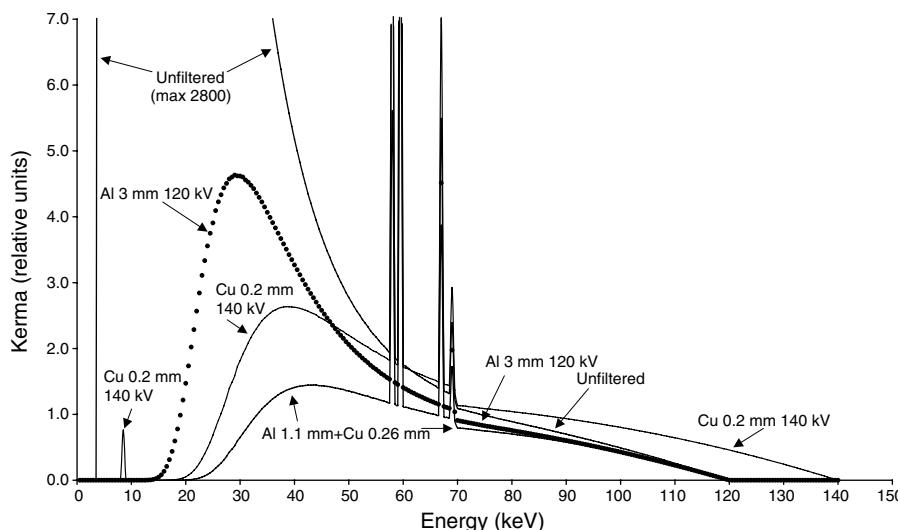

By a judicious choice of filter it is possible for beams of different penetrating properties to be produced by a single generating voltage. It is not practicable to measure the full spectrum on

---

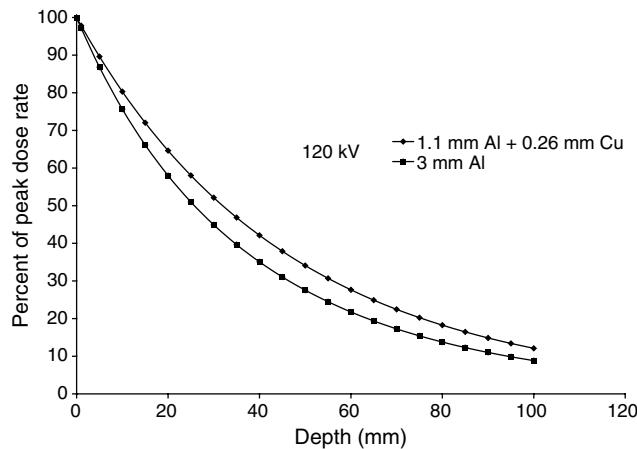

\* With very low energy x-rays an undesirably high surface dose can be delivered and this can be rectified by the use of a thin sheet of Mylar film which absorbs the lowest energy x-rays.

**FIGURE 21.1**

Spectra for a superficial x-ray unit with different combinations of filtration and generating potential. The *unfiltered* curve shows the output with only the inherent filtration of the x-ray tube for which the mean energy is 32 keV. With 3 mm of aluminium filtration the mean energy of the beam is increased to 54 keV. A more penetrating beam is obtained with 1.1 mm of aluminium and 0.26 mm of copper, for which the mean energy is 62 keV. Increasing the tube potential to 140 kV with 0.2 mm of copper reduces the penetrative quality in spite of the increase in mean energy to 65 keV. Spectra produced and mean energies calculated using the spectrum generator contained in IPEM Report 78. (IPEM, Scientific Report Series No. 78, *Catalogue of diagnostic x-ray and other spectra*, IPEM, York, 1997.)

**FIGURE 21.2**

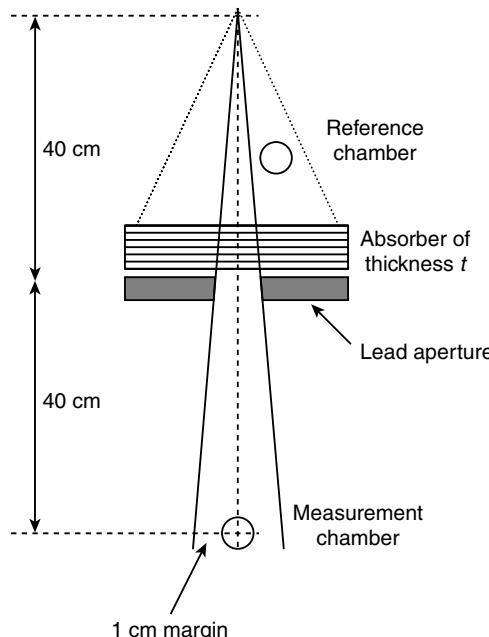

Air Kerma spectra for a superficial x-ray unit with different combinations of filtration and generating potential. These results are derived from those in Figure 20.1 by applying the air energy-transfer correction factor which decreases rapidly as the photon energy increases. The unfiltered curve goes off scale illustrating the dangers of treating without a filter. Note the contribution from the K-absorption edge of copper at around 9 keV that would be part of the beam if no aluminium were used in the filter. Spectra produced and mean energies calculated using the spectrum generator contained in IPEM Report 78. (IPEM, Scientific Report Series No. 78, *Catalogue of diagnostic x-ray and other spectra*, IPEM, York, 1997.)

**FIGURE 21.3**

Depth dose curves for kV x-ray beams generated with 120 kV, but with different filtration.

a routine basis, and therefore some method must be found to define the penetrative quality of the beam in an unambiguous way. This is done by measuring the attenuation of the beam by a metallic absorber in scatter-free conditions (see Figure 21.4). In such narrow-beam conditions, if the radiation is monoenergetic the attenuation will be exponential so that, for an absorber thickness  $t$  the dosimeter reading  $I$  will be related to the reading without the attenuator  $I_o$  by the equation:

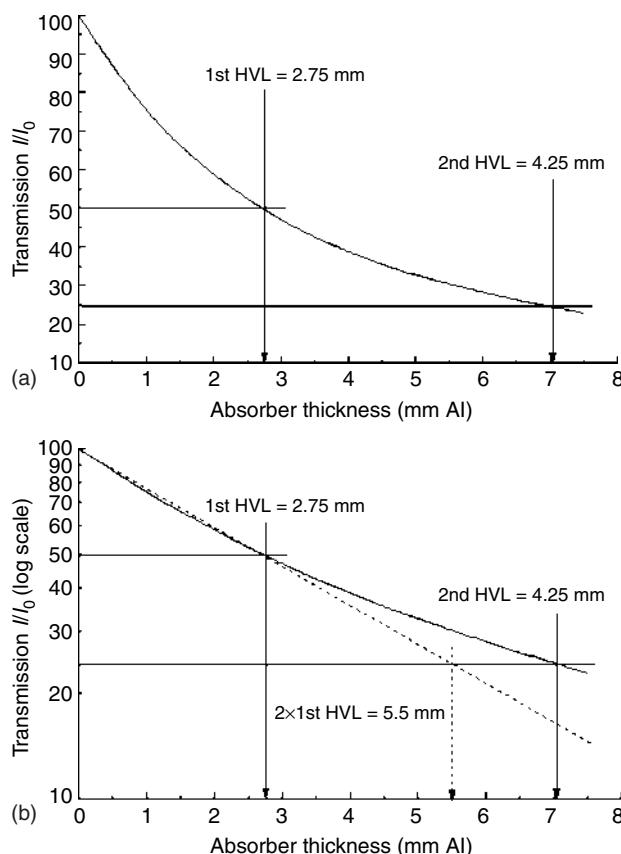

$$I = I_o e^{-\mu t} \quad (21.1)$$

**FIGURE 21.4**

Measurement arrangement in narrow-beam conditions for HVL measurement. The aperture is just large enough to expose uniformly the measurement ionisation chamber (using about 1 cm margin) and placed conveniently at about 40 cm from the source. The measurement chamber is located at twice this distance. A reference chamber can be placed above the aperture to allow correction for instability of the machine output.

The linear attenuation coefficient,  $\mu$ , could be used to characterise the penetrative beam quality, but it is more usual to express this quality as the thickness of material required to reduce the dose rate measured by the dosimeter to half of its original value. This is called the *half-value layer* (HVL). Since clinical beams are not monoenergetic, the increasing thickness of the absorber will remove the lower energies preferentially, and consequently the beam will become more penetrating (or *harder*). As a result, the attenuation will not follow the exponential relationship of Equation 21.1, and the thickness required to reduce the dose rate to a quarter of its original value will be greater than twice the amount required to reduce it to 50% (see Figure 21.5). When specifying the penetrative quality of the beam using the HVL, if not otherwise specified, it is the first HVL that is quoted.

It is customary to use aluminium for low energies (below 140 kV) and copper for higher energies. When making these measurements the beam should be collimated to an aperture that is just large enough to ensure that the whole of the ionisation chamber is covered by the beam with a margin of about 10 mm (see Figure 21.4). Ideally, two ionisation chambers should be used. The first chamber, used to monitor the constancy of the radiation, is placed above the aperture at such a position that it is not in the part of the beam which passes through the aperture. The second chamber is placed a long distance beyond the aperture. It is

**FIGURE 21.5**

Variation of relative dose rate (i.e. percent transmission) with thickness of absorber, measured as shown in Figure 21.4. Transmission is plotted with a linear scale in (a) and with a logarithmic scale in (b). Since the absorber removes preferentially the low energy components, the second HVL is larger than the first one. If the beam were monoenergetic, the attenuation would be exponential (straight dotted line on graph (b)) and the second HVL would be equal to the first HVL.

**TABLE 21.1**Mean Energy and Penetrative Quality for the Beams of [Figure 21.1](#)

Generating Potential (kV)	Filtration	Mean Energy (keV)	HVL of Aluminium (mm)
120	Inherent	32	0.08
120	3 mm Al	54	4.3
120	1.1 mm Al + 0.26 mm Cu	62	7.7
140	0.2 mm Cu	65	7.3

The data are calculated with the spectrum generator in IPEM Report 78, but although this is designed for diagnostic x-rays the results closely match measured results with actual therapeutic x-ray machines.

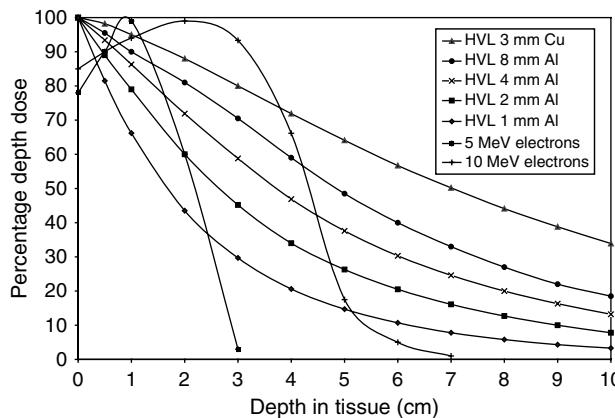

appropriate for the aperture to be about 400 mm from the source and the measurement chamber at about 800 mm. Thin sheets of the appropriate metal are placed to cover the aperture and the effect on the attenuation measured. The chemical purity of the metal sheets used is particularly important. It is also important to obtain measurements for absorber thicknesses close to the HVL and not to try to fit an exponential curve through experimental points.

Beams generated with the same generating potential may have different penetrative qualities. Table 21.1 shows the mean energy and HVL for the four different beams shown in Figure 21.1. It has been found that the HVL together with the generating potential provides a satisfactory measure of the quality of the beam with regard to penetrative ability and the amount of scattered radiation. The first HVL measurement, together with a dose measurement in some specified conditions, should therefore be sufficient to enable dose calculations for all other conditions of that beam using standard data (i.e. depth dose curves for the same HVL). Although this is an approximation it nevertheless works well in practice.

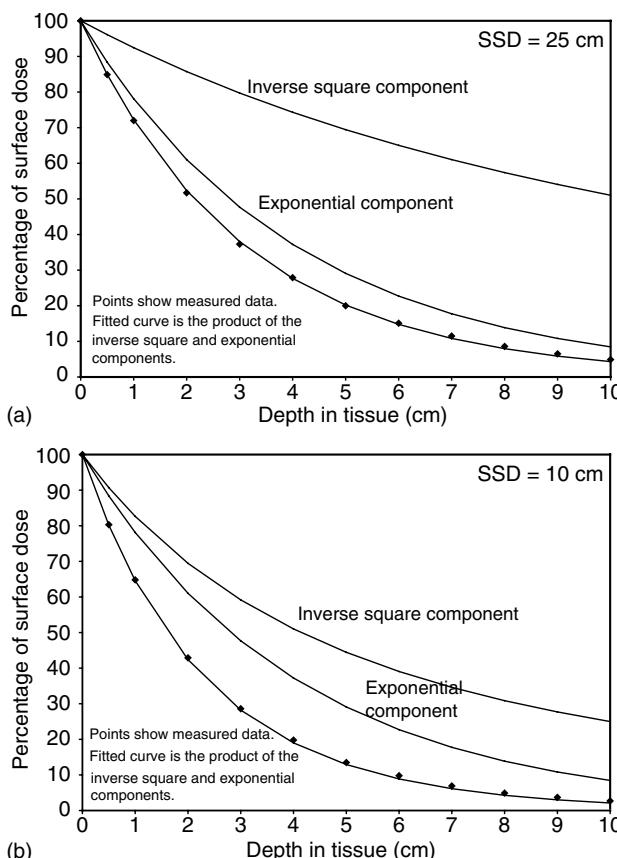

## 21.3 DEPTH DOSE CHARACTERISTICS

As discussed in [Section 20.2.1](#), the radiation intensity due to primary photons originating from a point source falls off as the inverse square of the distance from the source. However, the inverse-square law will break down in the event of scattering or absorption of the radiation. An x-ray beam measured in air will conform closely to the inverse-square law with respect to the distance from the measurement point to the source (i.e. the target). In a more dense medium there will be more significant interactions; some of the beam energy will be absorbed either through the photoelectric effect or as secondary Compton electrons which are themselves absorbed close to the site of the original interaction. The Compton interactions will also give rise to scattered photons which may have sufficient energy to travel a significant distance from the site of the interaction. In order to predict the variation of dose rate with depth in the medium we consider a detector placed on the beam central axis at different depths. For a sufficiently narrow beam the dose rate reduction as a function of depth will be caused by the loss of both the photons absorbed in the medium and the photons scattered outside of the narrow-beam which will not reach the central axis detector. This reduction is approximately exponential. The geometrical dispersion of the primary photons with the increasing distance from the source also contributes to the reduction in dose rate according to the inverse-square law. Thus in tissue the dose rate will fall off according to the relationship:

$$I = I_o \frac{(SSD + d)^2}{SSD^2} f(d, A) \quad (21.2)$$

**FIGURE 21.6**

Central axis depth dose curves for kilovoltage x-ray beams of different energies. Field size is a 10 cm diameter circle. The SSD for all except the 3 mm Cu HVL curve is 25 cm; for the 3 mm Cu HVL curve it is 50 cm. As the energy increases or the SSD decreases the depth dose curve becomes more dominated by the inverse square law. For comparison depth dose curves for 5 and 10 MeV electrons (see Chapter 24) are also shown. Graph drawn from data given in British Journal of Radiology Supplement 25. (From BIR, *Br. J. Radiol.*, Suppl. 25, 1996.)

**FIGURE 21.7**

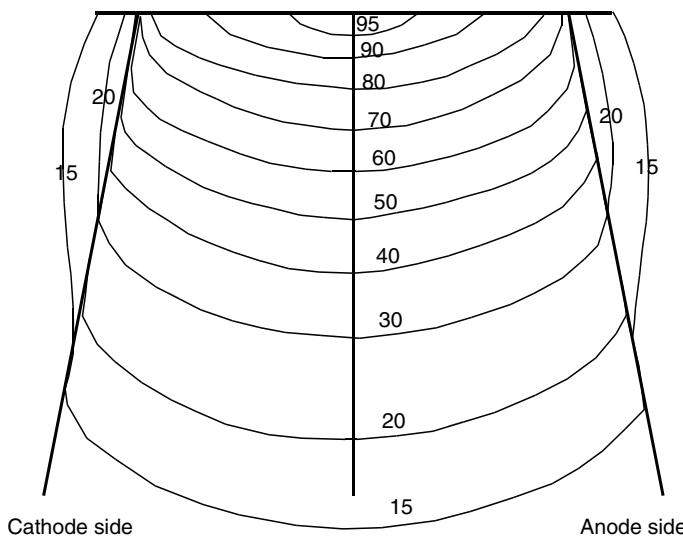

Comparison of the contribution to the depth dose curve for an x-ray beam of HVL 2 mm of Al and a 2 cm diameter field size. (a) shows the result for 25 cm SSD and (b) for 10 cm SSD. Graph drawn from data given in British Journal of Radiology supplement 25 with the effect of SSD calculated by the author. (From BIR, *Br. J. Radiol.*, Suppl. 25, 1996.)

where  $SSD$  is the distance of the surface of the phantom from the source,  $d$  is the depth within the phantom,  $A$  is the field size, and  $I_0$  is the dose rate at the surface of the phantom. For small field sizes and heavily filtered x-ray beams an exponential relationship (i.e.  $f(d,A) = e^{-\mu d}$ ) is a good mathematical approximation to the change in dose with depth. However, for clinical beams, the polyenergetic nature of x-rays and the increase of scatter as a function of depth ensure that an exponential relationship is not correct (i.e. the value of  $\mu$  is both depth and field size dependent). Some example depth dose curves are shown in [Figure 21.6](#). For shorter source skin distances (SSDs) and higher energies the inverse-square law becomes more important. This is illustrated in [Figure 21.7](#), that shows the relative contributions of the inverse-square law to the reduction in dose for 10 cm SSD and 25 cm SSD. The serious consequences of not using data that are appropriate to the SSD are apparent.

## 21.4 DOSE DISTRIBUTION

A sharp beam edge at all depths characterizes kilovoltage x-ray dose distributions, but scattered radiation causes radiation to be present outside the geometrically divergent beam as shown in [Figure 21.8](#). This figure also illustrates the standard way of displaying radiation dose distributions as isodose curves. The off-axis dose reduction, illustrated by the rounded isodoses, is caused partly by the increased distance from the source, from the beam axis to the edge of the beam (3% for a 25 cm square field at 50 cm SSD) and partly by the reduction in scattered radiation. In an inhomogeneous medium the beam will be significantly more attenuated in high atomic number materials—this effect being greater the lower the energy.

The profile of dose rate across a kilovoltage x-ray beam will be also affected by the heel effect (see [Section 10.3.1.3](#)). This will result in a variation in the dose rate of about 5% in the cathode to anode direction with the dose rate being lower at the anode end. Although in principle it would be possible to compensate for the heel effect with a filter, this is not normally done. Isodose curves from kilovoltage units are usually shown plotted in the orthogonal direction so that this effect is masked.

**FIGURE 21.8**

Isodose curve for 120 kV x-rays with HVL of 8 mm of Al. Applicator is a 10 cm circle at 25 cm SSD. Isodoses are shown relative to the surface dose in the centre of the beam. Note the slight asymmetry associated with the heel effect.

## 21.5 BEAM SHAPING

X-ray applicators are used to limit the radiation to the desired area as described in [Section 10.6](#). Further shaping can be achieved with a lead cut-out placed on the patient's skin. This should be 0.5 mm thick up to 90 kV and 1 mm thick up to 140 kV. For higher energies the weight of lead required makes detailed shaping in this way an option of last resort. Lead may also be placed behind the target volume (e.g. the ear lobe or the lip) to prevent further penetration, but in this case it is necessary to put a layer of wax, about 1 mm thick, on the lead to prevent an increased dose due to electrons back-scattered from the lead.

A uniform beam within 3% can be achieved up to field sizes of about 24 cm at 50 cm SSD in the direction orthogonal to the anode–cathode direction. However, in the anode–cathode direction the heel effect limits the field size over which the uniformity is 3% to 12 cm. The maximum beam divergence achievable is around 15°. For this large field size (26 cm diameter at 50 cm SSD) a variation across the field to between 10% and 20%, depending on the orientation can be expected.

Protection of the eye when treating tumours close to the eye can be achieved with a silver-coated lead internal eye shield that is placed beneath the lid. Such shields are very effective in reducing the eye dose and the possibility of shielding the eye may make orthovoltage x-rays preferable to electron beams when irradiating skin tumours close to the eye (Amdur et al. 1992). This is because with electrons the dose below the shield is increased by bremsstrahlung generated in the lead.

Scattered radiation will be emitted from an applicator as a result of interactions with the tube, tube housing, filter and applicator, and will be equipment dependent. Its effect on beam characteristics such as beam output, depth dose, and fall off in dose-rate with stand off from the applicator face must be determined therefore by measurement. Care must be taken when performing dose measurements with thin parallel-plate ionisation chambers; secondary photoelectrons generated in the collimation system may have sufficient energy to penetrate the thin chamber window leading to erroneous interpretation of dosimetric data if measurements are done in air without any overlying material (Klevenhagen et al. 1991; Lee and Chan 2001). Lee and Chan suggest the use of a piece of paper to eliminate these secondary photoelectrons.

The additional thickness of the plastic end-plate reduces the percentage dose at all depths compared with an open ended or diaphragm limited field. Depth dose data are provided in British Journal of Radiology Supplement 25 (BIR 1996) for both types of applicator and this publication includes a method of correcting the data according to end-plate thickness. For other field sizes, including those of irregular shape, the beam must be further collimated by the use of lead cut-outs taped to the skin.

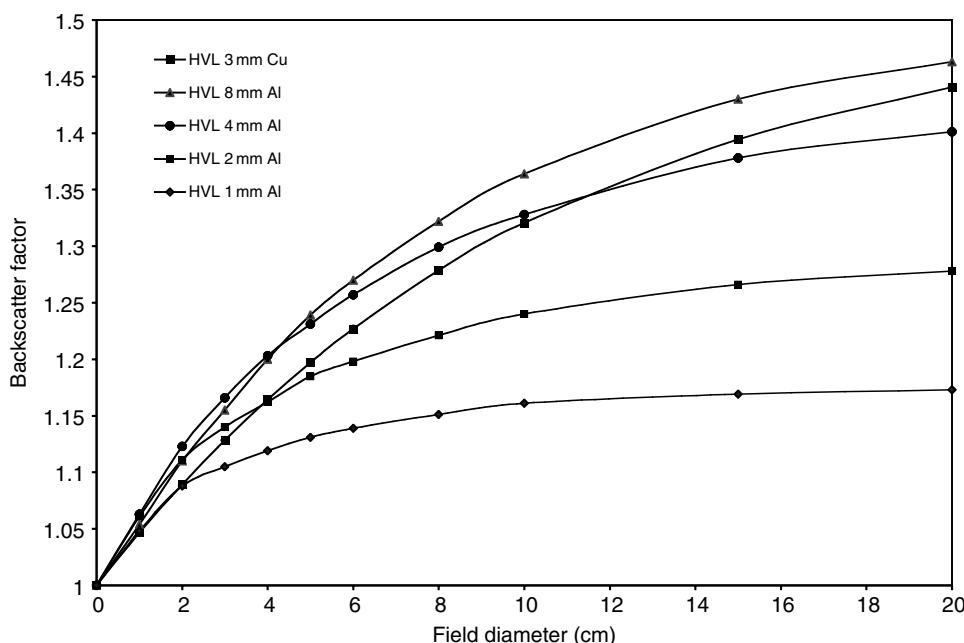

---

## 21.6 DOSE CALCULATIONS FOR KILOVOLTAGE X-RAYS

The dose delivered to the patient with a given x-ray energy is affected by two factors: the applicator used and the size of the area being treated. To facilitate dose calculation a table of applicator factors and back-scatter factors will be created at the time of commissioning. These two factors are described below.

### 21.6.1 BACK-SCATTER FACTORS

If dose rates are measured in scatter-free conditions at the end of an applicator, the dose rate measured will be lower than that measured at the surface of a phantom. This is because x-rays interacting at other points within the phantom will produce scattered secondary x-rays by means of Compton scattering. These secondary x-rays will be scattered in all directions so

**FIGURE 21.9**

Variation of back-scatter factor with field size. Data from IPSM (1991). Data are for 30 cm SSD for all except the 3 mm Cu for which the SSD is 50 cm.

that the radiation detector will be irradiated not only by the radiation coming directly from the radiation source, but also by secondary radiation from within the phantom. The amount of back-scattered radiation will depend on the area of the field. To quantify this the *back-scatter factor* (BSF) is defined as follows:

$$\text{BSF} = \frac{\text{Dose rate at the surface of the phantom for the given field size}}{\text{Dose rate in air for the same field size}}$$

Back-scatter factors are usually tabulated for equivalent circular fields or equivalent square fields. Accurate measurement of back-scatter is difficult to achieve because of the finite size of ionisation chambers (Klevenhagen et al. 1991). An alternative approach is to use back-scatter data calculated by Monte Carlo methods (e.g. Groswendt 1990; IPSM 1991; Knight 1993). This is the approach recommended by the IAEA (1997a) and the Institute of Physics and Engineering in Medicine (IPEM) (IPEMB 1996a). For higher energies the back-scatter factors vary slightly with SSD. Figure 21.9 shows how backscatter varies with field size and HVL.

### 21.6.2 APPLICATOR FACTORS

The dose rate normally will be measured for one standard applicator following the appropriate protocol (see [Section 18.6](#)). For other applicators the dose rate may be specified relative to the standard applicator by means of an *applicator factor*. Applicator factors are measured at the time of commissioning the unit, following the protocol for each applicator in turn. This may involve a measurement in water or a measurement in air. In the latter case it is then necessary to multiply by the appropriate BSF in order to obtain the dose rate in tissue. *Applicator factors* can be defined either as “the factor by which the dose per monitor unit for the standard applicator must be multiplied to give the dose per monitor unit for the applicator in question”, or as “the factor by which the number of monitor units calculated with the standard output must be multiplied to

give the required dose". These two approaches give inverted results, and therefore it is important that tables of output factors define clearly which of the two approaches is being taken. It is also important to specify systematically whether *in-air* or *at-surface* applicator factors are being used. Note that for two applicators being used at the same SSD the *at-surface* applicator factor will approximate to the ratio of the backscatter-factors for the two field sizes. However, because of the different amount of scatter from the side walls of the applicators, this calculation will not be exact. Then it will be necessary to measure the applicator factors directly. Applicator factors should be checked from time to time to verify that they have remained constant.

### 21.6.3 CUT-OUT FACTORS

It is often the case that the shape of a surface lesion to be treated is not the same as that of any of the applicators provided with the machine. In this event it is necessary to make a lead cut-out shaped to fit the patient's skin. The dose rate in this cut-out area will be less than that for the open applicator by the ratio of the BSF for the cut-out to the BSF for the applicator. For irregular shaped cut-outs the method of Clarkson integration may be applied (Clarkson 1941). The irradiated area is divided into sectors, and the equivalent diameter of each sector is measured. Using a table of backscatter factors against equivalent diameters the average backscatter factor can be calculated. The Clarkson method is illustrated diagrammatically in [Figure 23.5](#) (p. 490).

### 21.6.4 EXAMPLE OF MONITOR UNITS (OR TREATMENT TIME) CALCULATION

A basal cell carcinoma is 5 mm thick and has an elliptical shape with major axes of 1.8 cm and 2.3 cm and a surface dose of 45 Gy in 15 fractions has been prescribed\*. It is decided to treat it with a 140 kV beam with an HVL of 4 mm of Aluminium. (This has a depth dose of 87% at 5 mm and 75% at 10 mm.) The reference situation for this machine is a 10 cm diameter circular applicator for which the standard SSD is 25 cm. The applicator used must be larger than the cut-out so a 3 cm circle is chosen for which the SSD is also 25 cm. With this applicator it is found that because of the shape of the area being treated there is a standoff of 10 mm between the surface of the applicator and the lesion (i.e. the lesion is 10 mm further from the source than the applicator end). For the reference situation 100 MU is measured as giving a surface dose of 1.21 Gy. The *at-surface* applicator factor<sup>†</sup> for the 3 cm circle is 0.885. The backscatter factor for a 3 cm circle is 1.16. The equivalent diameter of the cut-out is 2.05 cm and the backscatter factor is 1.12. Therefore the surface dose rate may be calculated as:

$$\begin{aligned} \text{Dose per MU at surface} &= \text{Reference Surface Dose Rate} \times \text{Applicator Factor} \\ &\quad \times \text{Backscatter Correction Factor} \times \text{Standoff Factor} \end{aligned}$$

$$= \frac{1.21}{100} \times 0.885 \times \frac{1.12}{1.16} \times \frac{25^2}{(25 + 1)^2} = 0.00956 \text{ Gy/MU}$$

The number of monitor units for a prescribed surface dose of 3 Gy/fraction is then

$$N = 3/0.00956 = 314 \text{ MU}$$

Note that if the unit is sufficiently stable it may be appropriate to amalgamate the output factor with the applicator factor and have a table of applicator factors.

\* The common practice for kilovoltage x-rays is to prescribe the dose at the patient surface. This is different in megavoltage radiation where the dose is usually prescribed at a specified depth.

<sup>†</sup> Applicator factors in this example are defined as multiplying factors for the dose per monitor unit.

## 22.1 INTRODUCTION

Megavoltage\* photon beams are the most widely used radiation in radiotherapy because of their greater penetration compared to kilovoltage beams. Early megavoltage radiotherapy was carried out with cobalt-60 teletherapy units, and these are still the most suitable where the technical infrastructure is not adequate for the support of linear accelerators (IAEA 1998). Linear accelerators have the advantage of more penetrating beams, the versatility of the choice of beam energy, a smaller penumbra at the edge of the beam, and they deliver a higher dose rate. They also have the advantage that the source does not need to be replaced and the old source disposed of. A major advantage of megavoltage beams is the effect of skin sparing brought about by dose build-up (see [Section 22.3.1](#)). This effect is greater the higher the energy.

---

## 22.2 BEAM QUALITY

### 22.2.1 COBALT UNITS

Cobalt unit  $\gamma$ -rays are emitted at two well-defined energies (1.173 MeV and 1.332 MeV). Additional Compton emission generated in the source results in the beam incident on the patient having a continuum of energies below this, with a mean energy less than 1 MeV. At cobalt-60 energies the Compton effect is the principal interaction mechanism in the patient, which generates further low-energy scattered radiation. This results in the spectrum shown in [Figure 22.1](#).

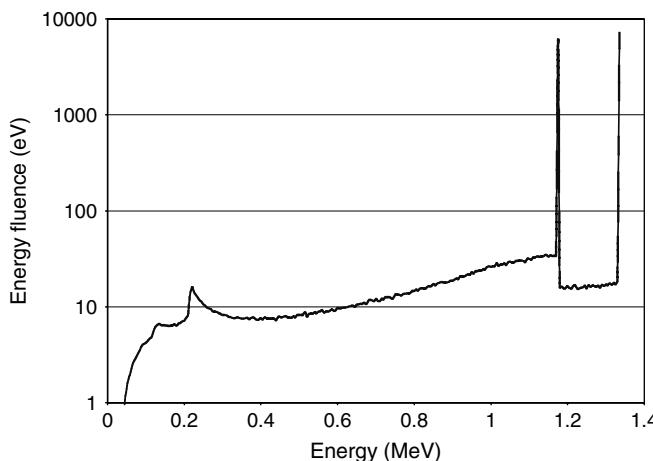

### 22.2.2 LINEAR ACCELERATORS

The spectrum of the beam from a linear accelerator is similar in shape to that of a kilovoltage x-ray beam (see [Figure 21.1](#)). A nominal 6 MV beam will have a mean x-ray energy of around 2 MeV, and the range of the secondary electrons produced by interaction in tissue will be about 16 mm.

As explained in [Section 11.4.1.2](#), a flattening filter is used to convert the forward-peaked bremsstrahlung distribution into a clinically useful beam. The choice of the material with which to make the flattening filter depends on the energy of the beam (Luxton and Astrahan 1988). [Figure 22.2](#) shows the variation of transmission with beam energy for steel and tungsten. At 6 MV either steel or tungsten would provide a satisfactory filter. However, at higher energies there is benefit to using steel rather than tungsten (in spite of the fact that the filter needs to be physically larger). This is illustrated in [Figure 22.3](#), which shows the spectrum of energies

---

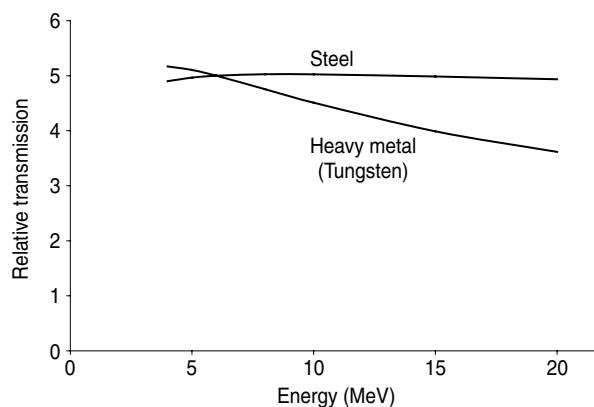

\* The term *megavoltage* refers to the range of energy of photon beams generated from linear accelerators (typically between 4 and 25 MV). In principle it is not appropriate for cobalt machines. However, since the photon beams emitted from cobalt-60 have similar characteristics, the same term is used here for both types of equipment.

**FIGURE 22.1**

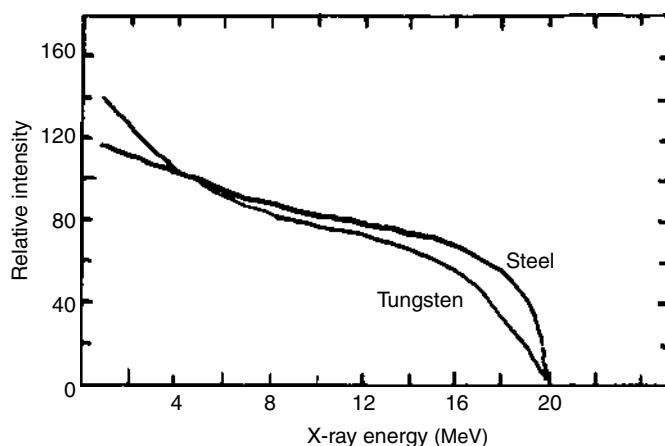

Spectrum of radiation in a cobalt-60 beam at 5 cm deep in water. Data were derived by Monte Carlo calculation. (Data provided by Price, R. A., private communication.)

transmitted by two filters of similar shape. Since more high energy radiation will be transmitted by a steel filter, the resulting beam will be more penetrating (see [Section 22.3.2.1](#)). There is also a significant problem with neutron activation of the flattening filter which is reduced if stainless steel is used (Rawlinson et al. 2002).

For practical radiotherapy the penetration of the radiation beam is the factor of interest, rather than the energy of the accelerated electrons hitting the target. The Half Value Layer concept as used for kilovoltage beams (see [Section 21.2.2](#)) would require the use of high atomic number materials and proves not to be very sensitive to quality. For this reason it is usual to specify quality in terms of the variation of dose with depth. This could be by specifying the dose at 5 cm or 10 cm as a percentage of the dose at the depth of dose maximum ( $d_{\max}$ ). However, measurements at  $d_{\max}$  are subject to unpredictable variations because of the effect of electrons and scattered x-rays produced in the collimating system. For this reason it is usual to use the ratio of the doses at two greater depths such as 5 cm and 15 cm or 10 cm and 20 cm. The latter leads to the *Quality Index* (see [Appendix D.3.1](#)) which is defined as the ratio of the

**FIGURE 22.2**

Variation of attenuation of steel and tungsten with energy. Graphs are based on linear attenuation coefficient data from the National Institute of Standards and Technology (NIST) web site (<http://physics.nist.gov/PhysRefData/XrayMassCoef/tab3.html>). Transmission is normalised to an arbitrary value of 5 at 6 MeV at which point the absolute transmission through steel is 1.8 times that of the same thickness of tungsten.

**FIGURE 22.3**

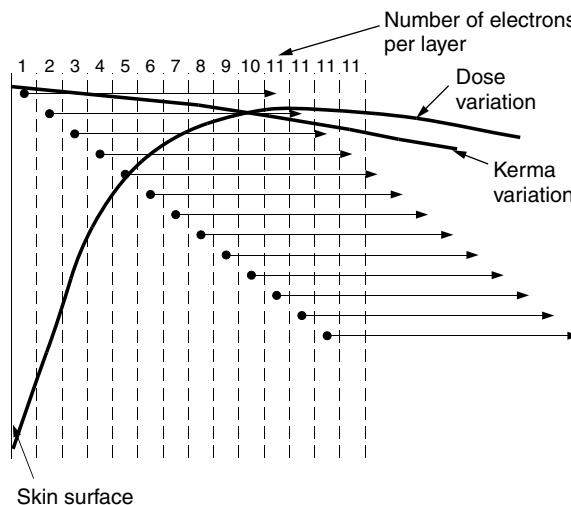

Effect of the flattening filter material on the spectrum of transmitted radiation for a 20 MeV maximum electron energy. (From information provided by Elekta Oncology Systems.)

tissue phantom ratio at 10 cm and 20 cm, or  $TPR_{20,10}$ . Andreo (2000) gives a detailed discussion of the reasons for choosing this measure of quality. The AAPM (Almond 1999) uses a different measure as described in [Section 22.3.1](#). It is, however, traditional to refer to, say, a 25 MV beam—this effective energy being based on the penetrative qualities of accelerator beams in the 1960s. This does not necessarily relate to the energy of the electrons in a modern accelerator, since the use of steel as a flattening filter material allows a more penetrating beam to be produced from the same initial electron energy. Care must be taken in applying the concept of the Quality Index since it is still possible to have two beams with the same Quality Index, but with different spectra—especially when comparing research accelerators to clinical ones. For such non-standard accelerators, knowledge of the beam spectrum or some other element of the beam energy is necessary when transferring the calibration of an ionisation chamber from a standards laboratory to a hospital.

## 22.3 CHARACTERISTICS OF PHOTON BEAMS

### 22.3.1 DOSE BUILD-UP

The depth dose curve for cobalt-60 and all megavoltage photon beams exhibits the phenomenon called *build-up*. The dose is higher a short distance below the skin compared to the dose at the surface. This is the result of the lack of *electronic equilibrium* at shallow depth, explained in [Section 6.5](#) and illustrated in [Figure 22.4](#). Absorbed dose is delivered not directly by the photons but by the secondary electrons generated by their interactions with tissues. At these higher energies the secondary electrons are principally Compton electrons directed in the forward direction and give up their energy further away from the point of interaction than is the case with low energy x-rays. The number of electrons passing through each layer of the phantom will progressively increase until the point at which equilibrium is reached. Since electrons lose energy almost uniformly along their path, the dose deposited will progressively increase until electron equilibrium is attained at a depth approximating to the range of the electrons. This depth is about 5 mm for a cobalt-60 beam. For a megavoltage beam the depth expressed in cm is approximately 1/4 of the maximum energy expressed in MeV (see also [Table 6.1](#)). On the other hand the kerma, is at a maximum at the skin surface and reduces continuously with increasing depth (see [Figure 6.9](#)).

**FIGURE 22.4**

Idealised representation of build-up of dose in a high energy beam. Electrons are generated in equal numbers in each layer of the patient (assuming no attenuation takes place). Build-up of the number of electrons traversing a layer continues until slice 10 at which point equilibrium is reached (10 slices approximately representing the range of the electrons). In practice, the number of electrons generated begins to decrease as photon attenuation takes place and the electrons do not travel in straight lines, but this is not shown in this idealised diagram.

The depth dose curve at shallow depths will also be affected by the secondary electrons produced in the collimator system (Nilsson and Brahme 1986), and this will result in differences in the build-up region of the depth-dose curves for different accelerators. The region of the depth dose curve affected by secondary electrons from the collimator extends beyond the depth of dose maximum. It is principally for this reason that reference dose measurements for high energy beams are made at depths below the depth of dose maximum (5 cm, 7 cm, or 10 cm deep depending on the dosimetry code being employed) rather than directly at the depth of dose maximum (see [Section 18.1](#)).

The value of the dose actually at the surface of the patient depends both on beam energy and field size. One might expect that the surface dose would be smaller the higher the energy. However, this is only the case for small field sizes. For field sizes above 10 cm square, the surface dose may be greater at very high energies. The reason for this is that the surface dose is actually determined by the electron contamination of the beam which derives partly from the collimators, but mainly from the flattening filter (Nilsson and Brahme 1986). The contamination is higher for large fields and more energetic beams. For a 5 cm × 5 cm field the surface dose is typically 5% of the maximum dose, whereas for a 40 cm × 40 cm it is typically 40%. The use of a perspex shadow tray in the beam to hold lead blocks or other beam modifiers increases the surface dose. A multileaf collimator defined field does not suffer from this problem. A metal (e.g. lead) sheet can be used to remove electron contamination (Leung and Johns 1977; Attix et al. 1983; Parthasaradhi et al. 1989; Rogers 1999) and when a fixed wedge is used, the surface dose can be reduced by a third because the metal wedge stops some of the electron contamination. A careful study of surface doses from Varian accelerators has been carried out by Kim et al. (1998a) and from Elekta accelerators by Klein et al. (2003). Lamb and Blake (1998a) have developed a model to predict the surface dose in various conditions.

In the AAPM TG51 code of practice for dosimetry (Almond 1999) the definition of photon beam energy is based on the percentage depth dose rather than  $TPR_{20,10}$ . Because depth dose measurements would be affected by the electron contamination of the beam for energies of 10 MV and above, they recommend the use of a 1 mm lead sheet to remove the

electron contamination. The measure of beam quality used is then the depth dose at 10 cm deep (100 cm Source Skin Distance) measured with such a lead sheet placed at 50 cm from the surface. A small amount of electron contamination remains due to the lead sheet itself, and a formula is provided to calculate the magnitude of this.

### 22.3.2 VARIATION OF DOSE WITH DEPTH

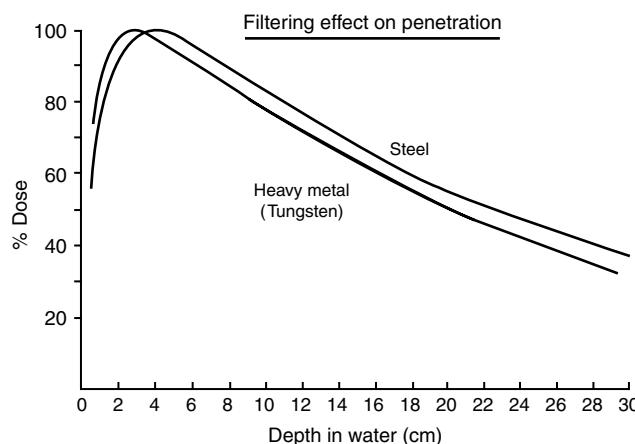

Beyond the point of dose maximum, and in addition to the dose rate decrease as a function of the distance to the source according to the inverse square law (see [Section 20.2.1](#)), the dose rate in the absorbing medium will eventually fall off in an approximately exponential manner. This fall-off is due to the attenuation of the primary photons which are either absorbed or scattered out of the primary beam. The overall depth-dose variation will depend on the energy of the beam, the field size, and the source-to-surface distance as well as on the composition of the medium.

#### 22.3.2.1 *Effect of Energy*

The attenuation of the primary photon beam will be determined by the mass energy attenuation coefficient and by the density of the attenuating material at the relevant energy. In biological tissue, for energies up to about 15 MV, attenuation will be primarily through the Compton effect and will therefore depend on the electron density (approximately analogous to the actual density). At higher energies pair production begins to occur and there will therefore be a dependence on the atomic number of the medium (Bradley et al. 1998). As explained in [Section 22.2.2](#), the depth dose for a given electron energy incident on the target will depend on the design and the material of the flattening filter. This is illustrated in Figure 22.5.

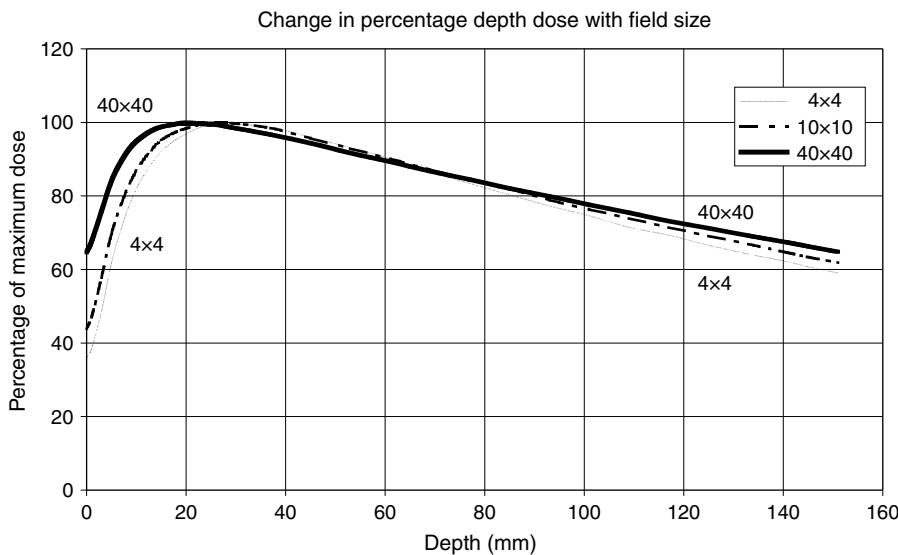

#### 22.3.2.2 *Effect of Field Size*

The Compton effect has two components: transfer of the photon energy to an electron and scattering of the photon. Both components contribute to attenuation of the beam. As the field size increases, the dose rate on the beam axis will increase because it will include a contribution from the Compton photons scattered from the rest of the irradiated volume. For small field sizes, the scatter contribution is small and does not change much as a function of depth. For larger field

**FIGURE 22.5**

Percentage depth dose for a beam flattened with a steel filter compared to a tungsten filter. (Data provided courtesy of Elekta Oncology Systems.)

**FIGURE 22.6**

Graph showing percentage depth dose variation for 3 different field sizes ( $4\text{ cm} \times 4\text{ cm}$ ,  $10\text{ cm} \times 10\text{ cm}$ , and  $40\text{ cm} \times 40\text{ cm}$ ) for a 15 MV beam (from a Varian 2100C). Note that generally the percentage depth dose is greater for larger fields, but that close to the surface this may not be the case.

sizes this contribution is greater and, since the field divergence is also greater, it will increase more rapidly as a function of depth and consequently the effective attenuation will be less.

As pointed out in [Section 22.3.1](#), the field size will also affect the build-up region, and the depth of the maximum will be smaller as the field size increases. As a consequence, in spite of the smaller effective attenuation for larger field sizes for the higher energies, the whole depth-dose curve will be shifted towards the patient surface resulting in an apparent decrease of the depth dose for some depths (see Figure 22.6).

### 22.3.2.3 Effect of Source Skin Distance

The Source Skin Distance (SSD) is a significant determinant of the change of dose rate with depth. The variation of dose with depth can be represented approximately by Equation 22.1:

$$D_d = D_{\max} \frac{(SSD + d_{\max})^2}{(SSD + d)^2} f(d, A) \quad (22.1)$$

Here  $D_d$  is the dose rate at depth  $d$  and  $D_{\max}$  is the dose rate at the depth of dose maximum,  $d_{\max}$ .  $f(d, A)$  is an approximately exponential function of the depth  $d$ , for the field  $A$ , and represents the beam attenuation beyond the maximum. A detailed derivation of the effect of the change of SSD is given in [Section 23.2.2.4](#). In Equation 22.1, the beam attenuation is enhanced by a factor including the ratio of the square of the distances from the source to  $d_{\max}$  and to the point of interest, respectively. In contrast with the dose rate which decreases as the distance to the source increases, the fall-off in dose with depth is smaller at large distances than at short ones. For example, with a cobalt-60 beam the percentage depth dose at 10 cm deep (i.e. relative to dose at  $d_{\max}$ ) is 56.4% at 80 cm SSD and 61.4% at 140 cm SSD (BIR 1996). Thus a cobalt-60 beam at 140 cm SSD would have the same effective penetration as a 5 MV x-ray beam at 80 cm SSD.

### 22.3.3 OFF-AXIS DOSE DISTRIBUTION

The off-axis dose distribution at the edge of the beam in linear accelerators or cobalt-60 beams is largely dependent upon the design of the collimator which is used to delineate the beam (see [Section 22.5.1](#)). In the central part of the beam, the off-axis distribution for an accelerator depends on the design of the flattening filter.

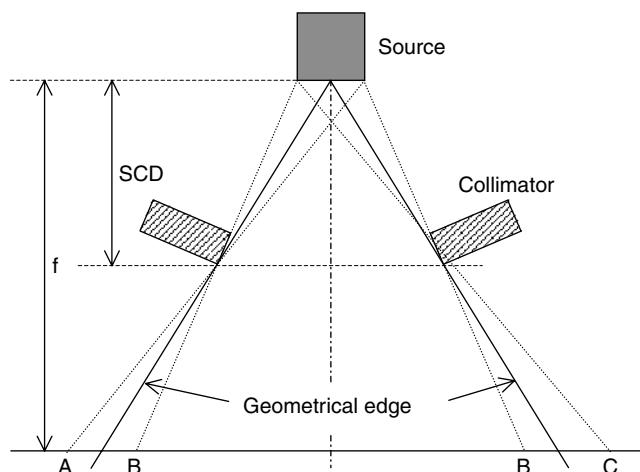

#### 22.3.3.1 Cobalt Beams

The shape of the cobalt-60 beam profile is affected by the large source size and by the effect of scatter. Unlike in an accelerator beam for which a flattening filter is used, the dose rate decreases towards the edge of the beam because of the reduced contribution of scatter dose as the beam edge approaches. This results in a rounded beam profile. At the longer distances associated with megavoltage units, the difference in SSD between the centre and the edge of the beam makes only a minor contribution to the fall-off in dose at the beam edge (3.5% for a 30 cm square field at 80 SSD).

The shape of the profile at the edge of the beam is determined largely by the size of the source. For a cobalt-60 beam the half value thickness of lead is 10 mm, so for beam shaping, lead collimators around 70 mm thick are needed to reduce the dose to 1%. Because of the large size of the source (usually 15 mm or 20 mm in diameter), the beam edge is less sharp than for a kilovoltage unit. This is caused by the fact that at the edge of the beam there is a penumbra region where part of the source will be shielded by the collimators and part will not (see [Figure 22.7](#)). The *geometric penumbra*,  $p_{\text{geom}}$ , at a given distance from the source is defined as the width of the region where the source is partly shielded by the collimator. It can be calculated from the following expression:

$$p_{\text{geom}} = d_{\text{source}} \frac{(f - \text{SCD})}{\text{SCD}} \quad (22.2)$$

where  $d_{\text{source}}$  is the source diameter,  $f$  is the distance from the source to the plane of interest, and SCD is the distance from the source to the collimator end. The penumbra width is smaller

**FIGURE 22.7**

Diagram showing the geometric and transmission penumbra for a cobalt-60 beam. A and B represent the external and internal limits of the geometric penumbra respectively. C is in the region where the transmission through the collimator is incomplete.

if the beam is collimated further from the source and increases as the distance to the collimator is greater.

If the collimator were made of only two separate orthogonal blocks, the penumbra from the collimator jaw closest to the source would be unacceptably large. So it is usual for this jaw to be split into at least two parts, one above and one below the orthogonal collimator pair. To produce a sharper beam an additional strip of lead, or tungsten, may be attached beneath the main collimator. This is called a penumbra trimmer. However, penumbra trimmers reduce the clearance between the treatment head and the patient, and many centres accept the increased penumbra rather than use them. If they are used, it is essential that they are precisely aligned, as otherwise the penumbra width could actually be increased. Since the collimators are usually slightly further from the source than half way between the source and the patient, the geometric penumbra width will be slightly smaller than the diameter of the source.

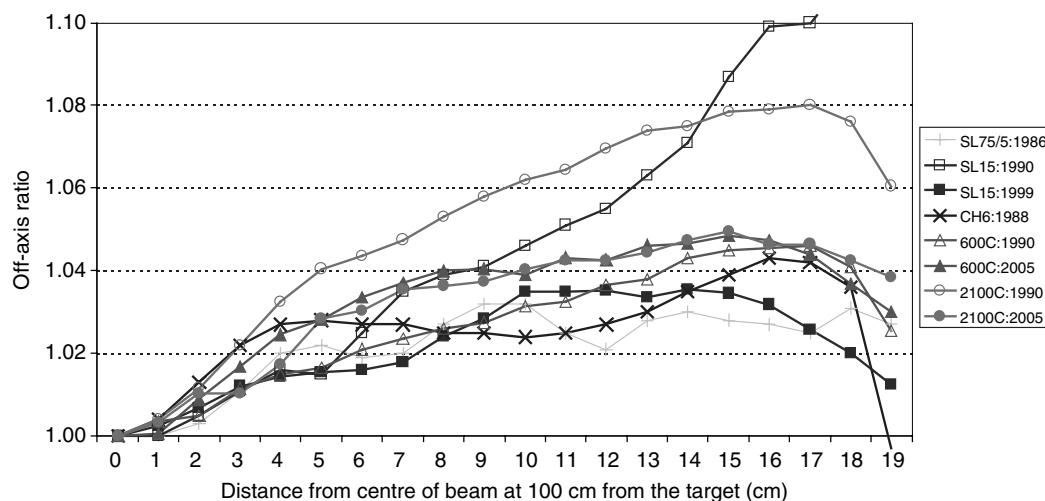

The overall penumbra is usually defined as the distance,  $p_{20-80}$ , separating the 20% and 80% of the dose on the beam axis at the depth of interest. This overall penumbra accounts also for the fact that some photons emitted by the distal parts of the source are only partially attenuated by the collimator, resulting in a *transmission* penumbra illustrated in Figure 22.7. It should be noted that when additional shielding blocks are used (see 22.5.3.1), the *geometric* penumbra at the edge of these blocks, which are closer to the patient skin, gets smaller; however, if they are not focused towards the source, the *transmission* penumbra gets larger. For cobalt-60 beams, at depth  $d_{\max}$ ,  $p_{20-80}$  is usually slightly smaller than the geometric penumbra at the same distance and typically of the order of 10 mm to 15 mm. As the depth increases,  $p_{20-80}$  increases. This is due to the increase of both the geometric penumbra and the scatter contribution in tissue and a larger *safety margin* must be used to ensure a uniform dose distribution within the target volume.

### 22.3.3.2 Linear Accelerators

*Beam edge:* The source size of a linear accelerator is the size of the electron spot incident on the target, which is typically of the order of a few millimetres. This results in a sharper beam edge than with a cobalt-60 unit, and  $p_{20-80}$  is typically about 6 mm at  $d_{\max}$ . This is larger than the geometric penumbra predicted from Equation 22.2 using source sizes quoted by manufacturers. Actually the flattening filter acts as a source of secondary photons, effectively broadening the focal spot. Secondly, the effect of scattered photons, which is greater at larger depth, leads to a broadening of the penumbra as the depth increases. Thirdly, the role of secondary electrons transported outside of the beam edge without being compensated for by electrons coming in becomes significant at energies above 10 MV (Day et al. 1990). For the larger energies (i.e. 20 MV to 25 MV), the penumbra width at the reference depth may even be the same order of magnitude as for a cobalt-60 beam.

Electron transport is also a problem for very small fields such as those used in stereotactic arc therapy where lateral electron equilibrium may not be achieved anywhere in the beam, thus reducing drastically the dose on the beam axis. It becomes important to use tissue equivalent dosimeters in this situation since the assumptions made in routine dosimetry are no longer valid. Computer algorithms designed for larger field sizes may be significantly in error for such fields. If real data for very small fields are input to the planning computer, this may cause a problem for larger fields because the algorithm is forced to extrapolate from a field size where there is equilibrium to a field size where there is not. In such circumstances it may be appropriate to omit the very small field sizes. Specially designed algorithms, or beam data files, should be used for the very small fields.

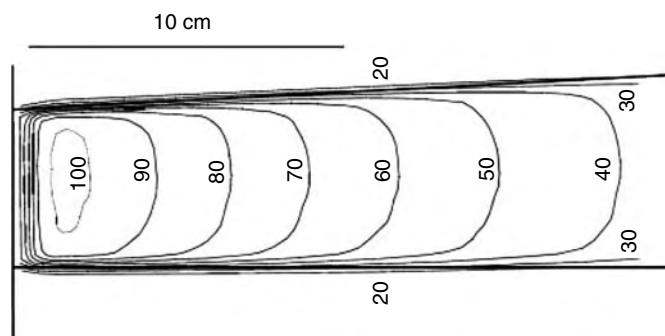

*Beam centre:* The shape of the central part of the beam profile will depend on the design of the flattening filter. The use of a flattening filter makes it possible to compensate for the lack of

**FIGURE 22.8**

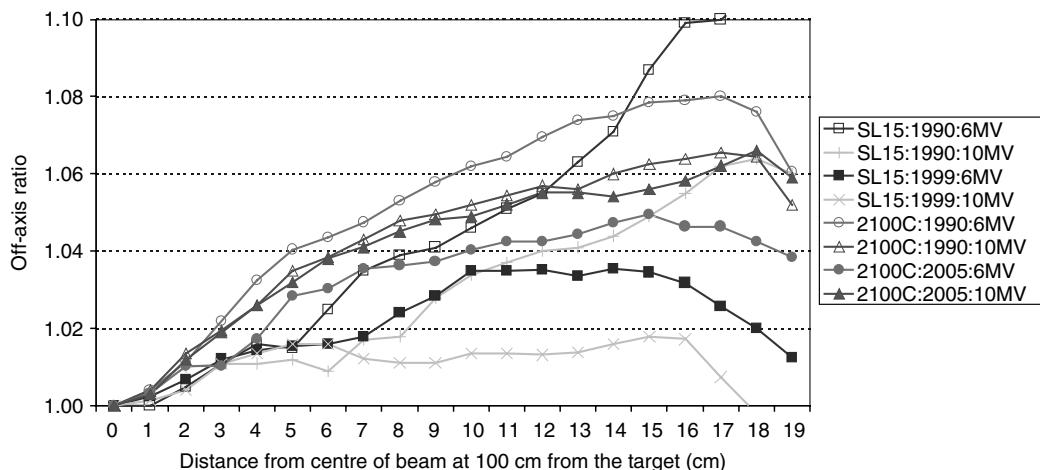

(See colour insert following page 590.) Profiles at peak depth for different low energy accelerators including a Philips SL75/5, two Elekta SL15s (one installed in 1990 and the other in 1999), an ABB CH6, two Varian 600Cs and two Varian 2100Cs installed at different times. Note the more pronounced increase in dose towards the edge for the SL15 and 2100C installed around 1990.

scatter at the edge of the field by deliberately designing a profile which increases towards the edges at shallow depth. The beam profile will therefore be very dependent on the detailed design of the flattening filter. Because of the flattening filter, the energy spectrum and consequently the Quality Index of the beam varies between the centre and periphery of the beam (Hanson et al. 1980, 1980a; Zefkili et al. 1994).

Differences between the design aims of different flattening filter designers can result in very different beam profiles for accelerators from different manufacturers—and indeed for different machines from the same manufacturer (Figure 22.8). For example, older Philips (now Elekta) accelerators such as the SL75/5 were designed to produce a flat beam at 5 cm deep. This resulted in a maximum off-axis ratio at the depth of peak build-up of 1.03. However, the flattening filter for the SL series accelerators was designed to produce a flat beam (within 3%) at 10 cm deep. For a typical SL series machine at 6 MV, the maximum off-axis ratio at the depth of peak build-up was 1.10. The International Electrotechnical Commission (IEC 1989a, 1989b) specifies that the ratio of the maximum to the minimum dose at the depth of dose maximum should be less than 1.07 over the central

**FIGURE 22.9**

Isodose curve for a half blocked field from an SL series (Elekta) accelerator.

**FIGURE 22.10**

(See colour insert following page 590.) Flatness profiles at peak depth for Varian (2100C) and Elektta (SL15) 6 MV beams compared to 10 MV beams. Two machines from each manufacturer installed at different times are compared. Note the higher doses at the beam edge for the earlier 6 MV beams which were designed for flatness at 10 cm deep.

80% of the beam width for field sizes between 5 cm and 30 cm and less than 1.09 up to the maximum square field\*. Note that IEC 976/977 is a disclosure standard—i.e. it defines how things should be specified—and, although maximum recommended values are given, they are not mandatory. The European Community (EC 1977) has specified acceptance criteria for accelerators which are mandatory in Europe (see [Section 38.1.3](#)), but these do not specify flatness at the peak.

When asymmetric fields are used, the scatter is no longer at a maximum on the central axis of the accelerator. This results in a profile for a half-blocked beam that is not symmetrical about the centre line of the open field (see [Figure 22.9](#)). It could be argued that, in striving to achieve flatter symmetric fields, the comparability of the beam profiles of asymmetric and symmetric fields is compromised.

For energies above 6 MV, there is less scatter and consequently less difference between the beam profile at the peak and that at 10 cm depth. For this reason the beam profile at the depth of peak build-up can be less peaked than that at 6 MV (see [Figure 22.10](#)) Because of the much thicker filter required for high energy beams the low energy filter may be used in conjunction with the high energy filter, as can be seen in [Figure 11.19](#).

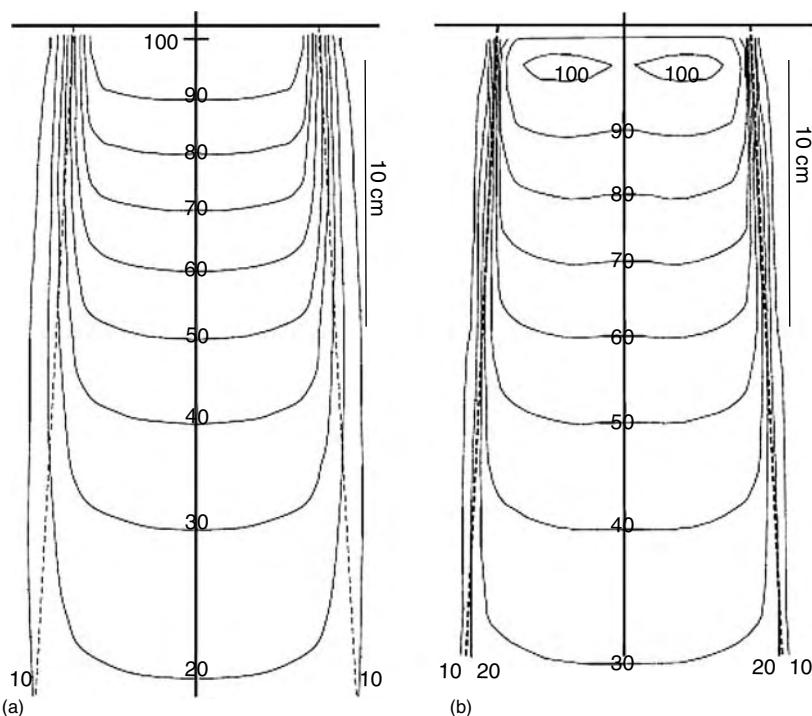

### 22.3.4 ISODOSE DISTRIBUTIONS

Isodose distributions from typical cobalt-60 and linear accelerator beams are shown in [Figure 22.11](#). Note the wider penumbra and more rounded isodoses of the cobalt-60 beam. The isodoses shown are those obtained in a uniform water phantom. In non-uniform media the isodoses may be significantly changed (see below, [Section 22.4.2](#)).

## 22.4 INFLUENCE OF PATIENT SHAPE AND COMPOSITION

The isodose distributions shown in [Figure 22.11](#) apply to a uniform water phantom. Real patients have irregular surfaces and inhomogeneous internal composition. For most regions of

\* Most manufacturers consider 35 cm to be the maximum size for this purpose because of the cut-off corners.

**FIGURE 22.11**

Isodose lines in the central plane (a) from an 80 SSD cobalt-60 beam and (b) from a 6 MV linear accelerator. The isodose lines close to the entrance surface are not represented. The dashed lines represent the edge of the geometrical field. Note the influence of the flattening filter and the tighter penumbra for the 6 MV beam.

the body it is appropriate to treat the patient as water equivalent. A more accurate patient representation can be obtained using a CT scan of the patient to show the patient shape and the real variation in density. Because CT scans are obtained with 120 kV beams (the attenuation of which is strongly affected by photoelectric interaction cross sections), it is necessary to make a conversion between CT numbers and relative electron density to obtain a density map of the patient (see [Section 39.2.1](#)). Methods of correction for oblique incidence and patient inhomogeneities are briefly presented here. They are dealt with in more detail in [Section 26.2.3](#).

#### 22.4.1 EFFECT OF OBLIQUE INCIDENCE

When a beam is incident obliquely on the surface of the patient, the isodoses will be changed compared to a beam incident on a flat surface (Garrett and Jones 1962). In this case the isodoses effectively become wedged. It might be expected that the isodose lines would remain parallel to the patient surface. This is not the case because part of the fall-off of the dose in depth is associated with the inverse-square law, independently of the tissue attenuation. To predict the effect it is possible to use the *isodose shift* method described by Barry (1970) and van der Giessen (1973). For a cobalt-60 unit at 80 cm SSD, the isodose curve is shifted by two-thirds of the distance between the line perpendicular to the skin entry point on the central axis and the skin surface. For linacs, particularly as the energy is increased, the shift is reduced (see [Table 22.1](#) and ICRU 1976).

The wedging effect due to the skin obliquity is usually not what is wanted and it is then necessary to compensate in some way. In some situations (such as breast treatments) this can be achieved with a wedge filter (see [Section 22.6.1](#)) whose angle should be about two-thirds of the

**TABLE 22.1**

Isodose Shift from Lines Perpendicular to the Beam Axis, Expressed as Fraction of the Air Gap between This Plane and the Skin, for Various Energies and SSDs

	Cobalt-60	5 MV	10 MV
100 cm SSD	0.69	0.67	0.59
80 cm SSD	0.67	0.64	0.55

These values are calculated from the ratio between depth-dose fall-off due to tissue attenuation alone and total depth-dose fall-off (combining both inverse square of the distance and attenuation).

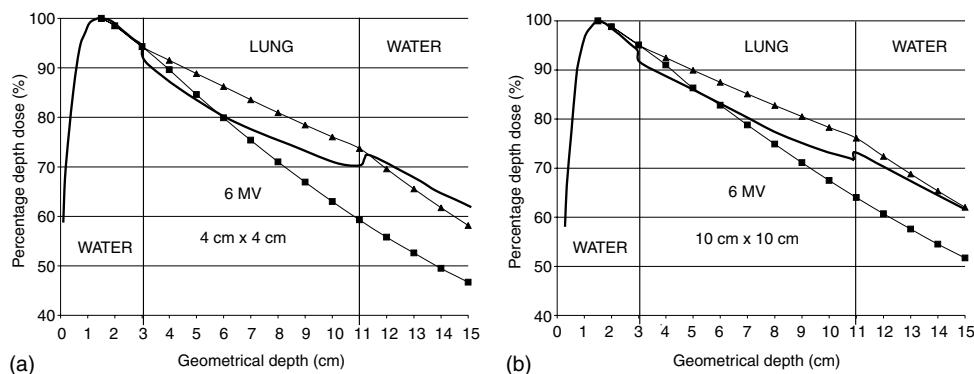

angle of the skin surface for a cobalt-60 beam and correspondingly shallower for a linear accelerator. This is illustrated in Figure 22.12.

#### 22.4.2 INHOMOGENEITIES

Where the tissue is not water, equivalent distortions to the beam profiles will occur. If the density is substantially less than that of water, as in lung or in air cavities, the attenuation will be reduced. The effect of this may be very approximately accounted for by considering the water equivalent path length,  $d_{\text{eff}}$ , calculated by correcting the geometrical depth  $d$  with the ratio of the density of the inhomogeneity to that of water. In this case,  $d_{\text{eff}}$  is then used instead of  $d$  in the  $f(d, A)$  term in Equation 22.1 (Section 22.3.2.3). While this approximation works well for points that are well beyond the inhomogeneity, it does not represent the dose variation within the inhomogeneity or just beyond it. This is for two different reasons: firstly, the equivalent path length approximation does not consider the modifications of the scatter component which have a greater influence within or close to the inhomogeneity; secondly, at the interface, there is a loss of electronic equilibrium and the inverse of the build-up effect occurs just inside the inhomogeneity. Just beyond the inhomogeneity the dose builds up again for the same reasons as is illustrated in Figure 22.13.

**FIGURE 22.12**

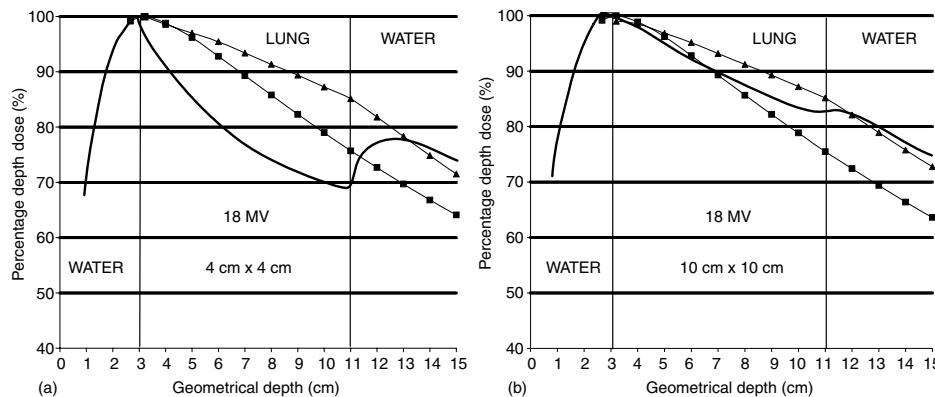

Effect of oblique incidence on isodose distributions. The patient surface is represented by a thick solid line. The isodose lines are parallel to the dotted line which is intermediate between the skin and a line perpendicular to the beam axis. On each line parallel to the beam axis, the isodose shift (DE=AB) is a constant fraction of the gap AC between the line perpendicular to the beam axis and the patient surface. For an accelerator at high energy (around 15 MV–20 MV) and 100 cm SSD, this fractional shift, AB/AC, is about 0.5. For a cobalt-60 beam, at 80 cm SSD, the shift is about 2/3. To compensate for this effect on the isodose lines and to restore them perpendicular to the beam axis, a wedge filter can be used with a wedge angle defined by the tangent to the dotted line representing the isodose shift—referred to as the *wedge angle* in the figure.

**FIGURE 22.13**

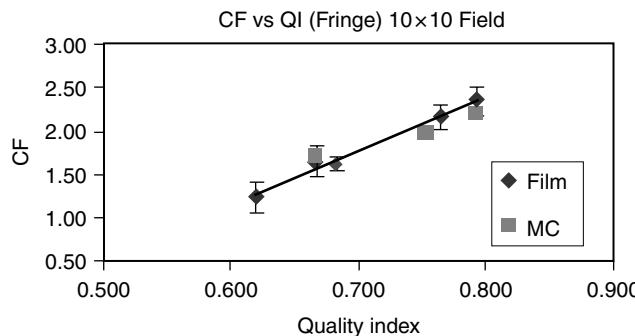

Comparison of the actual depth dose curve (thick solid line without symbol), the curve that would be obtained in a homogeneous medium (solid squares) and the result of an equivalent path length calculation (solid triangles) for 6 MV beam energy. The left side shows a  $4\text{ cm} \times 4\text{ cm}$  field and the right side shows a  $10\text{ cm} \times 10\text{ cm}$  field. The actual depth dose curve is based on the Monte Carlo calculations from Arnfield, M.R. et al., *Med. Phys.*, 27, 1266–1274, 2000 and the homogeneous dose values are taken from BIR, *Br. J. Radiol.*, Suppl. 25, 1996.

Figure 22.13 shows the effect on the depth-dose curve of an 8 cm thick block of lung for a 6 MV beam. The effect is slightly greater for the  $4\text{ cm} \times 4\text{ cm}$  field than for the  $10\text{ cm} \times 10\text{ cm}$  field and the rebuild-up effect is more marked. However, at 18 MV (Figure 22.14) there is a marked difference between the  $4\text{ cm} \times 4\text{ cm}$  field and the  $10\text{ cm} \times 10\text{ cm}$  field. For a 6 MV beam the depth of dose maximum is at 1.5 cm, so on the central axis electronic equilibrium is established for both field sizes. However for the 18 MV beam the depth of dose maximum is 3.2 cm, so there is a complete loss of electronic equilibrium for the small field.

In addition to the effect on the depth-dose curve, a low density region will also have an effect on the beam penumbra. The effect of electron transport will be particularly acute for high energy beams in low density media such as lung. The lack of electronic equilibrium in this situation means that there is a zone at the edge of the beam between the 50% and the 90% isodose, sometimes referred to as the beam fringe (Ekstrand and Barnes 1990; Miller et al. 1998; Engelmans et al. 2001; Tsiakkos et al. 2004), where the dose-rate is significantly reduced. The penumbra width and the beam fringe may increase by a factor greater than 2.5 in lung compared to a water-like medium when the energy is about 20 MV (see Figure 22.15).

**FIGURE 22.14**

The same comparison as in Figure 22.13 but with a beam energy of 18 MV. At this energy the depth of dose maximum is at 3.2 cm in water, and for a  $4\text{ cm} \times 4\text{ cm}$  field (a) there is a loss of electronic equilibrium in the lung and after the lung-water interface. (Data from Arnfield, M.R. et al., *Med. Phys.*, 27, 1266–1274, 2000 and BIR, *Br. J. Radiol.*, Suppl. 25, 1996. With permission.)

**FIGURE 22.15**

Increase of the beam fringe (distance from 50% to 90% of the central axis dose) as a function of the beam Quality Index (QI) in lung material of density  $0.3 \text{ g cm}^{-3}$  for a  $10 \text{ cm} \times 10 \text{ cm}$  field size. The correction factor CF represents the ratio of the fringe within lung material to the fringe in water-equivalent tissue obtained both from film measurements and Monte Carlo computation (MC). It increases from 1.2 to 2.6 as the energy increases from 4 MV ( $\text{QI} = 0.620$ ) to 20 MV ( $\text{QI} = 0.794$ ). (From Tsiakalos, M. F., Theodorou, K., Kappas, C., Zefkili, S., and Rosenwald, J. C., *Med. Phys.*, 31, 943–949, 2004.)

The equivalent-path-length method used to calculate the dose in the presence of inhomogeneities will be discussed again in [Section 23.3.4.5](#) with the corresponding equations. Other methods frequently used in computer based dose calculations will be presented in [Section 26.2.3.2](#).

## 22.5 BEAM DELINEATION

### 22.5.1 STANDARD COLLIMATORS

Most accelerators have standard collimators designed to produce a rectangular field and to reduce the unwanted dose to about 1% of the central axis dose. The geometric edge of the radiation beam so defined is obtained by considering the geometric projection of the distal end of the collimator from the centre of the source. For cobalt-60 beams, the point source to be considered is the centre of the proximal surface of the source relative to the collimator. For cobalt-60 and linear accelerator beams it is found that, whatever the distance and the depth, this geometrical edge coincides with the 50% dose relative to the central axis at the relevant depth. For cobalt-60 beams, the maximum aperture of the standard collimators is typically  $30 \text{ cm} \times 30 \text{ cm}$  at the treatment distance of 80 cm. For linear accelerators it is typically  $40 \text{ cm} \times 40 \text{ cm}$  at the treatment distance of 100 cm. For some accelerators the circular primary collimator limits the diameter of the maximum field so that a markedly lower dose is delivered to the corners of a  $40 \text{ cm} \times 40 \text{ cm}$  field (see also [Section 11.4.2](#)). This needs to be considered when using large fields as it may not be correctly modelled by the treatment planning system. One possibility is to place additional shielding in the corners of such fields so that some tissue is not partially irradiated (as is done automatically by the Elekta Multileaf Collimators).

### 22.5.2 REQUIREMENTS FOR ENHANCED BEAM SHAPING

The need for further field shaping arises as, in general, the projection of the radiotherapy target volume in the *Beam's-Eye View* (BEV) is not rectangular. The observation that rectangular beams were a limitation was pointed out as early as 1959 by Green et al. (1960) who stated that target volumes “are not composed of cubes and cylinders”, which are the volumes generated by the intersection of beams with rectangular cross sections. Clearly it did not take 40 years for the radiotherapy community to take notice of this observation, and the shaping

**TABLE 22.2**  
Volumes of Regular Shapes

		Volume (cm <sup>3</sup> )
Cube	8 cm	512
Cylinder	8 cm × 8 cm	402
Sphere	8 cm	268

of beams has been carried out at differing levels of sophistication for as long as radiotherapy has been available.

The use of beam shaping has two main purposes:

- It reduces the volume of normal tissue that is irradiated and therefore allows the radiation oncologist to exploit the inverse relationship between normal-tissue-tolerance dose and target volume irradiation. Empirical understanding of this relationship on the basis of clinical experience predates the development of radiobiological understanding and the concepts of Tumour Control Probability (TCP) and Normal Tissue Complication Probability (NTCP) (see [Chapter 36](#)).
- It reduces the dose to critical structures which are close to the boundary of the planned target volume to levels where unacceptable morbidity is avoided.

For a single beam the reduction in volume of tissue irradiated by a shaped beam is obvious, but is particularly marked when considering the use of multiple shaped fields which intersect to form the planned target volume. Beam shaping is very effective in reducing the treated volume below that achieved by the use of rectangular fields.

This is illustrated in Table 22.2 which shows the relative volume of three simple shapes all with major dimensions of 8 cm. A sphere can be formed by the intersection of multiple non-coplanar circular beams, a cylindrical volume by isocentric rotation of a square (or rectangular) beam and a cube by the intersection of two orthogonal pairs of square beams.

Assuming a partial volume effect relationship of the irradiated healthy tissue, the radiobiological consequences of these volume reductions according to the Lyman–Burman model of NTCP (see [Section 36.3.2](#)) can be evaluated from Equation 22.3:

$$TD_2 = TD_1 \left( \frac{V_2}{V_1} \right)^{-n} \quad (22.3)$$

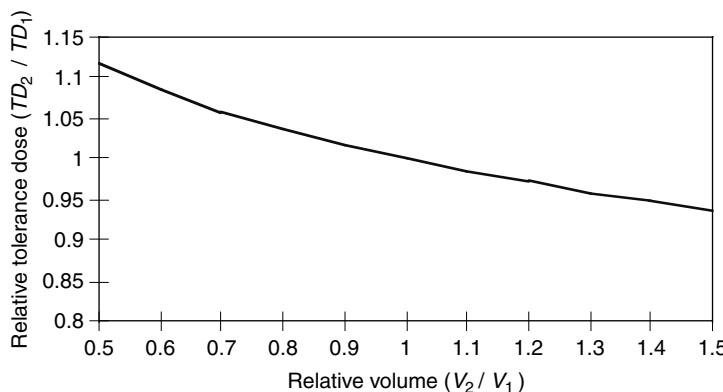

where  $TD_1$  is the 50% tolerance dose (i.e. the dose delivered uniformly to the volume  $V_1$  which would lead to complications in 50% of the population), and  $TD_2$  the 50% tolerance dose corresponding to a uniform irradiation of  $V_2$ . The exponent  $n$  is characteristic of the partial irradiation tolerance of each organ and is near unity if the volume effect is large as for parallel type tissue (see [Section 8.9](#)).

This relationship is shown graphically in [Figure 22.16](#) for  $n=0.16$ . If this relationship could be shown to be valid in clinical practice then a reduction of the target volume by 30% would allow for a 5% escalation in dose without incurring extra morbidity, and a 50% reduction would allow for a 10% dose escalation. If these were achieved then significant improvements in tumour control could be expected.

### 22.5.3 BLOCKS

#### 22.5.3.1 Simple Beam Blocking

As part of the planning process the shape of each beam is determined. The shape can then be described by marks applied to the patient's skin or by a template that can be placed in the optical beam projected through the collimation system. In each case beam shaping is achieved

**FIGURE 22.16**

Variation of tolerance dose with volume assuming a partial volume effect according to Equation 22.3 and taking a  $n$  value equal to 0.16.

by placing lead blocks on the shadow tray. These blocks are then aligned so that the optical beam from the accelerator projects a shadow to coincide with the area to be shielded. This method is limited for many reasons:

- It is time consuming.
- In its simplest form it uses blocks with parallel sides (compromising the beam penumbra).
- It requires ingenuity in supporting blocks on the tray when it is not horizontal.
- The blocks are heavy, which is a serious health and safety problem for both patients and radiographers.

#### 22.5.3.2 Customised Blocking

Some of the limitations in simple blocking can be overcome by manufacturing customised blocks for each patient. A customised block can be pre-mounted on a slide fitted to the shadow tray and can therefore be repositioned very accurately and used at any gantry orientation.

These customised blocks are cast from a low melting point alloy of lead and other metals. One such alloy is Cerrobend, or Wood's Metal, which can be cast into an expanded polystyrene mould formed with a hot wire cutter. Several simple commercial devices are available which allow the shape of the target to be traced from an outline drawn on a simulator radiograph and demagnified so that the resulting block is correctly scaled to the position of the shadow tray. Alternative *high tech* solutions to block manufacture include computer controlled milling machines linked to treatment planning systems.

Blocks cast with these devices have edges focused towards the target in order to achieve the best penumbra. In fact, the geometric penumbra (arising from the finite size of the focal spot) is somewhat smaller for a customised block than it is for the conventional rectangular collimator as the block is nearer to the patient than the collimator.

In many respects the customised block is the gold standard for blocking, but the method is not perfect for the following reasons:

- The blocks are still heavy and need to be handled manually (a few elaborate handling devices have been designed to overcome this problem but they have not been widely used).
- The blocks are cast from alloys which need careful handling as they contain toxic materials\*.

\* In the UK handling of such materials are covered by the Control of Substances Hazardous to Health (COSHH) regulations.

- The density of these alloys is usually lower than lead and therefore they need to be thicker.
- As with the simple blocks they need to be mounted near to the patient and secondary electrons generated in the shadow tray significantly increase the surface dose (Hounsell and Adams (1995) found that the surface dose increased from 25% to up to 50% of the peak dose).
- The manufacturing process is time consuming and as a result changes in blocking, which may be required during a course of treatment, are difficult to implement.

## 22.5.4 MULTILEAF COLLIMATION

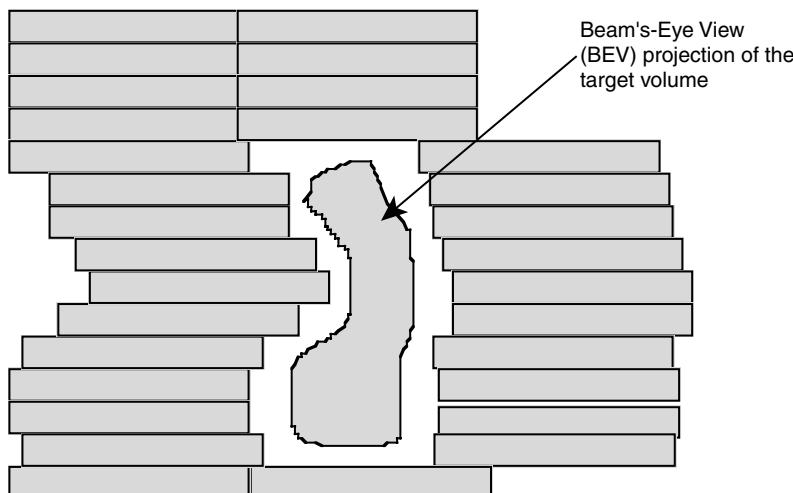

### 22.5.4.1 Standard Multileaf Collimators

The multileaf collimator (MLC) was designed as a way of overcoming most of these difficulties. Details of the construction of multileaf collimators have been discussed in [Section 11.4.3](#).

As compared with a conventional collimator, which has 4 collimators arranged as 2 orthogonal pairs, the MLC consists of 2 banks of leaves which can be individually positioned. The radiation field can therefore be shaped to match the projection of the target volume from each beam direction within the resolution of the leaves. Figure 22.17 illustrates the principle and shows the stepped beam edge which would be avoided with a customised block.

In considering the performance characteristics of a multileaf collimator the following considerations are important:

1. Radiation transmission and leakage:
  - a. Radiation transmitted through the leaf material
  - b. Radiation leakage between adjacent leaves
2. Resolution:
  - a. The size of the steps defining the beam edge
  - b. The maximum size of the field
  - c. The maximum projection of the leaves across the central axis
3. Penumbra:
  - a. How well the leaves are focused

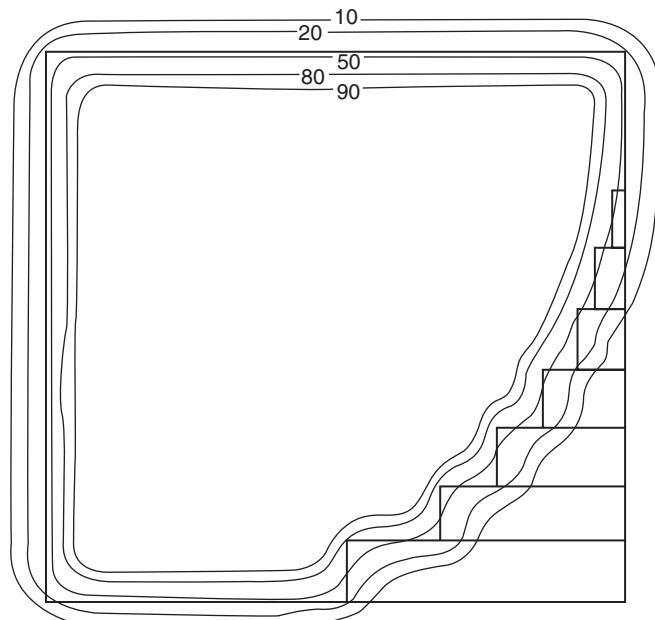

**FIGURE 22.17**  
Leaves shaping the beam to match the target with a margin.

4. Precision:
  - a. The accuracy of the leaf positioning
5. Beam modification:
  - a. How the MLC affects the clinical dosimetry of the beam (percentage depth dose, field size factors, etc.)

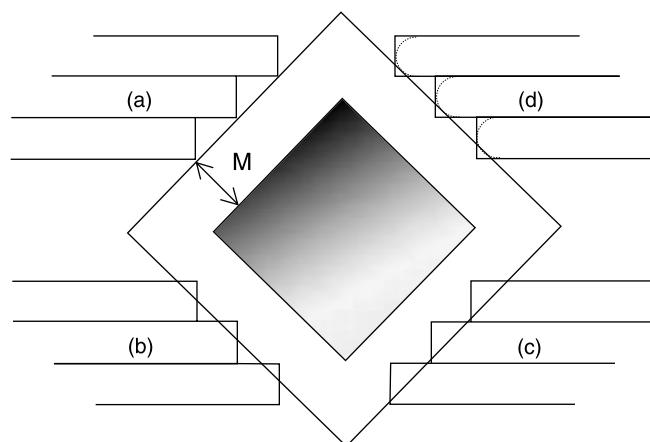

The position of the leaves is of some interest, but only as a surrogate for the position of the isodose curves. Clearly the precise position of each isodose depends on the geometry of the multileaf collimator and the radiation scattering processes that occur in the treatment head and in the patient or phantom. Figure 22.18 shows the isodoses on a plane normal to the central axis of a beam with a relatively simple shape.

It can be seen that even where the stepping of the beam edge is most evident the isodoses are relatively smooth. These isodoses were measured for a single field at  $d_{\max}$ . The effects of scatter in the patient will smooth the curves even further and for multiple beams the undulations from one field will not necessarily register with those from the other fields. However, this does not mean that lower level isodoses are unimportant. If the planned target volume is defined by the 90% isodose, then an undulating contribution at the 10% level from one field can add to a relatively smooth distribution which has reached the 85% level from other fields. It can also have a significant effect on the final position of the defining isodose.

There is no evidence that an MLC significantly alters the percentage depth dose as compared to customised blocks, but measurable changes to head scatter do occur (see [Section 23.2.1.12](#)). These result in changes to field area factors and have to be taken into account in accurate planning. The degree to which the collimator scatter factor is affected by the MLC will depend on the position of the MLC relative to the collimator jaws and monitor chamber. Thus the effect of the leaf positions on the head scatter factor will be greater with the Elekta design than with the Varian design.

**FIGURE 22.18**  
Typical isodose lines at  $d_{\max}$  for an MLC shaped field.

**FIGURE 22.19**

Leaf fitting strategies. A diamond-shaped planning target volume (shaded) is expanded uniformly along each of its edges by an MLC margin  $M$  to create an expanded BEV contour. Leaves are shown fitted to the expanded contour using touch (a) inner edge, (b) centre, (c) outer edge, (d) circle strategies. (From Fenwick, J. D. et al., *Phys. Med. Biol.*, 49, 1505–1519, 2004. With permission.)

As the edge of an MLC field is stepped, it is necessary to have some rules about where leaves should be positioned relative to the boundary of the expanded target volume. Figure 22.19 illustrates the problem. The leaves can be set so that:

- (a) Their tips touch the boundary.
- (b) The leaf centre is a best fit to the boundary.
- (c) The troughs touch the boundary.
- (d) Rounded tips touch the boundary.

The rule applied will depend on the main intention of the field shaping since the best compromise must be reached between irradiating the target correctly (a) and ensuring a good protection of healthy tissue (c). In clinical practice, the intermediate solution (b) is often preferred.

This is not a problem unique to the MLC. The geometric projection of any collimator is insufficient to describe the dose distribution. Any rules relating geometric edges of beams to the position of a particular isodose are only rules of thumb. If it is necessary to know where the beam edge is to a precision better than a few millimetres, the full 3D dose distribution must be considered. In the case of an MLC, it is important to establish that the planning system chosen can cope adequately with the stepped beam edges. It may be necessary to combine a knowledge of the geometric shape of the isodoses relative to the leaf positions obtained by measurement, with the knowledge of the relative contribution of the other beams.

The issue relative to fitting of MLC leaves for clinical situations is discussed further in [Section 32.4.4](#).

#### 22.5.4.2 Mini and Micro Multileaf Collimators

The reduction in treatment volume afforded by the use of standard MLCs is comparable with that of customised divergent blocks, but the precise delineation of the edge of the treatment volume is in many cases compromised by the projected width of the MLC leaves. The stepping of the field edge, caused by an MLC with a projected leaf width of 10 mm, has been identified as a potential limitation in the restriction of morbidity in up to 19% of cases (Galvin et al. 1992). The limitations imposed by the leaf width have been addressed by smoothing techniques and the development of MLCs with narrower leaves, described as mini or micro

MLCs. The distinction between *mini* and *micro* is arbitrary, but it has been suggested that MLCs with leaves projecting to between 2 mm and 5 mm should be considered as mini-MLCs and those below 2 mm as micro-MLCs (Bortfeld et al. 2000). It should be noted that by this definition the Varian 120 leaf MLC is a mini-MLC for fields up to 20 cm long.

Field edge smoothing can be achieved by the superposition of multiple fields, each of whose centres are shifted slightly relative to the next (Galvin et al. 1996). An alternative method of smoothing is to superimpose multiple fields rotated about the collimator axis, but the need to use a wedge filter may limit this approach. Superposition techniques provide smoothing but not increased resolution, and they are severely limited in cases where it is necessary to shape a field with features less than 1 cm in the direction normal to that of leaf movement. A further disadvantage is that movement of the patient between fields increases the complexity of verification compared to that required for treatment with a single field.

The improved resolution that is achievable by the use of MLCs with narrower leaves was discussed in [Section 11.4.3.2](#). The number of leaves and the leaf width determine the maximum field size, which in all cases is much smaller than for a conventional MLC. This has been justified if the main application is in stereotactic radiosurgery, where it has been estimated that 95% of cases can be treated within the range of field sizes from 1 cm to 6 cm (Schlegel et al. 1997). In other applications, if precise shielding of a critical structure adjacent to the periphery of a large field, or a field which is significantly offset relative to the central axis is required, these devices will have limitations. Specifically, their use to provide precisely-defined boosts to fields larger than the maximum covered by the micro-MLC presents the logistical difficulties of having to attach the micro-MLC to the treatment machine between the delivery of the main and boost fields to each patient.

---

## 22.6 BEAM MODULATION TECHNIQUES

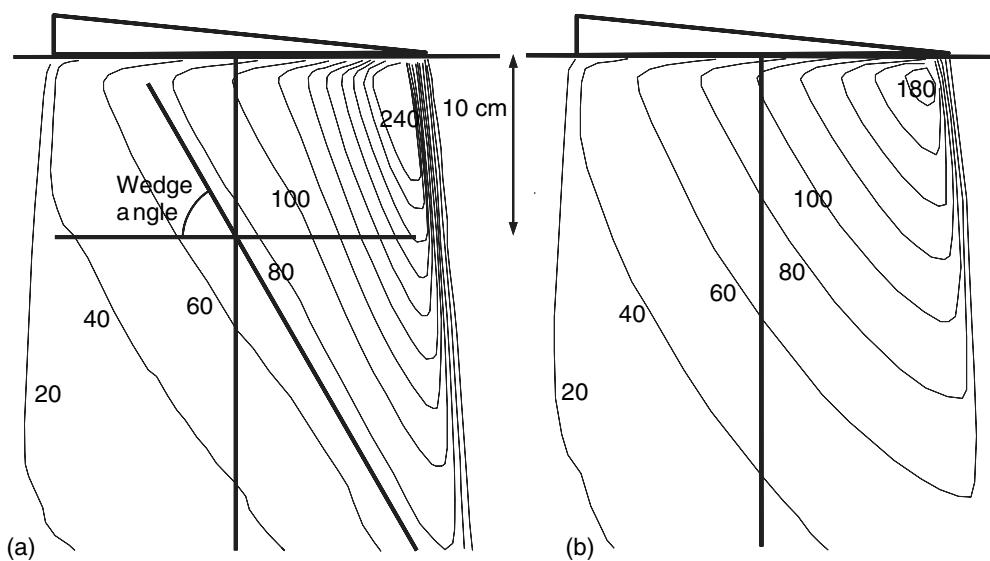

Although beam blocking is very effective in conforming the projection of each beam to the target volume, it does nothing to ensure uniformity of dose within the volume to be treated. This is important because, for a given mean dose, the maximum Tumour Control Probability is achieved with a uniform dose distribution within the target volume. However, a deliberately non-uniform dose may sometimes be desirable close to a sensitive normal tissue. More often, non uniform dose distributions are achieved on each individual beam of a composite treatment plan, either to compensate for surface irregularities or to obtain a resulting uniform dose from the addition of several modulated beams.

### 22.6.1 MECHANICAL FIXED OR MOTORISED WEDGE FILTERS

In order to produce a wedge shaped isodose distribution as shown in [Figure 22.20](#) wedge filters may be introduced into the beam. The different types of wedge filters currently used have been described in [Part C](#) (see [Section 11.4.4.1](#) for accelerators and [Section 12.2.4](#) for cobalt-60 machines).

A wedge is characterised by its *wedge angle*. This is defined as the angle between the wedge isodose lines and a line perpendicular to the central axis of the beam (see Figure 22.20a). According to the ICRU Report 24 (1976) this should be defined at a depth of 10 cm. The older definition of the angle of the 50% isodose is not recommended because it is more appropriate to cobalt-60 beams than to the more penetrating megavoltage beams. At greater depths the isodose angle will be smaller because the increased scattered radiation will reduce the wedge effect.

Another useful quantity is the *wedge factor (WF)* defined as the ratio of the dose with and without wedge for a specified field size and at a specified depth on the beam axis. This factor is mostly dependent on the on-axis transmission of the wedge for the primary beam. Therefore,

**FIGURE 22.20**

Dose distribution resulting from the introduction of a wedge filter into the beam. The results of two wedge designs is shown—(a) designed to produce isodoses that are at the wedge angle all the way across the field (Elekta SL75/5) and (b) a simple triangular shape (Elekta SL15). The definition of the wedge angle is illustrated in (a). Note that the symbol of the wedge does not represent the actual shape of the wedge (see [Figure 22.21](#)).

for a fixed mechanical wedge,  $WF$  is not very sensitive to changes of depth or field size.  $WF$  is used principally to calculate the number of monitor units (see 22.6.1.2 and [Chapter 23](#)).

If a limited number of mechanical filters are available, intermediate angles may be obtained from a weighted addition of beams with and without wedge. The proportion of the treatment for which the wedge is inserted into the beam in order to obtain the desired effective wedge angle can be calculated from the following expression (Petti and Siddon 1985):

$$\frac{\text{on-axis dose with wedge}}{\text{on-axis total Dose}} = \frac{\tan(\text{desired wedge angle})}{\tan(\text{maximum wedge angle})} \quad (22.4)$$

The same principle is applied in the case of automatically-moving (or motorised) wedges. Table 22.3 illustrates how intermediate angles may be obtained from the 60° motorised wedge filter of a GE Saturne accelerator.

**TABLE 22.3**

Example of Intermediate Wedge Angles Obtained for the 6MV Beam of a GE Saturne Accelerator Equipped with a 60°Motorised Wedge

Desired wedge angle	$\frac{\tan(\text{wedge angle})}{\tan(60^\circ)}$	Weight of the 60° wedged beam (dose)	Weight, $K_{MU}$ , of the 60° wedged beam (monitor units)	Equivalent wedge factor ( $WF_{eq}$ )
0°	0	0%	0%	1.00
20°	0.21	21%	40%	0.76
30°	0.33	33%	55%	0.67
40°	0.48	48%	70%	0.58
50°	0.69	69%	85%	0.49
<b>60°</b>	<b>1.00</b>	<b>100%</b>	<b>100%</b>	<b>0.40</b>

As can be observed from [Table 22.3](#) it is important to avoid confusion between the weight expressed in terms of *dose* (third column) and in terms of *monitor units* (fourth column). The former will be used to combine beams with and without wedge in a treatment planning system. The latter will be used at the treatment console or in a record and verify system to set the number of monitor units to be actually delivered by the accelerator. The fifth column represents the *equivalent wedge factor*,  $WF_{eq}$ , defined as the ratio of the total dose resulting from the combination of wedged and open field to the dose which would be obtained for the same number of MU in an open field.  $WF_{eq}$  is a useful practical quantity, as a replacement of  $WF$ , to calculate the number of MU for a preset combination of open and wedged filter (see [Section 23.3.4.2](#)).

The relationships between the quantities presented in Table 22.3 may be established as follows: Let  $\dot{D}_o$  be the dose per monitor unit in the open field at an on-axis reference point. For a given combination, the total dose at the reference point is:

$$D_t = D_o + D_w = (MU_o \times \dot{D}_o) + (MU_w \times \dot{D}_o \times WF) \quad (22.5)$$

where  $MU_o$  and  $MU_w$  are the number of monitor units used to deliver the dose  $D_o$  and  $D_w$  without and with wedge filter respectively. This can also be written in terms of the equivalent wedge factor:

$$D_t = \dot{D}_o(MU_o + MU_w) \times WF_{eq} \quad (22.6)$$

The *wedged MU factor*, defined as the proportion of MU with wedge (4th column of table 22.3) may be written as:

$$K_{MU} = \frac{MU_w}{MU_o + MU_w} \quad (22.7)$$

Combining Equation 22.6 and Equation 22.7, we can calculate the *equivalent wedge factor* as:

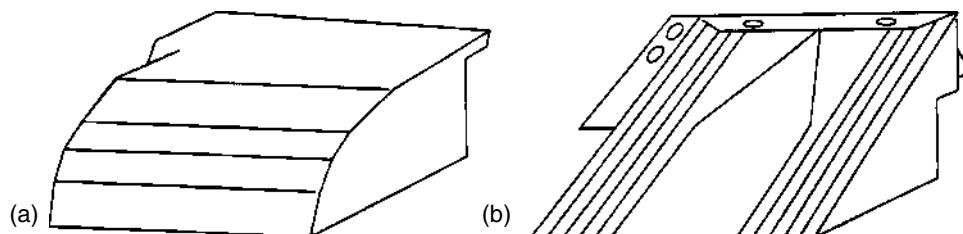

$$WF_{eq} = \frac{D_t}{\dot{D}_o (MU_o + MU_w)} = 1 - K_{MU}(1 - WF) \quad (22.8)$$

The *wedged dose weighting factor* of Equation 22.4 (3rd column of table 22.3) is then:

$$\frac{D_w}{D_t} = K_{MU} \times \frac{WF}{WF_{eq}} \quad (22.9)$$

Since  $WF$  is slightly field size and depth dependent the *wedged dose weighting factor* and the *equivalent wedge factor* may vary to some extent for a specified value of the *wedged MU factor*. However, fixed average values as shown in Table 22.3 are generally acceptable within 2% or 3%. Instead of being applied to preset combinations of wedged and open beams, Equation 22.4 to Equation 22.9 may be used in a continuous way to generate any angle intermediate between 0° and the maximum angle defined by the mechanical wedge.

It should be noted that the names given to the quantities discussed above have not gained general acceptance. Therefore, various manufacturers or medical physicists may use different terminologies or concepts. A thorough understanding of the local definitions is essential to avoid potential serious errors which could result from an improper use of all these wedge related factors.

**FIGURE 22.21**

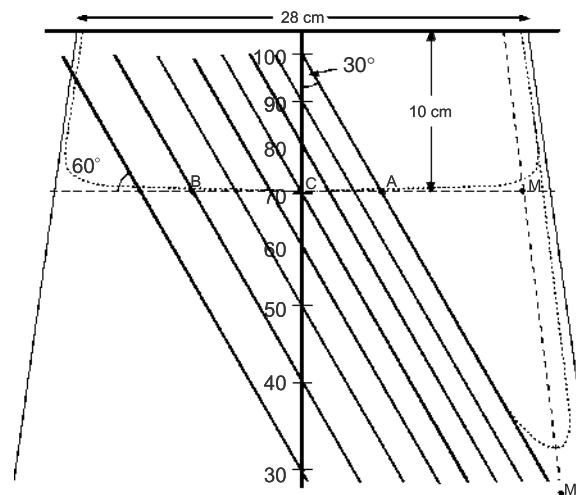

Wedge shapes used to produce the wedge profiles shown in Figure 22.20. The appearance of a rounded shape (a) is illusory as in fact there are two distinct values of the slope of the wedge face which changes on the central axis. In the design (b) — also pictured in Figure 11.27 — the slope is constant across the face of the wedge but the thickness varies in the unwedged direction to compensate both for the oblique path through the wedge and the less penetrating off-axis radiation. (Courtesy of Elekta Oncology Systems.)

### 22.6.1.1 Design of Mechanical Wedge Filters

The design of a manual mechanical wedge filter is based on an isodose curve of the largest open field size that is required to be wedged (Aron and Scapicchio 1966). The aim is to produce a series of isodose lines crossing a line perpendicular to the axis of the beam at 10 cm depth at the appropriate wedge angle. An idealised wedged isodose curve can be drawn on a template based on the central axis depth doses as indicated in Figure 22.22. If we assume that the wedge will not affect the depth dose characteristics of the beam, we can draw the central axis of the beam and, using the open field depth-dose data, mark off the points at which the isodose lines cross the central axis at, say, 10% intervals. Angled lines are drawn through these points. Figure 22.22 shows such an idealised curve for a wedge angle of 60°. The ray line M-M' represents the ray line at the tip of the wedge where there is no attenuation required. The dotted lines represent the unwedged isodose line and the wedged isodose line passing through the point A. Point A is the point at which the line through the dose maximum (100%) on the central axis crosses the line at 10 cm depth\*. The transmission at A and beyond must be calculated by consideration of the open field dose at the point M', where the wedged isodose through A intersects the zero attenuation ray line. In an idealised world the open field depth dose at M' where the line through A meets the projection of the ray line through M is about 28% compared to the dose rate at 10 cm deep (70%)†. We may deduce that the transmission required on the ray line through A is  $28/70 = p$ . A similar process can be carried out for other points to the right of A, for each point searching for the intersection with the ray line through M. It is easier to calculate the relative transmission required at points to the left of A. Considering point B, it will be seen that it is the 40% isodose that must pass through B so that if the transmission at A is  $p\%$ , the transmission at B must be  $p \times 40/100$ . The wedge factor can be calculated by considering the transmission on the central axis at C. The transmission here is  $p \times 70/100$ , i.e. 28%, which is comparable with the wedge factor measured in practice. To determine the shape of the wedge it is necessary to consider its position in the head of the treatment machine. Let us suppose that the wedge is to be placed 30 cm from the source. Point A is 4.9 cm from central axis and this corresponds to  $(4.9 \times 30)/110 = 1.34$  cm from the central axis at the wedge distance. Point B is equivalent to a point 1.93 cm from the central axis. The thickness of the wedge at the points can be calculated for the required attenuation based on the linear attenuation factor of the material of the wedge for the current energy spectrum.

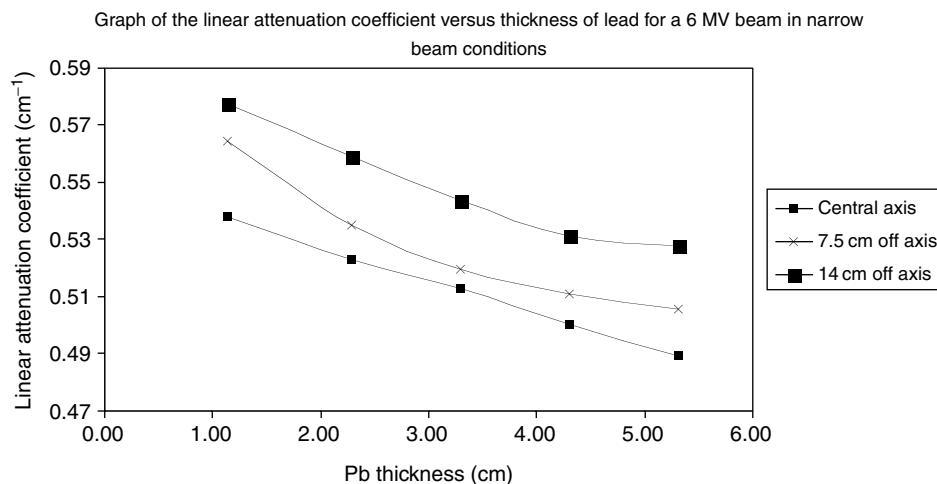

\* For a shallower wedge or a narrower field this point may lie outside the beam.

† As indicated by the dotted curves the real isodoses will be rounded towards the edge of the field, but using the points M and M' provides sufficient accuracy at this stage.

**FIGURE 22.22**

Wedge filter design for a 60° wedge for a 28 cm wide field and a 6 MV beam. See text for explanation.

A number of other factors must be considered when designing a real wedge. The idealised approach above assumes that the unwedged profile is perfectly flat. If at point A the off-axis factor was 1.02 the attenuation required along that ray line could be increased by 2%. The linear attenuation factor will decrease as the thickness of the wedge increases because of beam hardening as is shown in Figure 22.23. The attenuation factor is also dependent on the radial distance from the centre of the beam because of the beam-hardening effect of the flattening filter (see Section 22.2.2). The simplistic approach taken above is based on primary beam attenuation and takes no account of scatter (Mageras et al. 1991; Heukelom et al. 1994a). The effect of scatter will be to reduce the wedge effect and will require a thicker wedge. Calculating the effect of scatter is not easy and in practice it is simpler to make a prototype wedge and to measure the resulting isodose curves. Corrections can then be

**FIGURE 22.23**

Variation of lead effective attenuation coefficient with lead thickness and position within the field. (Data measured at Clatterbridge Centre for Oncology.)

calculated to improve the design. Finally account must be taken of the effect of the different energies if the wedge is to be used in a multi-energy accelerator. In practice this is not as great a problem as it would appear because both the value of the attenuation coefficient and the equivalent depth of water increase roughly in proportion for energies where Compton scattering dominates. The wedge isodose curves shown in [Figure 22.20a](#) would be produced if the above method of wedge design is followed.

Although this wedge design meets the specification, there are some problems with this approach. With the advent of asymmetric collimators, there has been a demand for larger and larger wedged fields and for these to be used in asymmetric mode. A large field size is particularly important in the unwedged direction. If half-blocked beams are being used to facilitate field matching, an unwedged field length up to 36 cm is required for a half field length of 18 cm, which would be typical of the size required for a breast treatment. The assumption made in most planning systems is that the beam profile in the unwedged direction is unaffected by the presence of the wedge. In order for this to be the case, the wedge needs to be thinner at the edges than at the centre because of the change in half-value thicknesses at different radial distances from the centre. When asymmetric fields are used in the wedged direction, the effect of scatter will change depending on whether the thin end or the thick end of the wedge is being used. There will therefore be a marked difference in the isodoses when the heel of the wedge (the thick part) or the toe (the thin part) is used. For this reason a wedge shape which has a uniform slope is preferred. The large wedge currently installed in Elekta linacs ([Figure 11.27](#)) conforms to the design shown in [Figure 22.20b](#) and [Figure 22.21b](#).

### 22.6.1.2 Dosimetry Considerations for Wedge Filters

Wedged fields will have a number of differences from open fields. The electron contamination of the beam is likely to be less, resulting in lower skin dose (Klein and Esthappen 2003). The hardening of the beam will also result in the beam being more penetrating than the open field. Thus it is important to measure the depth dose curve for the wedge directly and not to assume that it is the same as for the unwedged field (Knöös and Wittgren 1991; Heukelom et al. 1994b).

The introduction of a wedge into the beam will clearly reduce the dose rate on the central axis of the beam. The ratio of the dose rate at the depth of dose maximum with the wedge in place to the dose rate with an unwedged field is called the *wedge factor*. The wedge factor may also be defined as the ratio of the doses with and without the wedge at some different specified depth. In principle the magnitude of the wedge factor relates to the thickness of the physical wedge on the central axis of the beam, but because of the effects of scatter (see above) and of beam hardening the wedge factor will also vary with depth and field size. The wedge factor may be measured directly at the calibration depth making an exposure with and without the wedge, but, depending on the exact definition adopted for the wedge factor, it will be necessary to make a correction for the different percentage depth doses of the wedge and open fields (Knöös and Wittgren 1991). The wedge factor for a given wedge will depend on the maximum permitted field width in the wedged direction. This is because a greater width of the wedge also implies a greater thickness of material at the centre of the beam. The wedge factor will be smaller (i.e. the reduction in dose rate will be greater) as the wedge angle increases. For a typical 60° wedge allowing a field width up to 30 cm, the wedge factor will be about 0.3. For a given wedge it will also be a function of the actual field size used and wedge factors must therefore be measured over the full range of field sizes. On a cobalt-60 unit where the dose rate is already relatively low, it is common practice to have different wedges for small and large fields. Another technique that has been used is to attach the wedge by a pin to the collimator jaw on the thin side of the wedge so that the wedge thickness in the beam is the minimum necessary for the jaw opening. This has the drawback that the wedge factor varies rapidly with field size. It increases the risk of

error and has proved difficult to model in treatment planning computers. In measuring the wedge factor it is important to take the mean of the two values obtained when the wedge is rotated through 180° and to ensure that, if a thimble ion chamber is used, the thimble is parallel to the unwedged direction (see [Section 19.2.6](#)).

Another factor to be considered in the design of automatic wedges is the direction of wedge movement and the arrangements for ensuring that the wedge is correctly positioned. Ideally the wedge should slide along runners that are parallel to the unwedged direction. In this arrangement a small positioning error has no effect on the wedge factor. This arrangement is also to be preferred for manually inserted wedges, although it might be in contradiction with the IEC recommendation on wedge orientation (IEC 1996) or with practical ease of use. Wedges can be used to compensate for missing tissue or to allow beams to be brought in from two angled directions. In correcting for skin obliquity the wedge angle should be reduced in the proportion indicated in [Table 22.1](#) compared to the angle between the skin surface and a line perpendicular to the beam (see [Figure 22.12](#)). In combining two beams the wedge angle should be half the complement of the angle between them (see [Section 33.3.5](#)). Often the reason for use of the wedge is a combination of the two, and in a simplistic way the two angles can be added together. It is not essential to use the wedge angle defined by this method, which may in any case not be optimal, but it does provide a good starting point. For example, rather than use two 45° wedges a 60° and a 30° wedge may be used. However, in going away from the natural choice care must be taken that the balance of the distribution is not affected.

### 22.6.2 DYNAMIC WEDGES

The idea of moving the collimator jaws dynamically (i.e. with the beam on) is not new. The disadvantage of not having an automatic wedge system and the increase in the distance from the source to the front of the treatment head that would be involved in designing one has led Varian to pursue the development of the *dynamic* or *flying* wedge (Leavitt et al. 1990). To achieve a wedged beam profile one of the jaws is kept stationary and the other is moved during the treatment. When the dynamic wedge was first introduced each wedge angle used a different series of jaw positions with the jaw starting to move at the start of the beam and moving more or less slowly depending on the wedge angle. Verification and calculation of the wedge factor in such circumstances was difficult. To simplify things the enhanced dynamic wedge (EDW) was developed. This is similar to the automatic wedge described in [Section 22.6.1](#) in that an open field portion is first delivered followed by a wedged portion equivalent to a 60° wedge. There is thus in principle only one wedge that is required to be measured. In a treatment planning system the wedge can either be simulated by a combination of an equivalent solid 60° wedge and an open field, or the jaw positions used (contained in the so-called *Golden Segmented Treatment Table* [STT]) can be simulated directly. The wedge factor for the dynamic wedge depends almost entirely on the field size in the wedged direction (and varies by a much greater amount than fixed or automatic wedges). It is therefore mandatory that a planning system that uses an equivalent solid wedge can be set up to consider the effect of each pair of jaws on the output independently rather than use an equivalent square field. In the Siemens implementation the wedge angle is sensitive to the calibration of the secondary dose rate channel (see [Section 11.7.3.1](#)), but the wedge factor is within 2% of 1.0. Special consideration must be also given to asymmetric fields. It is possible to make direct use of the golden STT in dose calculation (Papatheodorou 1999). Another method for calculating dynamic wedge factors for use in hand calculations which is also able to cope with asymmetric fields is described by Yu (2002). This is based on the number of monitor units for which the point of interest is exposed during the dynamic delivery, i.e.:

$$\text{Wedge Factor} = \frac{\text{Dose for wedged field}}{\text{Dose for open field}}$$

$$= \frac{\text{Monitor units open field}}{\text{Monitor units by wedged field to the point}} \quad (22.10)$$

However, this formula\* does not take into account the change in scatter conditions when the jaw is moving. In practice the scatter dose to the point when the point is nominally shielded counterbalances the loss of scatter caused by the reduction in field size when the point is unshielded. To compensate for this, Yu proposes the revised formula:

$$\text{Wedge Factor} = \frac{\text{GS}(Y_0 + \alpha)}{\text{GS}(Y_F)} \quad (22.11)$$

where  $\text{GS}(Y)$  is the golden STT table value for the jaw position,  $Y_0$  represents the jaw position as it passes the measurement point,  $Y_F$  represents the fixed jaw position, and  $\alpha$  is an empirical factor which is found to have a value 0.6 cm.

The dynamic wedge has the advantage that there is no beam-hardening effect. The depth dose can therefore be considered as independent of the presence of the wedge.

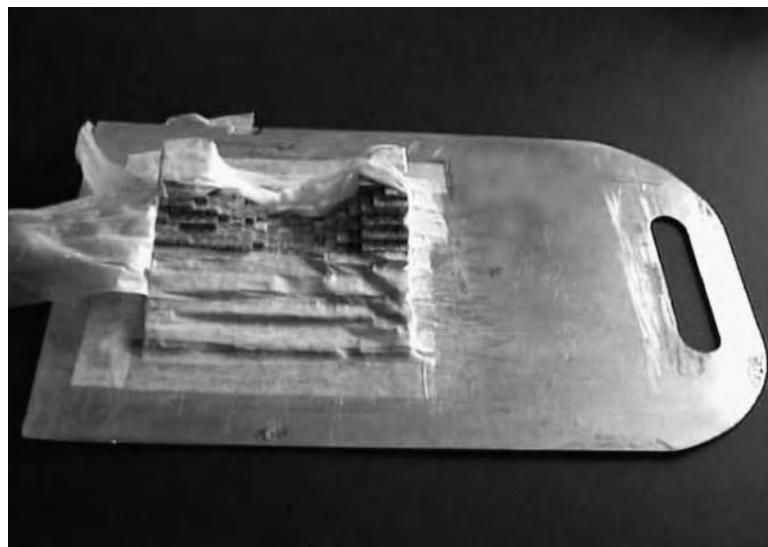

The dynamic wedge is potentially more flexible than fixed wedges because in principle it is possible to design any shape of beam profile that is required. In practice, however, the use of such concepts is limited by the difficulties of quality assurance and treatment planning. Convery and Rosenblom (1992) have shown how any beam profile can be produced if both the jaws can be moved simultaneously with the minimum beam on time. Another suggestion was that a field could be made up in segments (Cardarelli 1991). The problem with such methods of beam formation is that they increase the total beam-on time and this in turn increases the dose delivered to areas of the patient that are not intended to be treated. This approach can be considered as a 1D precursor of 2D intensity modulation (see [Section 22.6.4](#) and [Chapter 43](#)).

### 22.6.3 TISSUE COMPENSATORS

Although wedges provide adequate compensation for missing tissue in many situations, there are areas, such as the head and neck, for which it is very difficult to achieve a uniform dose distribution because of the irregular patient contours. In such situations a custom tissue compensator can be used. Many different approaches to the design of compensators exist. The simplest is to measure the distance to the skin surface from a line perpendicular to the beam. A fixed ratio of thickness of lead (Cardarelli et al. 1991; ICRU 1976) or aluminium (Ellis et al. 1959) to tissue is then used as a compensator (see [Figure 22.24](#)). Wax has also been used since, in principle, it is appropriate simply to scale down the compensator geometrically in the direction perpendicular to the beam axis to allow for beam divergence. However, higher atomic number materials cause less electron contamination (ICRU 1976). In order to obtain the data needed for the design of such missing tissue compensators, it is convenient to use a device to take multiple contours of the patient. This can be conveniently done using a laser outlining system, and the necessary measurements for the compensator can then be carried out automatically in the computer. Thus the inaccuracies associated with making a large number of physical measurements on the patient or the patient's cast are reduced. The problem with using a fixed relationship between tissue thickness and compensator thickness is that the relationship varies with depth and field size. Rather than use a table of equivalent

---

\* It must be stressed that Equation 22.10 is not valid for motorised wedges where the number of monitor units for a wedged beam must be increased, compared to the open beam monitor units, in order to compensate for the beam attenuation (see Equation 22.5 and [Table 22.3](#)).

**FIGURE 22.24**

Missing tissue compensator composed of aluminium blocks taped on a tray at distance from the patient skin.

thicknesses, a more satisfactory approach is to calculate the attenuation required and then to apply the appropriate thickness of compensating material. Even this method is not entirely accurate, as it does not account for the effect of scatter or the effect of increasing thickness on the effective attenuation (as illustrated in [Figure 22.23](#)). However, it does allow inhomogeneities inside the patient to be taken into consideration. In using this approach it is convenient to select a plane within the patient at which to create a uniform distribution (Valdagni et al. 1992). For example several centres have been trying to improve dose homogeneity in treatment of carcinoma of the breast (Solin et al. 1991; Valdagni et al. 1992). Here it is particularly important to allow for the reduced attenuation through the lung. Evans et al. (1995) used the transmission dose measured with a portal imaging device to design an appropriate compensator which automatically included a correction for the lung attenuation.

Such techniques are appropriate for simple single field treatments or for parallel opposed fields. For combinations of beams from several directions, dose homogeneity within the target volume may be improved by considering the combined effect of all the beams and specifically setting out to achieve a homogeneous dose distribution as a result of the combination of beams rather than compensating each beam independently. In the TARGET treatment planning system (developed by GE) an algorithm was developed in the early 1980s to calculate the necessary thickness of an appropriate attenuating material such as lead to produce a homogeneous distribution within the defined target volume. Maps were then printed out to show the compensator shape. In this case it is convenient to use thin lead sheets for the compensator, as these can be cut to the appropriate shape. A more recent development of this idea is to identify the target and the sensitive normal tissues and to assign the desired dose to each. An inverse planning method (see [Section 43.2](#)) is then applied to design the most appropriate fluence profile for each beam in order to optimise the dose distribution according to the specified criteria. Such an approach was adopted in the Nucletron Plato planning system which derives the thicknesses using an inverse planning algorithm. Although this approach was originally designed for use with multileaf collimators, it can also be applied to physical compensators where the quality control difficulties are less. Compensators designed in this way are likely to have a much greater dynamic range, sometimes requiring 4 or 5 half-value thicknesses of the compensator material. In calculating the appropriate thickness of the compensator material it becomes particularly important to consider the

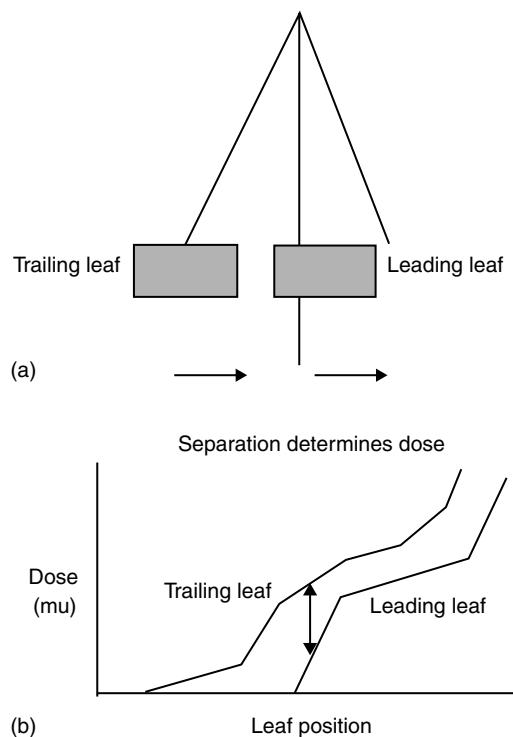

effect of the departure from exponential attenuation (see [Figure 22.23](#)) and to include the effect of the scatter from the compensating material (Castellanos and Rosenwald 1998).

Fabrication of compensators can be a time-consuming process. Automatic compensator production devices have been developed which use a milling machine to fabricate the compensator. These require the input of outline data for a number of slices, which can be obtained from multiple CT slices or from an automatic outlining device. These devices often cut negative formers out of polystyrene which must then be filled with an appropriate absorbing material. Cerrobend could be used but, because of its high density, both the former and its filler have to be more accurate than is easy to achieve. Consequently lower density fillers such as granulate of stainless steel (van Santvoort et al. 1995), loaded plaster of Paris, and tin loaded wax (Jursinic et al. 1994) have been developed.

#### 22.6.4 INTENSITY MODULATION WITH THE MLC

The flying or dynamic wedge concept, originally developed for conventional 4 block collimators can easily be extended for use with the MLC. By judicious prescription of the leaf trajectories the wedge angle need not be the same for each leaf pair and the direction of the wedge gradient can be chosen to be at any angle relative to the major axes of the collimator.

The ultimate delivery system for conformal therapy is the dynamically controlled MLC which is able to produce fields equivalent to compensated fields. Several methods of modulation are available and are further discussed in [Section 43.3.3](#). Figure 22.25 illustrates the method described by Convery and Rosenbloom (1992). Each pair of leaves generates a *sliding window* which is scanned across the field. As the window moves its width is varied so that points in the treatment plane are exposed for variable lengths of time and thus receive varying doses.

**FIGURE 22.25**

Beam modulation using the sliding window dynamic multileaf collimation technique (a) leaf separation (b) beam modulation. (From Convery, D. J. and Rosenbloom, M. E., *Phys. Med. Biol.*, 37, 1359–1374, 1992.)

As discussed in [Section 43.3](#), delivery of a modulated beam can be either by full dynamic control of the MLC where the leaves move during irradiation or by the sequential irradiation of multiple fixed beams, often called *step and shoot* delivery. Various algorithms, *interpreters*, and *sequencers* used to calculate leaf trajectories and sequences have to be integrated with the treatment planning process as, to achieve a particular dose distribution, account must be taken of the head and phantom scatter in addition to the primary beam fluence delivered by the MLC. Determination of trajectories must also take into account machine limitations including the maximum leaf speed, the startup characteristics of the linear accelerator, and any mechanical restrictions necessary to avoid collisions between opposing leaves.

The main difference between intensity modulation for compensation and intensity modulation for enhanced conformation comes from the method used to calculate the so-called *fluence map*. For conformal radiotherapy it is necessarily obtained from inverse planning involving all beams simultaneously, whereas for compensation more simple algorithms can be used on a beam per beam basis (i.e. surface compensation or effective transmission required to get a uniform dose distribution in a given plane). Once the fluence map is determined, the conversion into MLC segments will be carried out using exactly the same interpreter.

## 23.1 INTRODUCTION

Quantitative characterisation of clinical beams is needed in order to undertake the calculation of dose distributions within patients. This calculation is a two-step process where the starting point is the absolute dose calibration in standard conditions, followed by the derivation of the dose at other points in other conditions. Such derivation requires a deep understanding of the beam characteristics presented in [Chapter 22](#) and makes use of a number of quantities and parameters which must be part of a self-consistent system. Many of the parameters defined and discussed in this chapter were originally intended to describe the behaviour of orthovoltage photon beams (see [Section 21.6](#)) and have been adapted or expanded to fit the properties of high-energy (megavoltage) radiation. Only the latter will be considered in what follows. The treatment given here is based on the methodology of Khan (1984).

---

## 23.2 PARAMETERS FOR DOSE CALCULATIONS

### 23.2.1 DEFINITIONS

Given the wide variety in the terminology and symbols used in the literature, a careful definition of the quantities used for photon beam calculations is necessary for the sake of clarity. Notations and conventions used in this chapter are given in [Table 23.1](#) and related ones in [Table 23.2](#). All quantities discussed below are intrinsically a function of beam quality (energy spectrum).

#### 23.2.1.1 Percent Depth Dose

This is one of the basic measured quantities from which many of the other parameters are derived (Burns 1983a). Referring to [Figure 23.1](#) it is defined as

$$\text{PDD}(d, A_s, \text{SSD}) = 100D(d, A_s, \text{SSD})/D(d_{\max}, A_s, \text{SSD}) \quad (23.1)$$

**TABLE 23.1**

Notations and Conventions Used for the Definition of the Dosimetric Quantities Described in This Chapter

$d$	Depth in tissue from surface, measured parallel to beam axis
$d_{\max}$	Depth of dose maximum ( <i>peak</i> )
$d_{\text{ref}}$	Depth of dose reference point
$x$	Off-axis distance from collimator rotation axis (CAX)
SAD	Source to isocentre distance (axis of gantry rotation)
SSD	Source to surface distance
$A$	Field size at isocentre (set field)
$A_s$	Field size at surface, if not the same as above
$A_m$	Field size at $d_{\max}$ , if not the same as above
$A_d$	Field size at point of calculation, if not the same as above
$A_{\text{ref}}$	Reference field size for calibration (usually 10 cm $\times$ 10 cm)
ESQ	Equivalent square field at point of calculation
W	Wedge filter present
$D_0$	Calibration Dose/MU at the reference point for the reference field size (usually 1 Gy/100 MU except for isotope teletherapy machines)

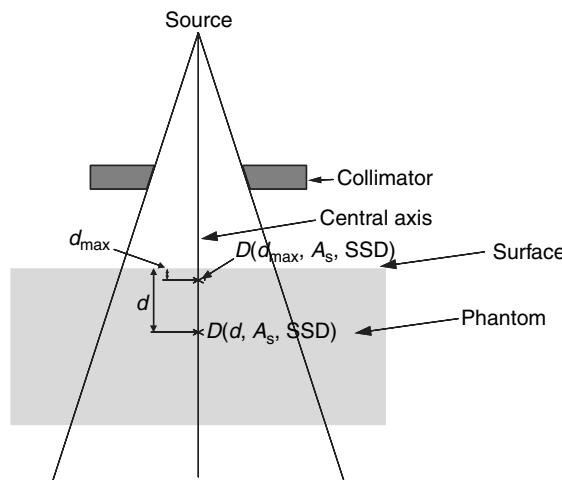

The concept of percentage depth dose (PDD) was the obvious choice for early orthovoltage clinical beams, where the distance from the source to the skin was fixed by the use of an applicator. It is most suited for measurements using a computer controlled water phantom, as the phantom geometry is stationary and the detector moves (see [Chapter 19](#)). The field size

**TABLE 23.2**

Summary of the Related Dosimetric Quantities Defined and Used throughout the Present Chapter

PDD( $d, A_s, \text{SSD}$ )	Percent Depth Dose at Depth $d$ in tissue for field size $A_s$ at surface at SSD
TAR( $d, A_d$ )	Tissue Air Ratio at depth $d$ for field size $A_d$ at calculation point
TMR( $d, A_d$ )	Tissue Maximum Ratio at depth $d$ for field size $A_d$ at calculation point
TPR( $d, A_d$ )	Tissue Phantom Ratio at depth $d$ for field size $A_d$ at calculation point
PSF( $A$ )	Peak Scatter Factor for field size $A$ , defined in tissue at $d_{\max}$
NPSF( $A$ )	Normalised Peak Scatter Factor, defined in tissue at $d_{\max}$
$S_p(d_{\text{ref}}, \text{ESQ})$	Phantom Scatter Factor, for given equivalent square (ESQ) at $d_{\text{ref}}$ , defined in tissue at $d_{\text{ref}}$
$S_c(A)$	Collimator Scatter Factor for set field $A$ , also called Air Output Factor
FOF( $d_{\text{ref}}, A, \text{ESQ}$ )	Field Output Factor, for set field $A$ and equivalent square (ESQ) at $d_{\text{ref}}$ , defined in tissue at $d_{\text{ref}}$
OAR( $x, d, A_d$ )	Off-Axis Ratio at Off-axis distance $x$ and depth $d$ in tissue for field size $A_d$ at calculation point
WF( $d_{\text{ref}}, A_d$ )	Wedge Factor for field size $A_d$ : ratio of output with and without wedge, measured in tissue at $d_{\text{ref}}$
$D(\text{air}, A, \text{SAD})$	Absorbed Dose to water (per MU <sup>a</sup> ) on the CAX in air at a distance SAD from the source, for field size $A$ at isocentre
$D(d_{\text{ref}}, A_d, \text{SSD})$	Absorbed Dose (per MU <sup>a</sup> ) on the CAX at depth $d_{\text{ref}}$ in tissue with surface at SSD for field size $A_d$ at calculation point
$D(d_{\max}, A_d, \text{SSD})$	Absorbed Dose (per MU <sup>a</sup> ) on the CAX at depth $d_{\max}$ in tissue with surface at SSD for field size $A_d$ at calculation point (= $D_{\max}$ )
$D(d, A_s, \text{SSD}, W)$	Absorbed Dose (per MU <sup>a</sup> ) on the CAX at depth $d$ in tissue with surface at SSD for field size $A_s$ at surface with (possibly) a wedge filter present
$D(d, A_d, \text{SSD}, W)$	Absorbed Dose (per MU <sup>a</sup> ) on the CAX at depth $d$ in tissue with surface at SSD for field size $A_d$ at calculation point with (possibly) a wedge filter present
$D(x, d, A_d, \text{SSD}, W)$	Absorbed Dose (per MU <sup>a</sup> ) at a point $x$ cm away from the CAX at depth $d$ in tissue with surface at SSD for field size $A_d$ at calculation point with (possibly) a wedge filter present

<sup>a</sup> For definition of monitor units (MU) see [Section 20.1.2](#).

**FIGURE 23.1**

Percent depth dose is  $100 \frac{D(d, A_s, \text{SSD})}{D(d_{\text{max}}, A_s, \text{SSD})}$ , where  $d$  is any depth and  $d_{\text{max}}$  is the reference depth of maximum dose.

parameter  $A_s$  refers to the value at the surface of the phantom (or, alternatively, at the depth of dose maximum), not at the point of measurement. Also, as the PDD is a ratio of doses at two different points in space, its value is dependent on the source surface distance (SSD) at measurement. We will discuss below how to convert PDD from one SSD set-up to another.

### 23.2.1.2 Tissue Air Ratio

With reference to Figure 23.2, tissue air ratio (TAR) is defined as the ratio of dose in water measured at depth on the beam central axis in a large phantom, to the dose to water measured in air at the same point (i.e. at same distance from the source):

$$\text{TAR}(d, A_d) = \frac{D(d, A_d, \text{SSD})}{D(\text{air}, A_d, \text{SAD})} \quad (23.2)$$

where in this case,  $\text{SSD} = \text{SAD} - d$ , to emphasise that the doses refer to the same point in space.

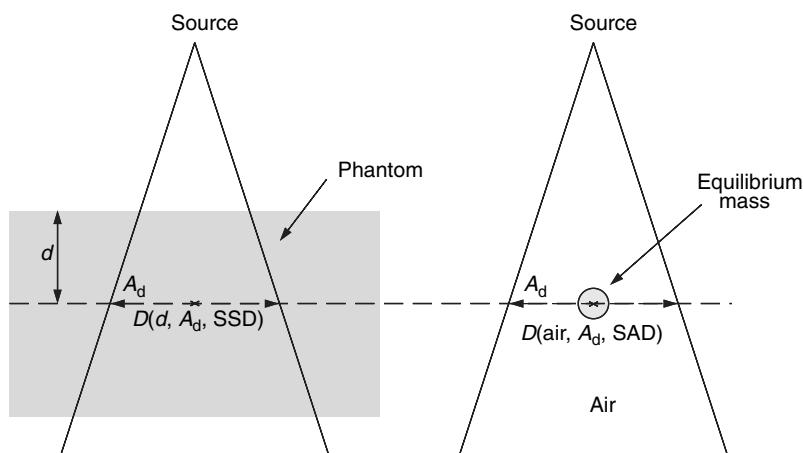

**FIGURE 23.2**

Illustration of the Tissue Air Ratio as defined in Equation 23.2.

In contrast to PDD, the field size parameter  $A_d$  always refers to the value at the point of measurement or calculation.

The original definition of TAR was given by ICRU 23 (1973) as, “the ratio of the absorbed dose at a given point in a phantom to the absorbed dose which would be measured at the same point in free air within a volume of the phantom material just large enough to provide *the maximum electronic build-up* at the point of reference”. In ICRU 24 (1976) the words in italic were replaced with *electronic equilibrium*.

Burns (1983b) and others pointed out several difficulties with this definition; mainly, the fact that, for high energy beams, the build-up volume becomes so large that the denominator  $D(\text{air}, A_d, \text{SAD})$  is not free of scattered contribution. Additional problems arise when we consider the TAR for field sizes smaller than the minimum diameter of the build-up material, and with the definition of peak scatter factor (PSF) (see below). An alternative definition replaces the denominator in Equation 23.2 with *absorbed dose at  $d_{\max}$  due to primary radiation only*. This definition makes the task of measuring TAR directly even more difficult than the original version. Measurements in air using ionisation chambers with a build-up cap are fraught with difficulties, while separating primary from scattered radiation is a task best left to Monte Carlo simulations. In spite of this, the TAR concept is still useful to relate dose in air, which is assumed to follow the *inverse square law* (see [Section 23.2.1.16](#)), to dose in tissue. For this reason, Burns (1983b) proposed an empirical, albeit somewhat circular, definition for TAR in terms of more easily measurable quantities:

$$\text{TAR}(d, A_d) = \text{TMR}(d, A_d) \cdot \text{PSF}(A_d) \quad (23.3)$$

where the other quantities are defined below. In practice, TAR values are frequently derived from measured PDD curves, as discussed in the next section.

### 23.2.1.3 Peak Scatter Factor

The definition of peak scatter factor (PSF) was adapted from the original definition of back scatter factor (BSF) that was defined at the surface for orthovoltage beams (see [Section 21.6.1](#)). The most recent definition refers to the depth of dose maximum (*peak*):

$$\text{PSF} = \frac{\text{absorbed dose in tissue at depth of dose maximum}}{\text{absorbed dose at same point due to primary radiation only}} \quad (23.4)$$

Thus, PSF is a special case of TAR, i.e.  $\text{PSF}(A_d) = \text{TAR}(d_{\max}, A_d)$ , and as such suffers from the same difficulties in measurement. Values for high-energy beams have been published, based on Monte Carlo calculations (Li 1999). In practice, for high-energy beams, it is the ratio of two PSF's that is utilised. This is called the *normalised peak scatter factor* (NPSF) as discussed in [Section 23.2.1.11](#). Note that, by definition,  $\text{PSF}(0) = 1$ .

### 23.2.1.4 Zero Field Tissue Air Ratio (TAR0)

An ancillary definition is the zero-field size TAR:  $\text{TAR0}(d) = \text{TAR}(d, 0)$ , a quantity that represents the attenuation of the primary beam in tissue with no scatter contribution. Its behaviour beyond the depth of maximum dose can be approximated by a simple exponential attenuation curve:  $\exp[-\mu(d - d_{\max})]$  where  $\mu$  is the effective linear attenuation coefficient for the beam in the given phantom. The value of  $\mu$  is energy dependent and requires some averaging for a polyenergetic beam. It will also change for fan lines at an angle from the central axis, because of the differential filtration of the flattening filter. This quantity can be measured using a column of water or solid phantom in a narrow beam geometry similar to HVL measurements for orthovoltage beams (Karlsson et al. 1993; Zefkili et al. 1994). More often, it is derived from extrapolation of the TAR values for finite field sizes. TAR0 is used

mainly to separate the primary and scatter components of the radiation beam. Note that, by definition,  $\text{TAR}_0(d_{\max}) = 1$ .

### 23.2.1.5 Scatter-Air Ratio

Cunningham (1972) introduced the scatter-air ratio (SAR), defined as “that part of the TAR that is due to radiation scattered solely within the phantom” (ICRU 1974) and calculated from the following expression:

$$\text{SAR}(d, A_d) = \text{TAR}(d, A_d) - \text{TAR}_0(d) \quad (23.5)$$

The SAR can be considered as independent of the distance to the source. We will encounter this quantity again when discussing scatter summation for irregular fields (see Section 23.2.1.8).

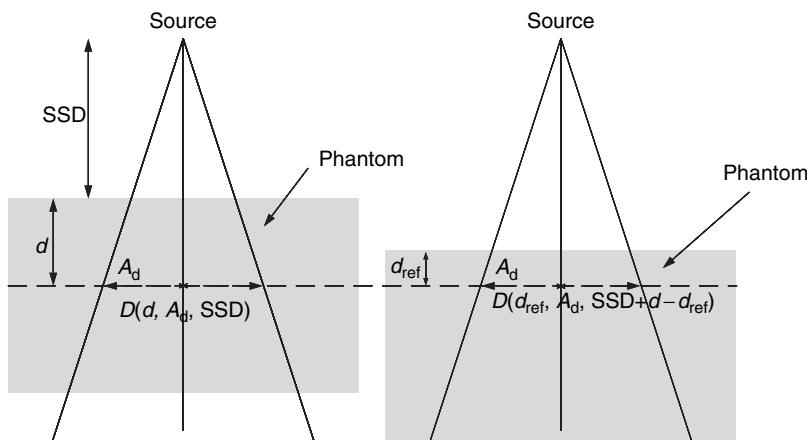

### 23.2.1.6 Tissue Phantom Ratio TPR (Tissue Maximum Ratio TMR)

Because of the above mentioned difficulties with in air measurements for high energy beams, a new quantity was introduced (Karzmark et al. 1965; Khan 1984) that relates two doses, both defined in phantom. The general form of this quantity, TPR, is defined as the ratio of the dose at a given point on the beam central axis in phantom to the dose at the same point at a fixed reference depth  $d_{\text{ref}}$ , all other machine parameters being constant, i.e.:

$$\text{TPR}(d, A_d) = \frac{D(d, A_d, \text{SSD})}{D(d_{\text{ref}}, A_d, \text{SSD} + d - d_{\text{ref}})} \quad (23.6)$$

When  $d_{\text{ref}}$  is chosen as  $d_{\max}$ , the TPR becomes the TMR (Figure 23.3).

These quantities are measured in water or water-substitute solid phantoms by keeping the detector at a constant distance from the source and varying the overlying depth of material. As small a detector as possible (such as a flat chamber with small gap) should be used when measuring close to  $d_{\max}$ , to avoid errors due to the displacement of water by the chamber cavity. As TPR is a ratio of two doses at the same point for the same field size, it is practically independent of the distance of the point in question from the source (as is true for TAR). Note that, by definition, both  $\text{TPR}(d_{\text{ref}}, A_d)$  and  $\text{TMR}(d_{\max}, A_d)$  are equal to 1.

**FIGURE 23.3**

Diagram illustrating the definitions of tissue phantom ratio (TPR) and tissue maximum ratio (TMR). TPR is defined as in Equation 23.6. If  $d_{\text{ref}}$  is the depth of maximum dose then the TPR becomes the tissue maximum ratio (TMR).

### 23.2.1.7 Zero Field Tissue Maximum Ratio ( $TMR_0$ )

An ancillary definition is the zero-field size TMR:  $TMR_0(d) = TMR(d, 0)$ , a quantity that is analogous (actually, numerically identical) to the zero-field size TAR discussed in [Section 23.2.1.4](#). The definition and derivation of scatter maximum ratio (SMR) (see [Section 23.2.2.5](#)) will have to wait until some necessary quantities are defined below.

### 23.2.1.8 Equivalent Square

The equivalent square (ESQ) concept is invaluable in clinical dose calculations for photon beams (Day and Aird 1983). As it is not practical to measure every single possible field size and shape, interpolations need to be made between measured (tabulated) values of quantities that are a function of scattered dose as well as of the primary radiation. Most of these quantities (TAR, TPR, PDD, NPSF, etc.) are measured for a series of square fields on accelerators with orthogonal collimators. Thus other field shapes need to be expressed in terms of an equivalent square for interpolation purposes. The definition of ESQ is the side of the square field that has the same SAR at the calculation point as the field in question. For example, circular fields of radius  $r$  have the same SAR as squares of the same area, i.e.  $ESQ = r\sqrt{\pi}$ . There are a number of ways to calculate ESQ for more irregular fields:

- *Table look up* (for rectangular fields). Tables of ESQ for rectangular fields can be found in BJR Supplement 25 (Day and Aird 1983). These tables were originally obtained by application of Clarkson's method (Clarkson 1941) for a particular energy, but are accurate for all clinically used beam qualities.
- *Sterling's formula* (Sterling et al. 1964). A reasonably accurate and simple method relates the ESQ to the ratio of the area to the perimeter of the field:

$$ESQ = \frac{4\text{Area}}{\text{Perimeter}} \quad (23.7)$$

This expression is mostly used for rectangular fields where it then becomes

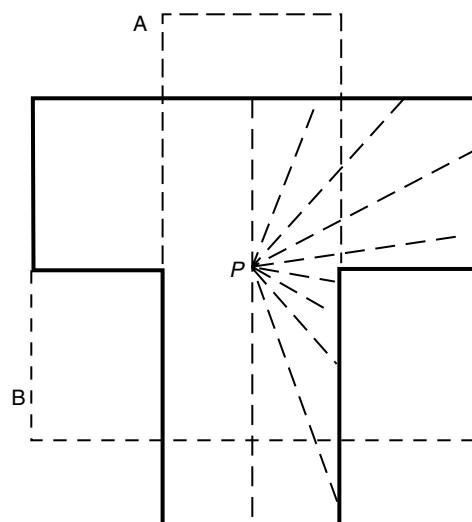

$$ESQ = \frac{2WL}{(W + L)} \quad (23.8)$$

for a rectangle of width  $W$  and length  $L$ . This gives reasonably good agreement with BJR Supplement 25. A useful discussion of this formula and others is given by McDermott (1998).

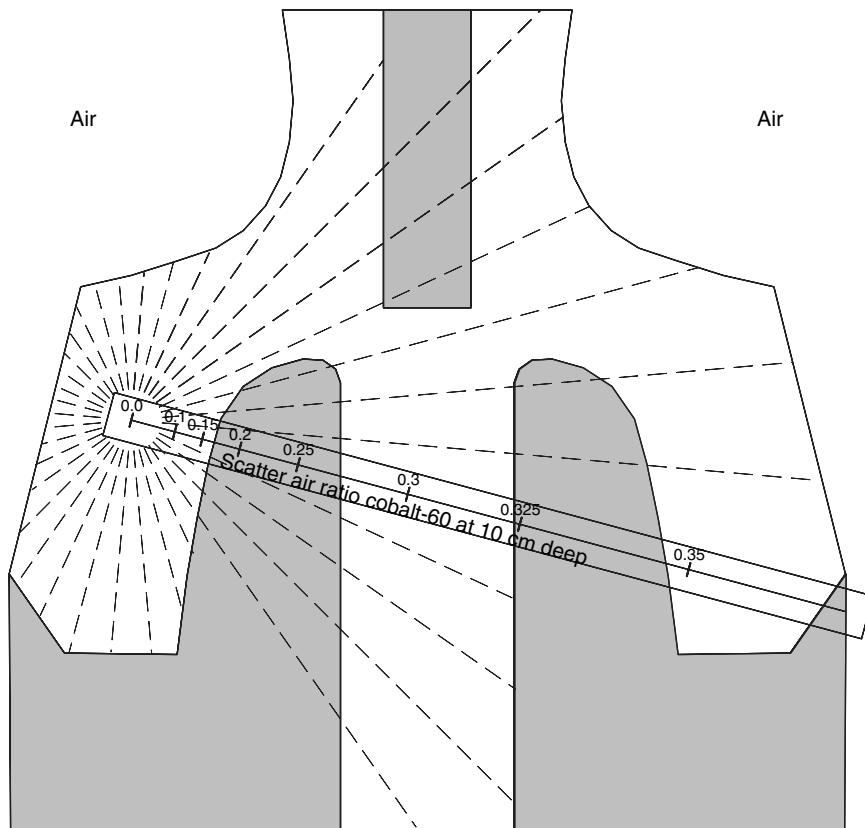

- *Summation of sub rectangles*. For reasonably regular field shapes, such as in [Figure 23.4](#), the ESQ can be obtained as the average of rectangles centred on the calculation point. This approach was first proposed by Day (1950), and it is also useful in calculating the scatter contribution to points not in the centre of the field (see also [Figure 23.15](#)).
- *Approximate equivalent rectangle*. For many odd-shaped fields, a useful rule of thumb consists in determining the area of the unshielded field, choosing one of the original sides of the set field (depending on the position of the blocks) and then calculating the other side of an equivalent rectangle to give the same area. The ESQ can then be derived from this equivalent rectangle.
- *Clarkson's Scatter Integration*. Clarkson's scatter integration (Clarkson 1941) is the most accurate, albeit the most labour-intensive method (unless a computer programme is used). The open part of any irregularly shaped field can be subdivided into  $N$  equal narrow sectors of arc, as shown in [Figure 23.5](#). Each sector can be thought of as a sector of a circle, and the SAR for each radius can be summed together:

$$SAR(\text{ESQ}) = \frac{\sum \text{SAR}(r_i)}{N} \quad (23.9)$$

ESQ is then determined by interpolation of tabulated SAR for squares.

**FIGURE 23.4**

Calculation of the equivalent square for point  $P$  both by Clarkson's integration method illustrated also in Figure 23.5, and by summation of sub-rectangles. The scatter contribution from the T shape field at point  $P$  is half the contribution of rectangle A summed with half the contribution of rectangle B. (From Khan, F. M., *The Physics of Radiation Therapy*, Williams and Wilkins, Baltimore, 1984.)

**FIGURE 23.5**

Clarkson's scatter integration over a highly irregular field. The cursor is scaled to the SAR at 10 cm deep for a cobalt-60 beam—different depths can be used as appropriate. The mean value of the SAR is then taken and used to look up the equivalent square field that would give this value.

### 23.2.1.9 Field Output Factor

The field output factor (FOF) is defined as the ratio of the output at the reference depth  $d_{\text{ref}}$  in a full scatter phantom for a given field size to that for the reference field geometry. FOF can be measured directly by placing a detector at  $d_{\text{ref}}$  in a phantom at standard geometry and varying the field size (see [Section 19.2.5](#)). Because of electron contamination (as discussed in [Section 22.3.1](#)), in order to obtain the FOF at  $d_{\text{max}}$ , it is preferable to make the measurements at a depth  $d_{\text{ref}}$  larger than  $d_{\text{max}}$  such as 5 cm or 10 cm (depending on the energy of the beam) and then to relate the measured outputs to  $d_{\text{max}}$  through the use of PDD or TMR (see [Section 23.2.1.1](#) and [Section 23.2.1.6](#)).

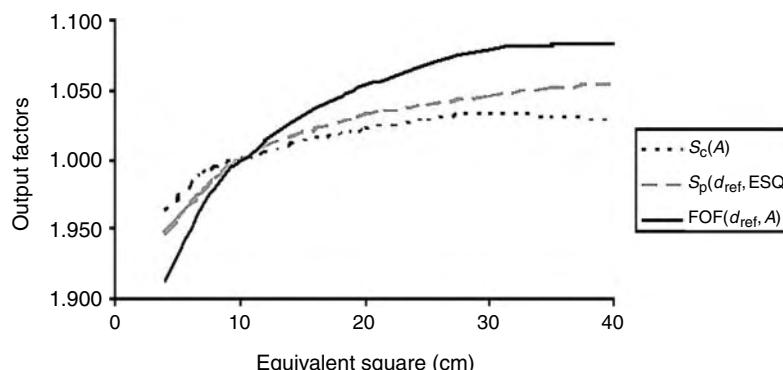

For open square and rectangular fields at the standard distance, FOF is the only quantity that would be needed for MU calculations. The value of FOF for those fields not originally measured can be derived by interpolation using the equivalent square concept (Day and Aird 1983). For rectangular fields, care must be taken to distinguish between the upper and lower jaws when interpolating, because of the collimator exchange effect (see [Section 23.2.1.13](#)). However, when beams are modified by blocks or MLC, or for non-standard geometries, the direct use of FOF becomes inadequate and can lead to large errors. This happens because the effects of the machine head geometry are then decoupled from the scatter conditions within the phantom. To address these situations, it is commonly assumed that the FOF can be described as the product of two independent factors, the collimator scatter factor and the phantom scatter factor (Figure 23.6) (Khan 1984) (defined in [Section 23.2.1.12](#) and [Section 23.2.1.10](#)):

$$\text{FOF}(d_{\text{ref}}, A) = S_c(A) S_p(d_{\text{ref}}, A_d) = S_c(A) S_p(d_{\text{ref}}, \text{ESQ}) \quad (23.10)$$

Parameter ESQ is used in the above equation as distinct to  $A$ , to emphasise that if the beam is modified in any way, such as extended distance or blocks, two different values of equivalent square need to be considered, one for the head geometry and one for the phantom scatter (Kim et al. 1998b).

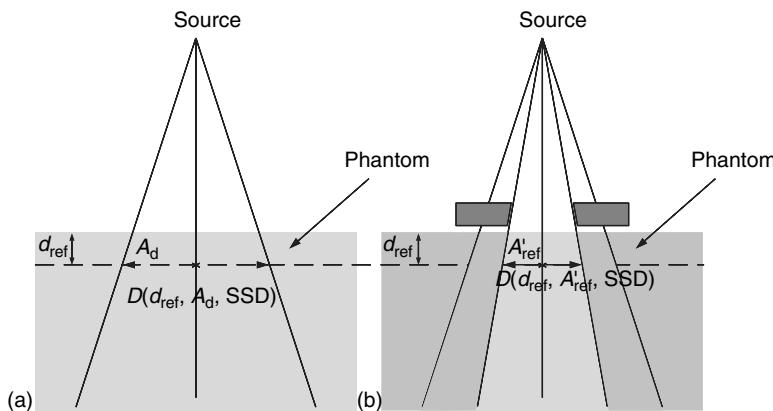

### 23.2.1.10 Phantom Scatter Factor $S_p$

The phantom scatter factor  $S_p$  essentially quantifies the variation of scatter contribution with field size to the dose in tissue at the reference depth, normalised to the reference field. Thus, it can be measured directly by varying the effective field size at the phantom, while keeping all other machine settings constant (Figure 23.7) (Khan 1984). Alternatively, it can be derived from the ratio of measurements of output factors in a full scatter phantom and *in air* (see [Section 23.2.1.12](#)).  $S_p$  is mostly a function of the beam quality (energy spectrum) and thus

**FIGURE 23.6**

Typical representation of field output factor (FOF) as a function of the equivalent square field ESQ. FOF can be considered as the product of the collimator scatter factor  $S_c$  and the phantom scatter factor  $S_p$ .

**FIGURE 23.7**

Diagrams to illustrate definition of  $S_p$ . (a) Dose in phantom at reference depth for a given field. (b) Dose at the same collimator opening. Note that  $A'$  has been used on the right hand side (b) to indicate that the field size is reduced by blocking to the reference field size rather than using the collimator.

has little or no dependence on machine head geometry. It is also a function of depth and of the effective field size at the point of calculation (ESQ), including the effect of SSD and blocks, and not only of the position of the collimators. Values of phantom scatter factors at 10 cm deep for high energy beams as a function of beam quality have been published (Storchi and Van Gasteren 1996). Note that  $S_p(d_{ref}, A_{ref})=1$  by definition. The relationship of  $S_p$  to TAR will be discussed in [Section 23.2.2.6](#).

### 23.2.1.11 Normalised Peak Scatter Factor

The normalised peak scatter factor (NPSF) is defined as the ratio of the PSF for the given field size to that for the reference field size (usually a 10 cm×10 cm square field).

$$\text{NPSF}(A) = \text{PSF}(A)/\text{PSF}(A_{ref}) \quad (23.11)$$

This quantity is coincident with  $S_p$  when the depth of reference is chosen at  $d_{max}$ , as is the case for PDD or TMR based calculations. NPSF is also mostly a function of the beam quality (energy spectrum) and independent of particular accelerator design.

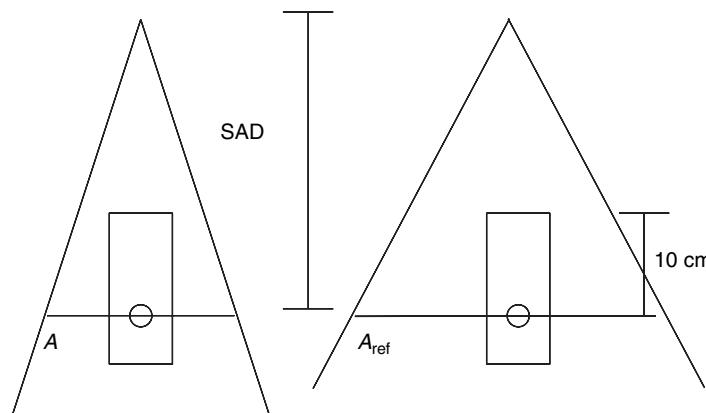

Note that, while by definition  $\text{PSF}(0)=1$ , it is  $\text{NPSF}(A_{ref})$  that equals unity by definition, and that  $\text{NPSF}(0)$  is always less than unity. Values for NPSF, averaged from the literature, are given in BJR Supplement 25 for several beam qualities. Values for PSF can be derived from these published values by extrapolating the NPSF to zero field size and applying the above definitions.

### 23.2.1.12 Collimator or Head Scatter Factor $S_c$

The collimator scatter factor (also known as head scatter factor or in air output factor), is defined as the ratio of the output in air for a given field size to that for the reference field, i.e.:

$$S_c = \frac{D(\text{air}, A)}{D(\text{air}, A_{ref})} \quad (23.12)$$

Thus, it could in principle be measured directly using an ion chamber in air with an adequate build-up cap. However, this method suffers from the difficulties mentioned above for TAR measurements, in as much as it fails for field sizes less than the build-up cap diameter. This minimum diameter, on the other hand, is not always sufficient to prevent electron

**FIGURE 23.8**

Direct measurement of the collimator scatter factor  $S_c$  using a mini-phantom. (Based on Dutreix, A., Bjarngard, B. E., Bridier, A., Minjinheer, B., Shaw, J. E., and Svensson, H., *ESTRO Booklet 3*, Garant, Leuven, Belgium, 1997. With permission.)

contamination produced in the machine head from reaching the ion chamber cavity. To overcome these difficulties, a new phantom geometry has been proposed for measurements of collimator scatter factors (Figure 23.8) (Van Gasteren et al. 1991; Dutreix et al. 1997). It is based on a *mini-phantom* which consists of a solid column of water-substitute material of cross-section sufficient to achieve lateral scatter equilibrium, and of thickness sufficient to position the detector at a depth where electron contamination becomes negligible. Typical dimensions for such a mini-phantom are  $4\text{ cm} \times 4\text{ cm}$  cross-section, a depth to the detector of 10 cm with 1 cm backscatter (Vadash and Bjarngard 1993). In this mini-phantom, the scatter contribution to the ion chamber is constant for field sizes larger than its cross-section. The dose at depth  $d$  in the mini-phantom is then:

$$D(A, d, \text{mini}) = D_0 S_c(A) S_p(d, \text{ESQ}_m) \quad (23.13)$$

where  $A$  is the set field and  $\text{ESQ}_m$  is the equivalent square corresponding to the mini-phantom cross-section. Then, values of  $S_c$  can be derived from measurements of dose in the mini-phantom as a function of field size, as long as the beam fully covers it. For beam cross-sections smaller than that of the mini-phantom,  $S_p(d, \text{ESQ}_m)$  becomes close to  $S_p(d, A)$ , except for the lack of full backscatter. This method, therefore, fails for field sizes comparable or smaller than the mini-phantom cross-section.

In these cases, it is preferable to derive  $S_c$  from the ratio of FOFs in a full scatter phantom and the corresponding  $S_p$  (see [Section 23.2.1.10](#)), as long as  $S_p$  can be determined independently (i.e. by extrapolation to very small field sizes or by Monte Carlo computation).

The value of  $S_c$  is assumed to be independent of distance from the source. This is not strictly true, especially for the contribution to  $S_c$  due to radiation scattered from the head components. This assumption is also equivalent to assuming that the effective source position for the inverse square law behaviour of output in air (see below) is independent of field size. This can be seen from Equation 23.12. If the virtual source position varied with field size, this ratio could not be the same at different distances.

The origin of the variation of  $S_c$  with field size is a subject of debate (Huang et al. 1987; Dunzenli et al. 1993). The major contributions are believed to come from (a) back scatter from the field defining jaws into the monitor chambers; (b) small angle scatter from the internal faces of the jaws; and (c) the shielding of the scattered dose from the flattening filter. Ideally, each of the three components causing the variation of  $S_c$  with collimator opening should be treated separately, since they are not affected similarly by the presence of filters, such as wedges or blocks, between the machine head and the phantom. However,

in most situations the assumption that the value of  $S_c$  depends only on the setting of the jaws can be considered acceptable.

### 23.2.1.13 Collimator Exchange Effect

The values of  $S_c$  for rectangular fields depend on which collimator (upper or lower) is used to define the long side. This is known as the collimator exchange effect, and is dependent on the design of each particular accelerator. It is assumed to originate mostly from the different amount of backscatter into the monitor chambers from upper and lower jaws defining the same width at the isocentre, since this contribution is more sensitive to the position of the jaws than the two others. Its importance is markedly accelerator-dependent. Based on this effect, a modified Sterling's formula for equivalent square (Equation 23.8) has been proposed for rectangular fields to correlate the Collimator Exchange Effect uniquely with square fields (Yu et al. 1995; Meyer et al. 1999):

$$\text{ESQ}' = \frac{(1+f)UL}{(U+fL)} \quad (23.14)$$

where the factor  $f$  is related to the distances of the upper ( $U$ ) and lower ( $L$ ) jaws from the monitor chambers and from the isocentre. In practice, the value of  $f$  is derived from a least square fit to the measured set of collimator scatter factors.

### 23.2.1.14 Wedge Transmission Factor

The wedge transmission factor (WF) (sometimes simply called wedge factor) is defined as the ratio of the outputs for a given field size, at the reference depth  $d_{\text{ref}}$  in a full scatter phantom at standard geometry, with and without the presence of a wedge filter (see also [Section 22.6.1](#)). Because of the differential attenuation through the wedge, the beam quality, and therefore the PDD or TMR for the wedged beam will be different to that of the corresponding unfiltered beam. It follows that the value of WF depends on the choice of  $d_{\text{ref}}$ . Generally, the value of WF defined as above also varies monotonically with field width. For fixed mechanical wedges the attenuation of the primary component of the radiation at the central axis is obviously constant, and independent of the position of the jaws. The fact that WF varies with field size, then, could be a consequence of the different scatter conditions within the phantom due to both beam quality changes (that is, a change in  $S_p$ ) and asymmetric primary fluence attenuation, as well as to modifications to collimator scatter ( $S_c$ ) due to the presence of the wedge. In other words, the definition of WF is given by:

$$D(d_{\text{ref}}, A_d, \text{SSD}, W) = \text{WF}(d_{\text{ref}}, A_d) \times D(d_{\text{ref}}, A_d, \text{SSD}, \text{op}) \quad (23.15)$$

where  $W$  indicates the wedged beam and  $\text{op}$  the open one.

By analogy with [Equation 23.13](#):

$$D(d_{\text{ref}}, A_d, \text{SSD}, \text{op}) = D_0 S_c(A) S_p(d_{\text{ref}}, A_d) \quad (23.16)$$

where  $D_0$  is the dose at the reference depth for the reference condition.

It is possible, in principle, to account separately for the variation in beam quality and in collimator scatter by determining values  $S_{p,w}$  and  $S_{c,w}$  appropriate for the wedged conditions. This could be done by the methods described above, e.g. by measuring  $S_{c,w}$  in a mini-phantom and by measuring  $S_{p,w}$  in a full scatter phantom using secondary blocking (or by using the ratio of TAR derived for the wedged beam quality). The remaining variation of wedged output with field size,  $\text{WF}'$ , would then relate only to the asymmetric attenuation of the primary fluence and

consequent scatter contribution to the central axis:

$$D(d_{\text{ref}}, A_{\text{d}}, \text{SSD}, W) = D_0 \text{WF}'(d_{\text{ref}}, A_{\text{d}}) S_{c,w}(A) S_{p,w}(d_{\text{ref}}, A_{\text{d}}) \quad (23.17)$$

The dependence of  $\text{WF}'$  on field size would be different from that of the measured  $\text{WF}$ . This analysis may seem more complex than necessary for regular wedged beams, but may be necessary for improved accuracy when dealing with asymmetric beams, where the quantities  $S_c$  and  $S_p$  could change as a function of the distance from the central axis as well as with the presence of the wedge.  $\text{WF}'$  is generally a slowly varying function of equivalent square at the point of calculation.

The situation is quite different with dynamic wedges (see [Section 22.6.2](#)). Some accelerators can produce wedge-shaped profiles by moving one independent jaw across the field while the beam is on. In this case, there is no beam hardening to worry about, and no significant expected influence on collimator scatter. The corresponding wedge transmission factor  $\text{DWF}$  is thus not expected to depend significantly on the choice of  $d_{\text{ref}}$ , and use of [Equation 23.15](#) would be justified. However, as mentioned in [Section 22.6.2](#), the  $\text{DWF}$  could be a strong function of the field width (the moving jaw direction), not of  $\text{ESQ}$ .

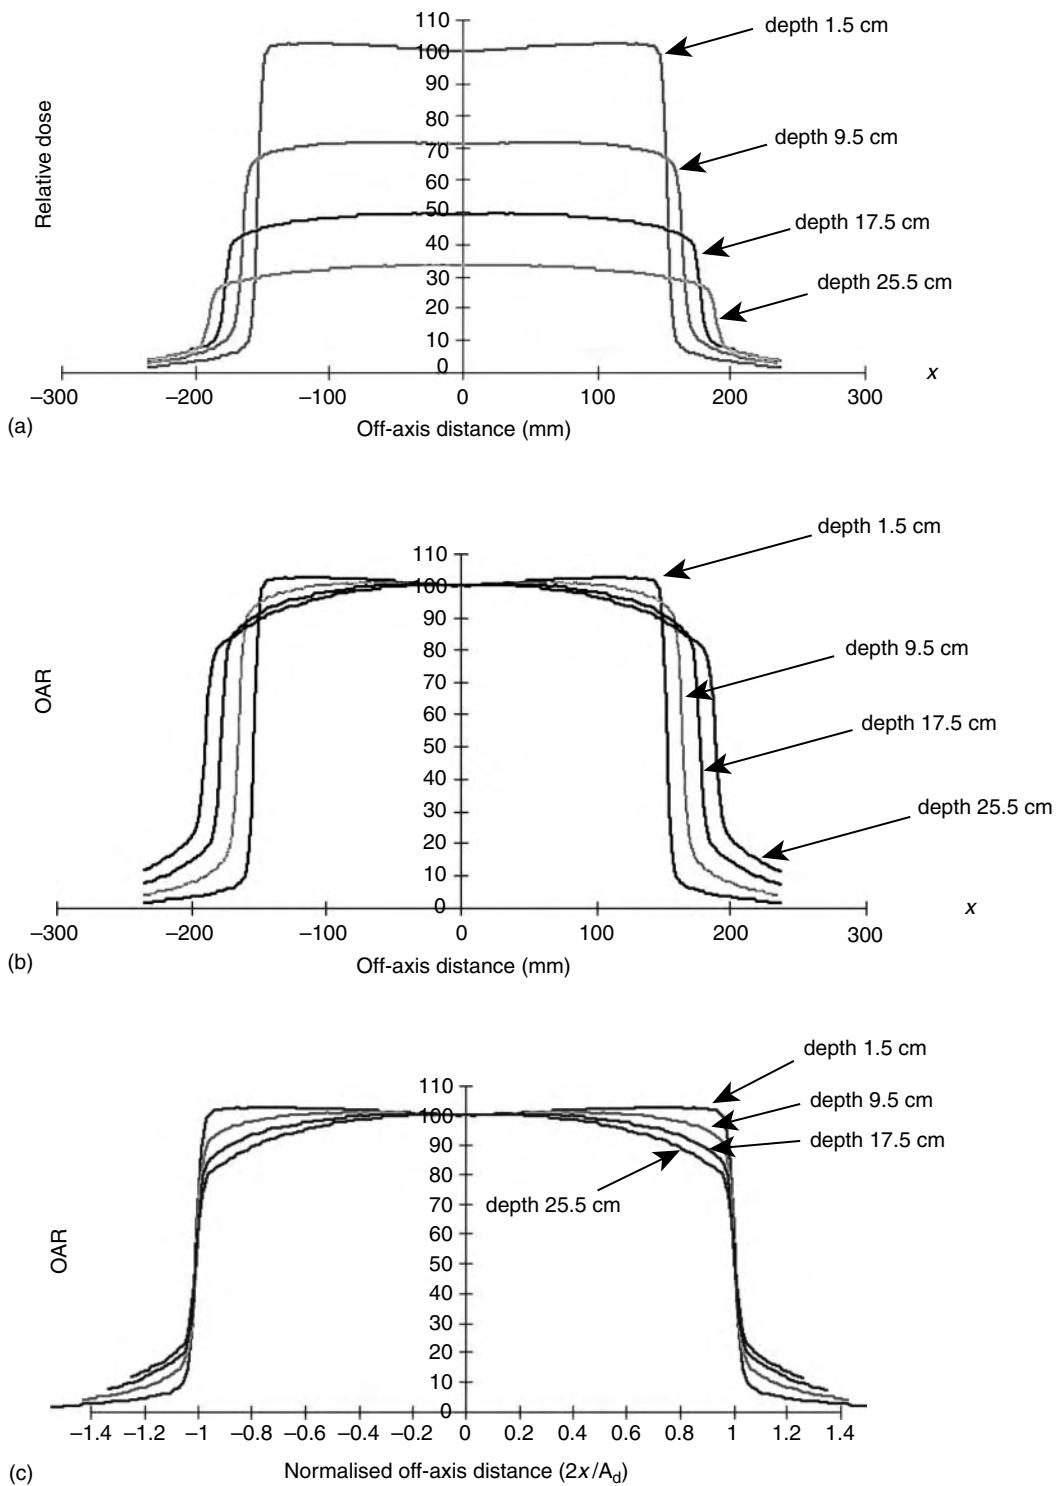

### 23.2.1.15 Off-Axis Ratio

The off-axis ratio (OAR) has been previously discussed in [Section 22.3.3](#). It is measured in planes perpendicular to the beam axis, and is defined as the ratio of dose at a point away from the central axis to the dose at the point on the central axis at the same depth:

$$\text{OAR}(x, d, A_{\text{d}}) = D(x, d, A_{\text{d}}, \text{SSD}, W) / D(0, d, A_{\text{d}}, \text{SSD}, W) \quad (23.18)$$

where  $W$  accounts for the possible presence of a wedge filter.

A plot of the variation of OAR with distance  $x$  from the central axis is known as a beam profile. These profiles are also easily measured using a computer-controlled scanning tank, by moving a small detector in the water. An example of open profiles at several depths is shown in [Figure 23.9a](#), plotted against actual distance and scaled according to the PDD, as they would be measured. Because of the definition of OAR, the same profiles are shown in [Figure 23.9b](#) normalised to 100% at the central axis. It can be seen more clearly in [Figure 23.9b](#) that the shape of the profiles changes with depth. First of all, because of the beam divergence, the profiles become progressively wider with depth. In fact, the definition of field width is intimately linked with the shape of these profiles: in most institutions, the width of the 50% decrement line (the distance between the 50% OAR values at each depth) is taken as the definition of field width. The geometrical field edge (defined by the centre of the source and the collimators) and the light field edge are made to coincide with these 50% points. This definition has many advantages, not least when matching abutting fields: by matching the geometric edge, the two fields are matched at the 50% OAR, thus providing the smoothest dose distribution across the match. The fact that the 50% OAR closely follows the geometric edge is illustrated in [Figure 23.9c](#), where the same profiles are plotted as a function of normalised off-axis distance. In this plot, points with the same ordinate lie on the same fan line (a diverging line from the centre of the source) at all depths. The profiles all overlap close to the 50% OAR, at the geometric edge, where  $2x/A_{\text{d}}=1$ . Profiles at shallow depths show the horns produced by the flattening filter. These horns gradually decrease with depth, even along fan lines. This effect is due partly to an in-scatter/out-scatter imbalance at the edge of the beam and partly to the fact that the quality of the radiation becomes progressively softer (the attenuation coefficient increases) away from the central axis, because of the effect of the flattening filter shape.

**FIGURE 23.9**

Plot of off-axis curves for a  $30\text{ cm} \times 30\text{ cm}$  field size at  $100\text{ cm}$  SSD with 3 different scalings: (a) without normalization. (b) OAR with dose normalization on the beam axis. (c) same as (b) but plotted as a function of the normalised off-axis distance  $2x/A_d$ .

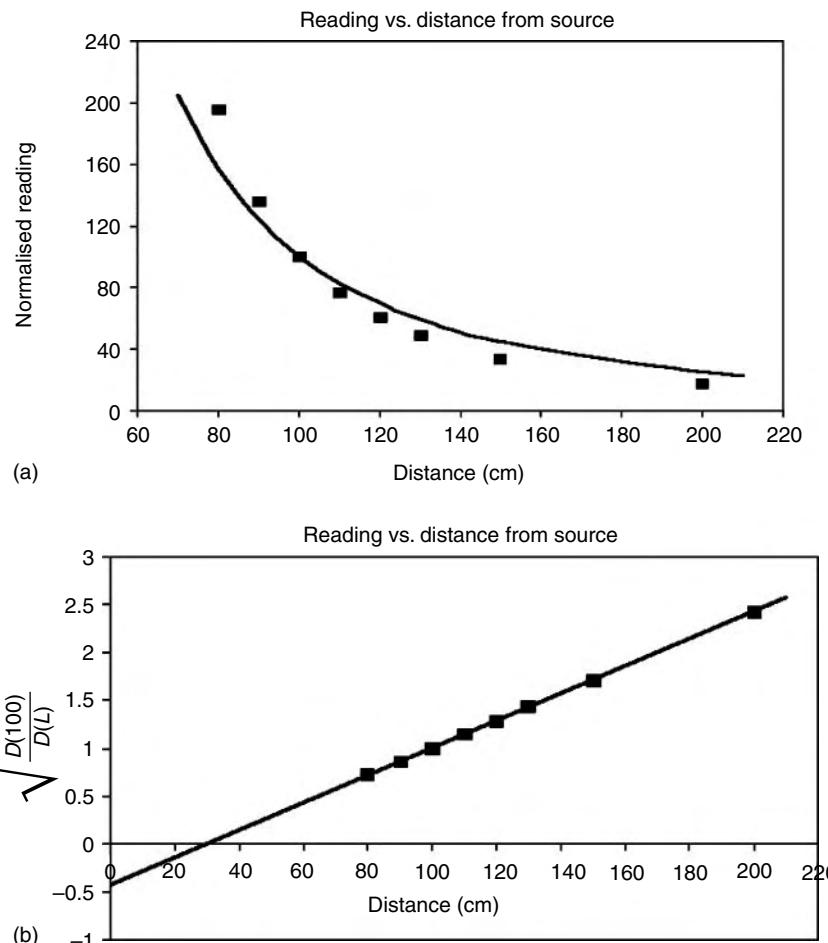

### 23.2.1.16 Inverse Square Law

As discussed in [Section 20.2.1](#) isotropic radiation from a point source will fall off in a vacuum according to the inverse square law:

$$\frac{D(L_1)}{D(L_2)} = \left(\frac{L_2}{L_1}\right)^2 \quad (23.19)$$

where  $L_1$  and  $L_2$  are distances measured from the point source. In the case of radiation from an accelerator, the source (target) is not a point, and radiation is scattered in the beam direction by the flattening filter and the primary collimators, as well as by the field defining jaws, monitor chambers and other objects. Nevertheless, the output in air follows the inverse square law reasonably well.

For more accurate calculations, an effective source position can be determined by measuring the output in air at several distances from the isocentre used as a reference to establish the distances to the *physical* target (Figure 23.10a). Once a set of dose rates  $D(L)$  as a function of nominal distance to this target are obtained, the results are plotted in the

**FIGURE 23.10**

Determination of the effective source position by measuring and plotting the dose rate at different distances from an arbitrary point (in principle taken coincident with the *physical* source). The solid line is a fit to the inverse square law and the filled rectangles are the measured points. (a) The quantity plotted is the normalised dosimeter reading; there is a small deviation of the experimental values compared to the inverse square law. (b) The quantity plotted is the normalized inverse square root of the reading; the experimental points are aligned and the extrapolation to zero (i.e. infinite dose) yields the effective source position.

form  $y = \sqrt{D(L_0)}/\sqrt{D(L)}$  vs. distance to obtain a linear regression (Figure 23.10b). The intercept of the linear fit with the abscissa axis ( $y=0$ ) will yield the shift of the virtual source from whatever value is taken for the reference distance  $L_0$ .

The reason for this derivation can be seen by following the algebra. Call  $S_v$  the virtual source shift upstream from the *physical* source. Then:

$$D(L) = D(L_0) \frac{(L_0 + S_v)^2}{(L + S_v)^2}$$

and therefore, by rearranging to get a linear relationship ( $y=mx+c$ ):

$$\frac{\sqrt{D(L_0)}}{\sqrt{D(L)}} = \frac{1}{(L_0 + S_v)} L + \frac{S_v}{(L_0 + S_v)} = 0 \quad \text{at} \quad L = -S_v$$

A negative value of  $S_v$  (interception for  $L > 0$ ) implies that the effective source of the radiation is downstream from the assumed position of the *physical* target.

## 23.2.2 RELATIONSHIPS AND DERIVATIONS

Armed with the preceding definitions and assumptions, we can now proceed to discuss the relationships among the above quantities and some more derivations. These relationships are useful, for instance, to convert measured quantities into other quantities more appropriate for dose calculations. Many of the derivations are based on the inverse square assumption.

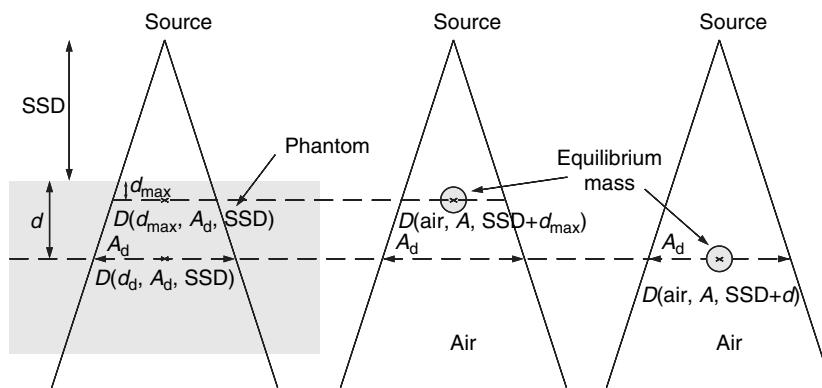

### 23.2.2.1 PDD from TAR

Referring to Figure 23.11, the dose in air at depth  $d$  is related to the dose in air at depth  $d_{\max}$  by the inverse square law:

$$D(\text{air}, A, \text{SSD} + d) = D(\text{air}, A, \text{SSD} + d_{\max}) \left( \frac{\text{SSD} + d_{\max}}{\text{SSD} + d} \right)^2 \quad (23.20)$$

The dose in tissue at depth  $d$  is then given by the application of TAR:

$$D(d, A_d, \text{SSD}) = D(\text{air}, A, \text{SSD} + d) \text{TAR}(d, A_d) \quad (23.21)$$

**FIGURE 23.11**  
Relationship between PDD and TAR.

where:

$$A_d = A \left( \frac{SSD + d}{SAD} \right) \quad (23.22)$$

Similarly, at  $d_{\max}$ , the dose in tissue is derived from the PSF:

$$D(d_{\max}, A_m, SSD) = D(\text{air}, A, SSD + d_{\max}) \text{PSF}(A_m) \quad (23.23)$$

where:

$$A_m = A \left( \frac{SSD + d_{\max}}{SAD} \right) \quad (23.24)$$

Thus, the PDD is given by:

$$\begin{aligned} \text{PDD}(d, A_s, SSD) &= 100 \frac{D(d, A_d, SSD)}{D(d_{\max}, A_m, SSD)} \\ &= 100 \frac{\text{TAR}(d, A_d)}{\text{PSF}(A_m)} \left( \frac{SSD + d_{\max}}{SSD + d} \right)^2 \end{aligned} \quad (23.25)$$

Usually, PDD is the measured quantity, and the inverse relationship (Burns 1983a) is used to derive TAR, given the values of PSF. These could be extracted from published PSF tables, as they vary slowly with beam quality.

### 23.2.2.2 TPR and TMR from TAR

Referring to Figure 23.2 and Figure 23.3, the TPR or TMR can be derived from:

$$\text{TPR}(d, A_d) = \text{TAR}(d, A_d)/\text{TAR}(d_{\text{ref}}, A_d) \quad (23.26)$$

and, in particular

$$\text{TMR}(d, A_d) = \text{TAR}(d, A_d)/\text{PSF}(A_d) \quad (23.26a)$$

as the ratio is of doses at the same point. This last relation is the reverse of Burn's definition of TAR (Burns 1983a) (See Equation 23.3 above).

### 23.2.2.3 PDD from TMR

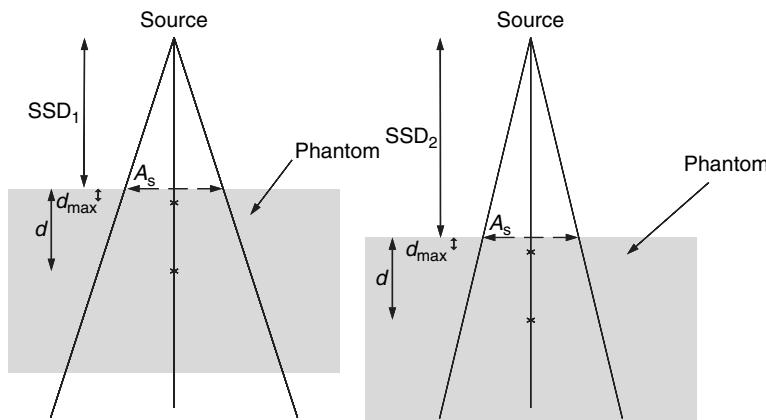

The derivation of percentage depth dose from the tissue maximum ratio follows from the above two relations (Equation 23.25 and Equation 23.26a):

$$\text{PDD}(d, A_s, SSD) = 100 \text{TMR}(d, A_d) \frac{\text{PSF}(A_d)}{\text{PSF}(A_m)} \left( \frac{SSD + d_{\max}}{SSD + d} \right)^2 \quad (23.27)$$

As with TAR, it is usually the inverse relation that is used to derive TMR from measured PDD. Often, the ratio of PSFs is ignored in the derivation, as it is close to unity for high-energy beams.

### 23.2.2.4 PDD from One SSD to Another (TAR Method)

When changing the SSD from  $SSD_1$  to  $SSD_2$ , the  $\text{PDD}_1$  measured at  $SSD_1$  will be modified, because of both a difference in scatter conditions and a difference in distance relations (Figure 23.12). From the above Equation 23.25, for the same field size  $A_s$  at the surface (which implies different set fields at isocentre):

**FIGURE 23.12**

Relationship between PDD at one SSD and another. In both cases the field size at the surface  $A_s$  and depth  $d$  are the same.

$$\text{PDD}_1(d, A_s, \text{SSD}_1) = 100 \frac{\text{TAR}(d, A_{d1})}{\text{PSF}(A_{m1})} \left( \frac{\text{SSD}_1 + d_{\max}}{\text{SSD}_1 + d} \right)^2$$

where  $A_{d1}$  and  $A_{m1}$  are defined as above (Equation 23.22 and Equation 23.24). Similarly:

$$\text{PDD}_2(d, A_s, \text{SSD}_2) = 100 \frac{\text{TAR}(d, A_{d2})}{\text{PSF}(A_{m2})} \left( \frac{\text{SSD}_2 + d_{\max}}{\text{SSD}_2 + d} \right)^2$$

Thus, the relation between the two PDDs is:

$$\begin{aligned} \text{PDD}_2(d, A_s, \text{SSD}_2) &= \text{PDD}_1(d, A_s, \text{SSD}_1) \frac{\text{TAR}(d, A_{d2})}{\text{PSF}(A_{m2})} \frac{\text{PSF}(A_{m1})}{\text{TAR}(d, A_{d1})} \\ &\quad \left( \frac{\text{SSD}_2 + d_{\max}}{\text{SSD}_2 + d} \right)^2 \left( \frac{\text{SSD}_1 + d}{\text{SSD}_1 + d_{\max}} \right)^2 \end{aligned} \quad (23.28)$$

Rearranging the above expression, and neglecting the ratio of  $\text{PSF}(A_{m1})/\text{PSF}(A_{m2})$  as being very close to unity:

$$\begin{aligned} \text{PDD}_2(d, A_s, \text{SSD}_2) &= \text{PDD}_1(d, A_s, \text{SSD}_1) \frac{\text{TAR}(d, A_{d2})}{\text{TAR}(d, A_{d1})} \\ &\quad \left\{ \left( \frac{\text{SSD}_2 + d_{\max}}{\text{SSD}_1 + d_{\max}} \right) \left( \frac{\text{SSD}_1 + d}{\text{SSD}_2 + d} \right) \right\}^2 \end{aligned} \quad (23.29)$$

The expression in the {} brackets is known as Mayneord's F factor (Mayneord and Lamerton 1944). This factor is larger than unity if  $\text{SSD}_2$  is greater than  $\text{SSD}_1$ . This purely geometrical inverse square factor is thus modified by the ratio of the TARs for the two projected field sizes at depth. A similar relationship, derived by Burns (1983a) for the case when the field size is the same at the depth of calculation (and therefore not the same at the surface or the isocentre) can also be derived from the above full relationship (Equation 23.28). An alternative formulation using NPSFs is given by Knight and Mayles (1991).

### 23.2.2.5 Scatter Maximum Ratio

The scatter maximum ratio (SMR) is the analogous scatter component for TMR as SAR was for TAR (see [Section 23.2.1.5](#)). It can be used in determining ESQ instead of SAR, thus avoiding having to bring in air doses into the discussion (Johns and Cunningham 1983; Khan 1984).

Thus, SMR should be defined similarly to Equation 23.5 above:

$$\text{SMR}(d, A_d) = \text{TMR}(d, A_d) - \text{TMR}0(d)$$

However, this simple analogy is incorrect (even though it has been used in several text books). Given that  $\text{TMR}(d_{\max}, A_d) = \text{TMR}0(d_{\max}) = 1$  (see [Section 23.2.1.6](#)), it would force  $\text{SMR}(d_{\max}, A_d)$  to be identically zero for all field sizes, implying that there is no scatter contribution at  $d_{\max}$ . Following Kahn (1984), we can define SMR as:

$$\text{SMR}(d, A_d) = \text{SAR}(d, A_d)/\text{TMR}0(d_{\max}) \quad (23.30)$$

and, rewriting Equation 23.5 in terms of TMR:

$$\text{SAR}(d, A_d) = \text{TMR}(d, A_d) \text{PSF}(A_d) - \text{TMR}0(d) \quad (23.31)$$

remembering that  $\text{TMR}0(d) = \text{TAR}0(d)$ . Further, from the definition of NPSF ( $= S_p$  at  $d_{\max}$ ), (Equation 23.11), it can be shown that:

$$\text{PSF}(A_d) = \text{NPSF}(A_d)/\text{NPSF}(0) = S_p(d_{\max}, A_d)/S_p(d_{\max}, 0) \quad (23.32)$$

Combining Equation 23.30 through Equation 23.32, we finally obtain the correct relationship between TMR and SMR (Khan 1984):

$$\text{SMR}(d, A_d) = \text{TMR}(d, A_d)[S_p(d_{\max}, A_d)/S_p(d_{\max}, 0)] - \text{TMR}0(d) \quad (23.33)$$

### 23.2.2.6 Phantom Scatter Factor $S_p$ from TAR

Consider the step-by-step derivation of dose at  $d_{\text{ref}}$  for an arbitrary beam, starting from the standard reference dose in tissue  $D_0$  produced by reference field  $A_{\text{ref}}$  at reference depth  $d_{\text{ref}}$  at isocentre. Each step relies on the definition of the quantity used.

(i) The dose *in air* at isocentre for the reference field  $A_{\text{ref}}$  is given by:

$$D(\text{air}, A_{\text{ref}}, \text{SAD}) = D_0/\text{TAR}(d_{\text{ref}}, A_{\text{ref}}) \quad (23.34)$$

(ii) The dose *in air* at isocentre for any other field  $A$  is given by:

$$D(\text{air}, A, \text{SAD}) = D(\text{air}, A_{\text{ref}}, \text{SAD}) S_c(A) \quad (23.35)$$

(iii) The dose in tissue at depth  $d_{\text{ref}}$  at isocentre ( $\text{SSD} = \text{SAD} - d_{\text{ref}}$ ) for field  $A$  is given by:

$$D(d_{\text{ref}}, A_d, \text{SSD}) = D(\text{air}, A, \text{SAD}) \text{TAR}(d_{\text{ref}}, A_d) \quad (23.36)$$

(iv) Substituting from Equation 23.34 and Equation 23.35 into Equation 23.36 gives:

$$D(d_{\text{ref}}, A_d, \text{SSD}) = D_0 S_c(A) \frac{\text{TAR}(d_{\text{ref}}, A_d)}{\text{TAR}(d_{\text{ref}}, A_{\text{ref}})} \quad (23.37)$$

(v) On the other hand, from the definition of FOF and its components Equation 23.10:

$$D(d_{\text{ref}}, A_d, \text{SSD}) = D_0 \text{FOF}(d_{\text{ref}}, A_d) = D_0 S_c(A) S_p(d_{\text{ref}}, A_d) \quad (23.38)$$

Therefore, comparing Equation 23.37 and Equation 23.38, the relationship between  $S_p$  and TAR is given by:

$$S_p(d_{\text{ref}}, A_d) = \text{TAR}(d_{\text{ref}}, A_d) / \text{TAR}(d_{\text{ref}}, A_{\text{ref}}) \quad (23.39)$$

It follows that, when  $d_{\text{ref}}$  is chosen to be at  $d_{\text{max}}$ :

$$S_p(d_{\text{max}}, A_d) = \text{PSF}(A_d) / \text{PSF}(A_{\text{ref}}) = \text{NPSF}(A_d) \quad (23.39a)$$

## 23.3 MONITOR UNIT CALCULATIONS

### 23.3.1 GENERAL METHODOLOGY

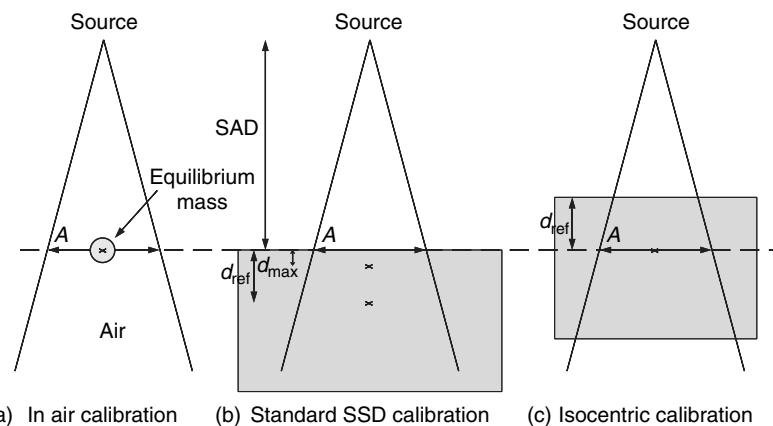

In spite of the almost universal use of computers for carrying out calculations in radiotherapy, there is still a need for physicists to be able to do quick point dose calculations by hand, both to verify the computer plans and to perform double checks of the number of monitor units used clinically for patients. This practice is also invaluable as a teaching tool to understand the physics behind computerised systems and to acquire a sound judgement about the results of computation.

Various methods for calculating monitor units for standard and complex situations have been proposed (Khan et al. 1986; Rosenberg et al. 1995). Some of these procedures involve a large number of correction factors, often predicated on a large amount of additional measurements (e.g. with a mini-phantom (Van Gasteren et al. 1991; Dutreix et al. 1997; Mijnheer et al. 2001)), to improve accuracy in non-standard situations. While these efforts are useful, especially if incorporated in computerised planning, there is a danger that the link between the calculations and the basic beam data can be lost among the numerous correction factors. This would defeat the main purpose of performing hand calculations. These calculations should be easily traceable to measured beam data acquired during commissioning (as described in [Chapter 19](#)), or to straightforward derivations from these measured data (as described in [Section 23.2.2](#)), and should be able to deal simply with the variety of modifications to the measured beam geometry necessitated by clinical needs. This approach is followed throughout this chapter.

Let us apply the quantities discussed above to calculate the dose at a point at depth  $d$  in a phantom with a given SSD using available tabulated data. What we want to calculate in each case is the dose per monitor unit (MU), or conversely the MU for a required dose. To be able to do this, though, we must first discuss the various ways a treatment machine can be calibrated (see also [Section 20.1.2](#)).

### 23.3.2 CALIBRATION CONVENTIONS

The process of calibration consists in setting and maintaining (or, in the case of an isotope teletherapy machine, determining and verifying) the dose output (or dose rate)  $D_0$  per MU at the reference point for the reference field size and geometry. Several options for the reference geometry are or have been in general use ([Figure 23.13](#)). Although it used to be common practice to measure  $D_0$  according to any of the three setups shown in Figure 23.13, direct measurements of  $D_0$  in air or at  $d_{\text{max}}$  are no longer recommended. Nevertheless, it is still useful to deal with these calibration methods since the corresponding quantities are often used in manual or computer based calculations.

**FIGURE 23.13**

Possible options for calibration quantities: (a) In Air (b) SSD (c) Isocentric. Actual measurements should be performed with SSD or isocentric set up at a reference depth larger than  $d_{max}$  (typically 5 cm or 10 cm).

### 23.3.2.1 In Air Calibration

In air calibration was used for isotope teletherapy units ( $^{60}\text{Co}$  and  $^{137}\text{Cs}$ ). The reference field size was usually a  $10\text{ cm} \times 10\text{ cm}$  square field, and the reference point was located in air at the isocentre (usually the centre of rotation of the gantry if so mounted), at the source to axis distance SAD. The dose output  $D_0$  was measured in air with an appropriate build-up cap. As the radiation is produced by radioactive decay, the output will decrease with time following a predictable exponential function. Output factors, namely the in air collimator scatter factor  $S_c(A)$ , would also be defined at the reference point, i.e. at the isocentre (Figure 23.13a).

### 23.3.2.2 Standard SSD Calibration at $d_{max}$

The definition of  $D_0$  as the dose rate at  $d_{max}$  at a standard SSD was the ideal choice where most treatments were delivered at a fixed source to surface distance (SSD), but is still often used for historical reasons. It is well adapted to dose calculation based on the percentage depth dose. The reference field size is usually a  $10\text{ cm} \times 10\text{ cm}$  square field, and the reference point is located at the depth of maximum dose ( $d_{max}$ ) in a phantom with a standard SSD equal to the SAD. The distance from the source to the reference point is thus equal to  $\text{SAD} + d_{max}$ . Output factors, namely  $\text{FOF}(A) = S_c(A)S_p(d_{max}, A_m)$ , would also be defined at the reference point, where  $S_c$  is the collimator scatter factor and  $S_p$  is the phantom scatter factor, which at  $d_{max}$  is equal to  $\text{NPSF}(A_m)$ . The PSF is strictly defined for the field size  $A_m$  but it is commonly tabulated according to  $A$  (Figure 23.13b).

### 23.3.2.3 Isocentric Calibration

This method is the most convenient for institutions where most treatments are delivered isocentrically, i.e. with the centre of the target volume at the machine isocentre. It is well adapted to dose calculation based on tissue maximum ratios (TMR) or tissue phantom ratios (TPR). The reference field size is usually a  $10\text{ cm} \times 10\text{ cm}$  square field, and the reference point is located at the reference depth ( $d_{ref}$ ) in phantom at a distance from the source equal to the SAD. A number of institutions still use  $d_{ref} = d_{max}$ , although larger depths such as 5 cm or 10 cm are recommended. Output factors, namely  $\text{FOF}(A) = S_c(A_{ref})S_p(d_{ref}, A_{ref})$ , would also be defined at the reference point, i.e. at the isocentre (Figure 23.13c).

**TABLE 23.3**

Relationship between the Recommended Measured Dose Rate  $D_{ref}$  and the Calibration Quantity  $D_0$

Calibration ref. quantity $D_0$	Relationship with the Measured Quantity $D_{ref}$
In air (cobalt)	$D_0 = D_{ref}/TAR(d_{ref}, A_{ref})$
SSD at $d_{max}$	$D_0 = D_{ref}/PDD(d_{ref}, A_{ref}, SSD)$
Isocentric at $d_{max}$	$D_0 = D_{ref}/TMR(d_{ref}, A_{ref})$
Isocentric or SSD at $d_{ref}$	$D_0 = D_{ref}$

*Note:* These relationships can be used to derive the number of MU required to deliver a given dose at a specific point in defined conditions.

#### 23.3.2.4 Relationships with the Recommended Protocols for Absolute Dose Determination

Although still corresponding to the local practice in a number of institutions, some of the calibration methods described above differ significantly from the recommended procedure described in Chapter 18 for absolute dose determination in reference conditions. However, this is not in contradiction provided that the measurement is actually performed within the phantom at depth  $d_{ref}$  and that the  $D_0$  calibration reference quantity is recalculated from the relationships given previously. For clarification, the corresponding relationships are recalled in Table 23.3. This methodology is essential to ensure consistency and to guarantee that recalculation in reference conditions (using *exactly* the same quantities) will return accurately the measured dose rate. Care must be taken to ensure that distances to the measuring point and field size specifications are unambiguous and self consistent.

### 23.3.3 CALCULATIONS FOR RECTANGULAR FIELDS AT THE STANDARD DISTANCE

To illustrate the process of calculation based on the above approaches, we describe here systematically, for both SSD and isocentric beam set up, the possible solutions of using a given calibration method, in conjunction with each of the principal dosimetric parameters (TAR, PDD, or TMR/TPR). Although all combinations are possible, some are easier to implement and Table 23.4 illustrates the recommended choices. A step by step derivation is used, based on the previous definitions for each parameter. This is intended to illustrate the relationships between calibration conditions and dosimetric quantities. It should be noted that, in all of the following, the dose in air is the only quantity assumed to follow the inverse square law. Therefore, it needs to be included in the derivation for most cases.

#### 23.3.3.1 SSD Beams

SSD beams are set up with the surface of the patient at the isocentre, i.e.  $SSD = SAD$ . For a point at depth  $d$  on the central axis we want to calculate  $D(d, A_s, SSD) = D(d, A_s, SAD)$ .

*In Air Calibration:*  $D_0$  is here defined as the output in air at SAD.

**TABLE 23.4**

Dosimetric Parameters for Dose Calculation

Beam Set Up	In Air (Cobalt)	Calibration SSD (at $d_{\max}$ )	Iso-centric
SSD	<b>TAR</b> or PDD or TMR	TAR or <b>PDD</b> or TMR	TAR or PDD or <b>TMR</b>
Iso-centric	<b>TAR</b> or PDD or TMR	TAR or PDD or <b>TMR</b>	TAR or PDD or <b>TMR</b>

Recommended choice for the use of appropriate dosimetric parameters when combining various possibilities of beam set up and calibration method. All possibilities are listed, but the recommended solutions are shown in bold type. In all cases the tissue phantom ratio (TPR) could be used advantageously instead of the tissue maximum ratio (TMR).

## (a) TAR Method

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d) = D_0 \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d) S_c(A)$$

From the definition of TAR in Equation 23.2:

$$\begin{aligned} D(d, A_s, \text{SAD}) &= D(\text{air}, A, \text{SAD} + d) \text{ TAR}(d, A_d) \\ &= D_0 S_c(A) \text{ TAR}(d, A_d) \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2 \end{aligned} \quad (23.40)$$

where  $A_d = A(\text{SSD} + d) / \text{SAD}$ .

## (b) PDD Method

From Equation 23.18:

$$D(\text{air}, A, \text{SAD} + d_{\max}) = D_0 \left( \frac{\text{SAD}}{\text{SAD} + d_{\max}} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} + d_{\max}) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\max}, A_s, \text{SSD}) = D(\text{air}, A, \text{SSD} + d_{\max}) \text{ PSF}(A_m)$$

From the definition of PDD in Equation 23.1:

$$\begin{aligned} D(d, A_s, \text{SAD}) &= D(d_{\max}, A_s, \text{SAD}) \text{ PDD}(d, A_s, \text{SSD}) \\ &= D_0 S_c(A) \text{ PSF}(A_m) \text{ PDD}(d, A_s, \text{SSD}) \left( \frac{\text{SAD}}{\text{SAD} + d_{\max}} \right)^2 \end{aligned} \quad (23.41)$$

where  $A_m = A(\text{SSD} + d_{\max}) / \text{SAD}$ .

## (c) TMR Method

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d) = D_0 \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\max}, A_d, \text{SAD} + d - d_{\max}) = D(\text{air}, A, \text{SAD} + d) \text{PSF}(A_d)$$

The definition of TMR ([Section 23.2.1.6](#)) leads to:

$$\begin{aligned} D(d, A_s, \text{SSD}) &= D(d_{\max}, A_d, \text{SAD} + d - d_{\max}) \text{TMR}(d, A_d) \\ &= D_0 S_c(A) \text{PSF}(A_d) \text{TMR}(d, A_d) \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2 \end{aligned} \quad (23.42)$$

where  $A_d = A (\text{SSD} + d) / \text{SAD}$ .

*SSD Calibration at  $d_{\max}$ :*  $D_0$  is here defined as the output in tissue at  $d_{\max}$  at distance  $\text{SAD} + d_{\max}$ .

## (a) TAR Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) = \frac{D_0}{\text{PSF}(A_{\text{m, ref}})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) \left( \frac{\text{SAD} + d_{\max}}{\text{SAD} + d} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d) S_c(A)$$

From the definition of TAR in Equation 23.2:

$$\begin{aligned} D(d, A_s, \text{SSD}) &= D(\text{air}, A, \text{SAD} + d) \text{TAR}(d, A_d) \\ &= \frac{D_0}{\text{PSF}(A_{\text{m, ref}})} S_c(A) \text{TAR}(d, A_d) \left( \frac{\text{SAD} + d_{\max}}{\text{SAD} + d} \right)^2 \end{aligned} \quad (23.43)$$

where  $A_{\text{m, ref}} = A_{\text{ref}} (\text{SSD} + d_{\max}) / \text{SAD}$

## (b) PDD Method

Using the definition of field output factor ([Section 23.2.1.9](#)):

$$D(d_{\max}, A_s, \text{SSD}) = D_0 \text{FOF}(A) = D_0 S_c(A) S_p(d_{\max}, A_m)$$

as can be seen from Equation 23.10. The definition of percentage depth dose in Equation 23.1 leads to:

$$\begin{aligned} D(d, A_s, \text{SSD}) &= D(d_{\max}, A_s, \text{SSD}) \text{ PDD}(d, A_s, \text{SSD}) \\ &= D_0 S_c(A) S_p(d_{\max}, A_m) \text{ PDD}(d, A_s, \text{SSD}) \end{aligned} \quad (23.44)$$

(c) TMR Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) = \frac{D_0}{\text{PSF}(A_m, \text{ref})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) \left( \frac{\text{SAD} + d_{\max}}{\text{SAD} + d} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\max}, A_d, \text{SAD} + d - d_{\max}) = D(\text{air}, A, \text{SAD} + d) \text{ PSF}(A_d)$$

The definition of TMR ([Section 23.2.1.6](#)) leads to:

$$\begin{aligned} D(d, A_s, \text{SSD}) &= D(d_{\max}, A_d, \text{SAD} + d - d_{\max}) \text{ TMR}(d, A_d) \\ &= \frac{D_0}{\text{PSF}(A_m, \text{ref})} \left( \frac{\text{SAD} + d_{\max}}{\text{SAD} + d} \right)^2 S_c(A) \text{ PSF}(A_d) \text{ TMR}(d, A_d) \\ &= D_0 S_c(A) S_p(d_{\max}, A_d) \text{ TMR}(d, A_d) \left( \frac{\text{SAD} + d_{\max}}{\text{SAD} + d} \right)^2 \end{aligned} \quad (23.45)$$

by combining the previous equations and the definition of  $S_p$  in [Section 23.2.1.10](#).

*Iso-centric Calibration at  $d_{\max}$ :*  $D_0$  is here defined as the output in tissue at  $d_{\max}$  with the detector at a distance SAD from the source.

(a) TAR Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, \text{SAD}) = \frac{D_0}{\text{PSF}(A_{\text{ref}})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD}) \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d) S_c(A)$$

From the definition of TAR in Equation 23.2:

$$D(d, A_s, \text{SSD}) = D(\text{air}, A, \text{SAD} + d) \text{ TAR}(d, A_d)$$

$$= \frac{D_0}{\text{PSF}(A_{\text{ref}})} S_c(A) \text{TAR}(d, A_d) \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2 \quad (23.46)$$

by combining the previous equations.

(b) PDD Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, \text{SAD}) = \frac{D_0}{\text{PSF}(A_{\text{ref}})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\text{max}}) = D(\text{air}, A_{\text{ref}}, \text{SAD}) \left( \frac{\text{SAD}}{\text{SAD} + d_{\text{max}}} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A_m, \text{SAD} + d_{\text{max}}) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\text{max}}) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\text{max}}, A_m, \text{SSD}) = D(\text{air}, A_m, \text{SAD} + d_{\text{max}}) \text{PSF}(A_m)$$

The definition of percentage depth dose in Equation 23.1 leads to:

$$D(d, A_s, \text{SSD}) = D(d_{\text{max}}, A_m, \text{SSD}) \text{PDD}(d, A_s, \text{SSD})$$

$$= D_0 S_c(A) S_p(d_{\text{max}}, A_m) \text{PDD}(d, A_s, \text{SSD}) \left( \frac{\text{SAD}}{\text{SAD} + d_{\text{max}}} \right)^2 \quad (23.47)$$

by combining the previous equations and the definition of  $S_p$  in [Section 23.2.1.10](#).

(c) TMR Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, \text{SAD}) = \frac{D_0}{\text{PSF}(A_{\text{ref}})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD}) \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} + d) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\text{max}}, A_d, \text{SAD} + d - d_{\text{max}}) = D(\text{air}, A, \text{SAD} + d) \text{PSF}(A_d)$$

The definition of TMR ([Section 23.2.1.6](#)) leads to:

$$D(d, A_s, \text{SSD}) = D(d_{\text{max}}, A_d, \text{SAD} + d - d_{\text{max}}) \text{TMR}(d, A_d)$$

$$= \frac{D_0}{\text{PSF}(A_{\text{ref}})} \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2 S_c(A) \text{PSF}(A_d) \text{TMR}(d, A_d)$$

$$= D_0 S_c(A) S_p(d_{\max}, A_d) \text{TMR}(d, A_d) \left( \frac{\text{SAD}}{\text{SAD} + d} \right)^2 \quad (23.48)$$

by combining the previous equations and the definition of  $S_p$  in [Section 23.2.1.10](#).

### 23.3.3.2 Isocentric Beams

Isocentric beams are set up with the target point of calculation at the isocentre, i.e.  $\text{SSD} = \text{SAD} - d$  for a point at depth  $d$  on the central axis. We want to calculate  $D(d, A_d, \text{SSD}) = D(d, A_d, \text{SAD} - d)$ .

*In Air Calibration:*  $D_0$  is here defined as the output in air at SAD.

#### (a) TAR Method

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD}) = D_0 S_c(A)$$

From the definition of TAR in Equation 23.2:

$$\begin{aligned} D(d, A_d, \text{SSD}) &= D(\text{air}, A, \text{SAD}) \text{TAR}(d, A_d) \\ &= D_0 S_c(A) \text{TAR}(d, A_d) \end{aligned} \quad (23.49)$$

#### (b) PDD Method

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} - d + d_{\max}) = D_0 \left( \frac{\text{SAD}}{\text{SAD} - d + d_{\max}} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD} - d + d_{\max}) = D(\text{air}, A_{\text{ref}}, \text{SAD} - d + d_{\max}) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\max}, A_d, \text{SSD}) = D(\text{air}, A, \text{SAD} - d + d_{\max}) \text{PSF}(A_m)$$

From the definition of PDD in Equation 23.1:

$$D(d, A_d, \text{SSD}) = D(d_{\max}, A_d, \text{SSD}) \text{PDD}_m(d, A_s, \text{SSD})$$

$$= D_0 S_c(A) \text{PSF}(A_m) \text{PDD}_m(d, A_s, \text{SSD}) \left( \frac{\text{SAD}}{\text{SSD} + d_{\max}} \right)^2 \quad (23.50)$$

where  $\text{PDD}_m(d, A_s, \text{SSD})$  represents the PDD modified for the new  $\text{SSD} = \text{SAD} - d$  according to Equation 23.29.

#### (c) TMR Method

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD}) = D_0 S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\max}, A_d, \text{SSD}) = D(\text{air}, A, \text{SAD}) \text{PSF}(A)$$

The definition of TMR (Section 23.2.1.6) leads to:

$$\begin{aligned} D(d, A_d, \text{SSD}) &= D(d_{\max}, A_d, \text{SSD}) \text{TMR}(d, A_d) \\ &= D_0 S_c(A) \text{PSF}(A) \text{TMR}(d, A_d) \end{aligned} \quad (23.51)$$

*SSD Calibration at  $d_{\max}$ :*  $D_0$  is here defined as the output in tissue at  $d_{\max}$  at distance  $\text{SAD} + d_{\max}$ .

(a) TAR Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) = \frac{D_0}{\text{PSF}(A_m, \text{ref})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SAD}) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) \left( \frac{\text{SAD} + d_{\max}}{\text{SAD}} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SAD}) = D(\text{air}, A_{\text{ref}}, \text{SAD}) S_c(A)$$

From the definition of TAR in Equation 23.2:

$$\begin{aligned} D(d, A_s, \text{SSD}) &= D(\text{air}, A, \text{SAD}) \text{TAR}(d, A_d) \\ &= \frac{D_0}{\text{PSF}(A_m, \text{ref})} S_c(A) \text{TAR}(d, A_d) \left( \frac{\text{SAD} + d_{\max}}{\text{SAD}} \right)^2 \end{aligned} \quad (23.52)$$

(b) PDD Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) = \frac{D_0}{\text{PSF}(A_m, \text{ref})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SSD} + d_{\max}) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) \left( \frac{\text{SAD} + d_{\max}}{\text{SSD} + d_{\max}} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A_{\text{ref}}, \text{SSD} + d_{\max}) = D(\text{air}, A_{\text{ref}}, \text{SAD} + d_{\max}) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\max}, A_d, \text{SSD}) = D(\text{air}, A_d, \text{SSD} + d_{\max}) \text{PSF}(A_m)$$

The definition of percentage depth dose in Equation 23.1 leads to:

$$\begin{aligned} D(d, A_d, \text{SSD}) &= D(d_{\max}, A_d, \text{SSD}) \text{PDD}_m(d, A_s, \text{SSD}) \\ &= \frac{D_0}{\text{PSF}(A_m, \text{ref})} S_c(A) \text{PSF}(A_m) \text{PDD}_m(d, A_s, \text{SSD}) \left( \frac{\text{SAD} + d_{\max}}{\text{SSD} + d_{\max}} \right)^2 \end{aligned}$$

$$= D_0 S_c(A) S_p(d_{\max}, A_m) PDD_m(d, A_s, SSD) \left( \frac{SAD + d_{\max}}{SSD + d_{\max}} \right)^2 \quad (23.53)$$

Where  $PDD_m(d, A_s, SSD)$  represents the PDD modified for the new  $SSD = SAD - d$  according to Equation 23.29.

### (c) TMR Method

From the definition of PSF in Equation 23.4:

$$D(\text{air}, A_{\text{ref}}, SAD + d_{\max}) = \frac{D_0}{PSF(A_m, \text{ref})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, SAD) = D(\text{air}, A_{\text{ref}}, SAD + d_{\max}) \left( \frac{SAD + d_{\max}}{SAD} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, SAD) = D(\text{air}, A_{\text{ref}}, SAD) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\max}, A_d, SAD - d_{\max}) = D(\text{air}, A, SAD) PSF(A_d)$$

The definition of TMR ([Section 23.2.1.6](#)) leads to:

$$\begin{aligned} D(d, A_d, SSD) &= D(d_{\max}, A_d, SAD - d_{\max}) TMR(d, A_d) \\ &= \frac{D_0}{PSF(A_m)} \left( \frac{SAD + d_{\max}}{SAD} \right)^2 S_c(A) PSF(A_d) TMR(d, A_d) \\ &= D_0 S_c(A) S_p(d_{\max}, A_d) TMR(d, A_d) \left( \frac{SAD + d_{\max}}{SAD} \right)^2 \end{aligned} \quad (23.54)$$

by combining the previous equations and the definition of  $S_p$  in [Section 23.2.1.10](#).

*Isocentric Calibration at  $d_{\text{ref}}$ :*  $D_0$  is here defined as the output in tissue at  $d_{\text{ref}}$  with the detector at a distance SAD from the source.

### (a) TAR Method

From the definition of TAR in Equation 23.2:

$$D(\text{air}, A_{\text{ref}}, SAD) = \frac{D_0}{TAR(d_{\text{ref}}, A_{\text{ref}})}$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, SAD) = D(\text{air}, A_{\text{ref}}, SAD) S_c(A)$$

From the definition of TAR in Equation 23.2:

$$\begin{aligned} D(d, A_d, SSD) &= D(\text{air}, A, SAD) TAR(d, A_d) \\ &= \frac{D_0}{TAR(d_{\text{ref}}, A_{\text{ref}})} S_c(A) TAR(d, A_d) \end{aligned}$$

$$= D_0 S_c(A) S_p(d_{\text{ref}}, A_d) \frac{\text{TAR}(d, A_d)}{\text{TAR}(d_{\text{ref}}, A_d)} \quad (23.55)$$

by combining the previous equations and Equation 23.39. This can also be written in terms of the TPR as in Section 23.2.12.6:

$$= D_0 S_c(A) S_p(d_{\text{ref}}, A_d) \text{TPR}(d, A_d) \quad (23.56)$$

### (b) PDD Method

From the definition of TAR in Equation 23.2:

$$D(\text{air}, A_{\text{ref}}, \text{SAD}) = \frac{D_0}{\text{TAR}(d_{\text{ref}}, A_{\text{ref}})}$$

From Equation 23.18:

$$D(\text{air}, A_{\text{ref}}, \text{SSD} + d_{\text{max}}) = D(\text{air}, A_{\text{ref}}, \text{SAD}) \left( \frac{\text{SAD}}{\text{SSD} + d_{\text{max}}} \right)^2$$

From the definition of  $S_c$  in Equation 23.12:

$$D(\text{air}, A, \text{SSD} + d_{\text{max}}) = D(\text{air}, A_{\text{ref}}, \text{SSD} + d_{\text{max}}) S_c(A)$$

From the definition of PSF in Equation 23.4:

$$D(d_{\text{max}}, A_d, \text{SSD}) = D(\text{air}, A, \text{SSD} + d_{\text{max}}) \text{PSF}(A_m)$$

The definition of percentage depth dose in Equation 23.1 leads to:

$$\begin{aligned} D(d, A_d, \text{SSD}) &= D(d_{\text{max}}, A_d, \text{SSD}) \text{PDD}_m(d, A_s, \text{SSD}) \\ &= \frac{D_0}{\text{TAR}(d_{\text{ref}}, A_{\text{ref}})} S_c(A) \text{PSF}(A_m) \text{PDD}_m(d, A_s, \text{SSD}) \left( \frac{\text{SAD}}{\text{SAD} + d_{\text{max}}} \right)^2 \end{aligned} \quad (23.57)$$

by combining the previous equations and the definition of  $S_p$  in [Section 23.2.1.10](#). Here  $\text{PDD}_m(d, A_s, \text{SSD})$  represents the PDD modified for the new  $\text{SSD} = \text{SAD} - d$  as according to Equation 23.29.

### (c) TPR Method

From the definition of  $S_c$  in Equation 23.12:

$$\begin{aligned} D(d_{\text{ref}}, A_d, \text{SSD}) &= D_0 \text{FOF}(A) \\ &= D_0 S_p(d_{\text{ref}}, A_d) S_c(A) \end{aligned}$$

from Equation 23.9. The definition of TPR (see [Section 23.2.1.6](#)) leads to:

$$\begin{aligned} D(d, A_d, \text{SSD}) &= D(d_{\text{ref}}, A_d, \text{SSD}) \text{TPR}(d, A_d) \\ &= D_0 S_c(A) S_p(d_{\text{ref}}, A_d) \text{TPR}(d, A_d) \end{aligned} \quad (23.58)$$

by combining the previous equations and the definition of  $S_p$  in [Section 23.2.1.10](#). Here  $\text{SSD} = \text{SAD} - d$ .

As already indicated in [Table 23.4](#) it is clear from the above exercise that, although any system of dosimetric calculations can be used with any calibration convention and any patient set-up, some parameters are naturally linked to particular calibration conventions and beam geometry. Thus, an institution that prefers to treat all its patients at a constant SSD would be better off to calibrate its accelerators at the standard SSD also, and to use a system based on

PDD. Conversely, where most patient treatments are given isocentrically, an isocentric calibration and a dosimetry system based on TPR/TMR would be more appropriate.

### 23.3.4 CALCULATIONS FOR MODIFIED BEAMS

The basic principles included in the above formulae can be transposed to cover a number of beam modifications. Some possibilities are discussed in this section.

#### 23.3.4.1 Blocked Fields

Take, for example, an isocentric beam treated on a machine with isocentric calibration. Using the TPR method (see Section 23.3.3.2.3), the dose at the target point is given by:

$$D(d, \text{ESQ}, \text{SSD}) = D_0 S_c(A) S_p(d_{\text{ref}}, \text{ESQ}) \text{TPR}(d, \text{ESQ}) \text{TF} \quad (23.59)$$

where ESQ is the equivalent square field determined at the calculation point, after taking account of the blocks. Thus, both  $S_p$  and TPR are modified by the presence of the block, while  $S_c$  is assumed to depend only on the set field. In some accelerators models, the MLC actually replace one of the sets of jaws. In this case,  $S_c$  will depend on the MLC shape and will also vary with ESQ ( $S_c(\text{ESQ})$ ). Also there is a possibility, depending on each particular design, that the presence of blocks or MLC between the machine head and the patient will modify  $S_c$  by filtering (Meyer et al. 1999) or, conversely, amplifying the radiation scattered from the jaws. This variation could be studied by measuring  $S_c$  in mini-phantom conditions and parametrising it as a function of the block shape and geometry. However, in keeping with the overall simplicity of the present approach, it is generally acceptable to ignore such variations, which often amount to less than 1% (in particular for additional blocks). If the blocks are supported in the beam by a tray, a tray attenuation factor (TF) needs to be added to the above expression. If the blocking is achieved with an MLC assembly, the TF will be unity.

#### 23.3.4.2 Wedge Filters

The presence of a wedge filter in the beam modifies the beam profiles. It will also introduce an attenuation characterised by the wedge transmission factor (WF) at the central axis, which may be a function of field size. In addition, the wedge may harden the beam by filtering out some of the lower energies in the spectrum (Knöös and Wittgren 1991) (see Section 22.6.1). For an SSD beam treated on a machine with SSD calibration, the dose at depth  $d$  on the beam axis will be given by the expressions given in Section 23.2.1.14 and Section 23.3.3.1.2:

$$D(d, A_s, \text{SSD}) = D_0 \text{FOF}(A) \text{PDD}_w(d, A_s, \text{SSD}) \text{WF}(A) \quad (23.60)$$

Again, the output factors and wedge factors could be dissected, as in the *mini-phantom* methodology (Van Gasteren et al. 1991; Dutreix et al. 1997) into wedge dependent  $S_{p,w}$  and  $S_{c,w}$ , *primary wedge attenuation factor*, and other factors, in order to account for the modifications in beam energy and fluence produced by the presence of the wedge. In practice, though, the variation of PDD (TPR) for wedged fields (Knöös and Wittgren 1991) is often ignored in hand calculations, and an average WF is used for all field sizes, unless the variation is more than 3%. Some accelerators can produce wedge-shaped profiles by moving one independent jaw across the field while the beam is on (*dynamic wedges*, see Section 22.6.2). In this case there is no beam hardening to worry about, and the open field PDD (TPR) can properly be used. The effective collimator scatter factor  $S_c$ , DW, averaged

over the many positions of the moving jaw, could well be different from the value of  $S_c$  for the starting field. This variation is usually ignored and its effects are incorporated into the overall wedge factor. On the other hand, the effective WF can be a strong and unpredictable function of the variable field dimension (in contrast to the equivalent field size), and care must be taken in interpolating for the wedge factors. (see [Section 22.6.2](#))

### 23.3.4.3 Non-Standard SSD

There are a couple of cases where neither PDD nor TPR as such are sufficient by themselves, when patients are treated at an SSD different from the standard. On the one hand, larger distances from the source can sometimes be used to obtain a larger field size at the skin. On other occasions, even though the SSD is shorter than the SAD, the prescription point is not at the isocentre. In both cases, the inverse square law needs to be invoked. The dose rate at a point at an arbitrary depth  $d$  and non-standard source to skin distance  $SSD_2$  will be calculated in two ways.

*SSD Calibration, PDD System:* This is analogous to Example given in [Section 23.3.3.1.2\(b\)](#) (SSD set up, SSD calibration, PDD method), if SSD is set to  $SSD_2$  instead of  $SAD-d$ . Thus:

$$D(d, A, SSD_2) = D_0 S_c(A) S_p(d_{\max}, A_2) \text{PDD}_2(d, A_2, SSD_2) \left( \frac{SAD + d_{\max}}{SSD_2 + d_{\max}} \right)^2$$

where  $A_2$  is the field size at the surface of the extended  $SSD_2$ :  $A_2 = A SSD_2 / SAD$  and  $\text{PDD}_2(d, A_2, SSD_2)$  represents PDD modified for the new SSD (see [Equation 23.29](#)).

$$\text{PDD}_2(d, A_2, SSD_2) = \text{PDD}_1(d, A_2, SSD_1) \left[ \frac{\text{TAR}(d, A_{d2})}{\text{TAR}(d, A_{d1})} \right] \left\{ \left( \frac{SSD_2 + d_{\max}}{SSD_1 + d_{\max}} \right) \left( \frac{SSD_1 + d}{SSD_2 + d} \right) \right\}^2$$

Rearranging and simplifying, and neglecting the ratio of TAR in the square brackets:

$$D(d, A, SSD_2) = D_0 S_c(A) S_p(d_{\max}, A_2) \text{PDD}_1(d, A_2, SSD_1) \left( \frac{SSD_1 + d}{SSD_2 + d} \right)^2 \quad (23.61)$$

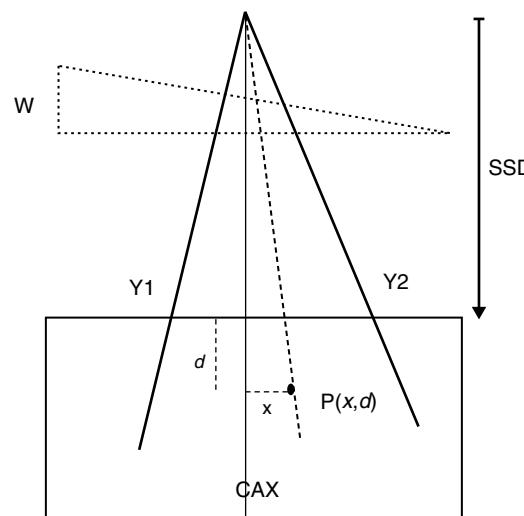

*Isocentric Calibration, TPR System:* This is analogous to the example given in [Section 23.3.3.1.3\(c\)](#) (SSD set up, isocentric calibration, TMR method), if SSD is set to  $SSD_2$  instead of  $SAD$ :

$$D(d, A, SSD_2) = D_0 S_c(A) S_p(d_{\text{ref}}, A_2) \text{TPR}(d, A_2) \left( \frac{SAD}{SSD_2 + d} \right)^2 \quad (23.62)$$

with the same definition of  $A_2$  as above.

### 23.3.4.4 Asymmetric Fields and Off-Axis Calculation Points

Modern accelerators are equipped with independent jaws capable of producing fields which are asymmetric about the central axis of the beam (CAX, defined as the axis of rotation of the collimator assembly). While this option makes adjusting fields on patients much easier for the radiation oncologist it complicates the calculation for the physicist. The prescription point can now be in the centre of the open field (COF), rather than on the CAX, or it can still be on the CAX, but with a different scatter geometry than with symmetric fields. This innovation has stimulated a number of works discussing the dosimetry of such fields (e.g. Khan et al. 1986; Rosenberg et al. 1995). A relatively simple approach, suitable for hand calculations, makes use of the concept of effective or equivalent field (Rosenberg et al. 1995). Referring to [Figure 23.14](#), the dose output (Gy/MU) at any point  $P(x, d)$  in the open portion of an asymmetric field AS (potentially modified by a wedge W) is given by a

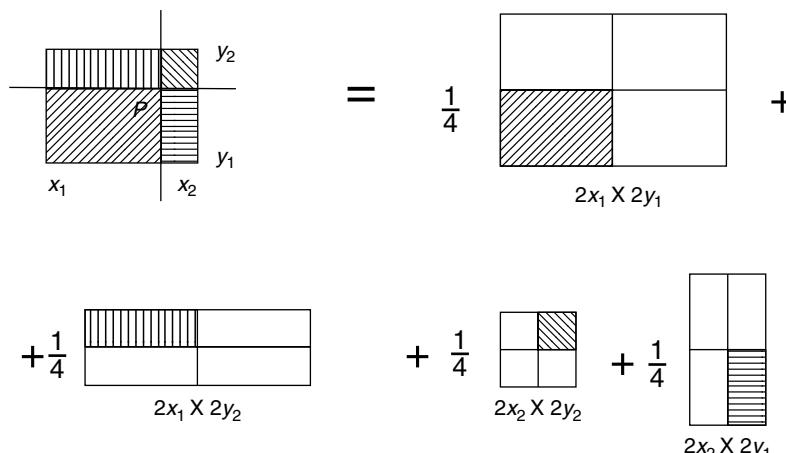

**FIGURE 23.14**

Calculation of the dose rate for an off-axis point  $P$  with an asymmetric field in presence of wedge filter. (From Rosenberg, I. et al., *Med. Phys.*, 22, 55–61, 1995. With permission.)

modification of Equation 23.38:

$$D_p(x, d, \text{SSD}, \text{AS}, W) = D_0 S_c(\text{eff}) S_p(d_{\text{ref}}, \text{eff}) \text{WF TPR}(d, \text{eff}) \text{OAR}(x, d, W) G \quad (23.63)$$

where  $\text{OAR}(x, d, W)$  denotes an OAR potentially modified by a wedge and  $G$  is the geometrical inverse square law factor consistent with the machine calibration convention. In Equation 23.63, eff, the effective field size at the calculation point for which the field size dependent factors,  $S_c$ ,  $S_p$ , and TPR, are to be calculated, can be obtained (following Day 1950) from an average of four rectangular fields centered on the point (see Figure 23.15). Note that this definition of effective field size makes the values for these three parameters,

**FIGURE 23.15**

The Day method allows calculation of the scatter phantom factor  $S_p$  at any point  $P$  for a symmetric or asymmetric rectangular field by considering separately the contribution of each quadrant as being the quarter of the contribution of the corresponding centred symmetric field. (Adapted from Day, M. J., *Br. J. Radiol.*, 23, 368, 1950. With permission.)

dependent not only on the position of the individual jaws or blocks, but also on the location of the calculation point relative to the field edges.

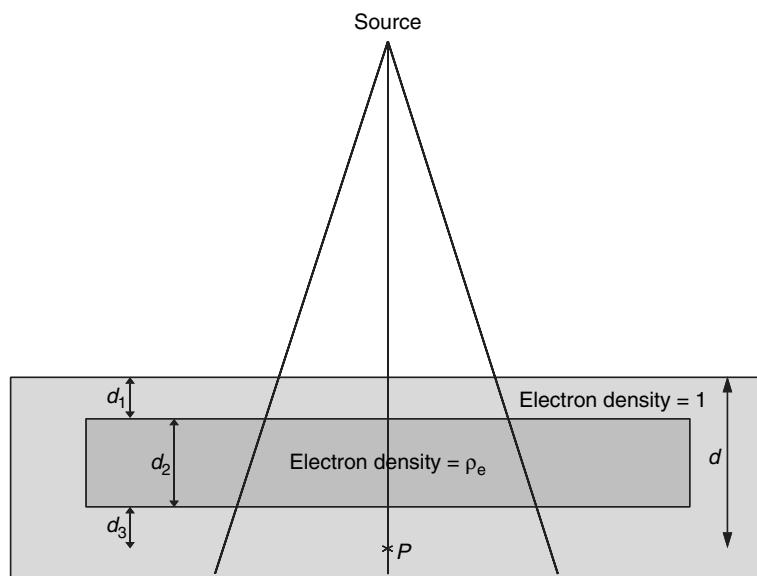

In this simple approach to asymmetric dosimetry several factors are not specifically taken into account. The beam quality, on which  $S_c$ ,  $S_p$ , and TPR all depend, will change with off-axis distance, due to differential hardening by the flattening filter. The *primary* OAR at a given off-axis distance may also be a function of the asymmetric jaw positions. The *mini-phantom* methodology could, in principle, measure the variation of those quantities. However, if parameterization were required for points at both COF and CAX for different degrees of asymmetry, the number of measurements would be unmanageable. The simple expression given above, by using  $OAR(x, d, W)$ , that is, off-axis ratios measured at depth, partially accounts for off-axis beam quality variations and differential attenuation in phantom.

### 23.3.4.5 Corrections for Inhomogeneities

In contrast to the water phantoms in which the basic beam information is acquired, patients contain structures with different densities. The task of calculating the full effect of these inhomogeneities on the dose distribution is covered in [Chapter 26](#) and is mostly beyond the scope of hand calculations. A simple method for estimating the approximate effect of an intervening inhomogeneity is the equivalent path length correction, where an effective depth is used to calculate the depth dependent parameters.

Referring to Figure 23.16, the effective depth  $d_{\text{eff}}$  to point  $P$  in, say, Equation 23.45, would be changed from  $d = (d_1 + d_2 + d_3)$  to  $d_{\text{eff}} = (d_1 + d_3) + d_2 \rho_e$ , where  $\rho_e$  is the electron density of the inhomogeneity relative to that of water. Thus:

$$D(d, A_s, \text{SSD}) = D_0 S_c(A) S_p(d_{\text{max}}, A_d) \text{TMR}(d_{\text{eff}}, A_d) \left( \frac{\text{SAD} + d_{\text{max}}}{\text{SAD} + d} \right)^2 \quad (23.64)$$

**FIGURE 23.16**

Schematic diagram showing a water equivalent phantom containing an inhomogeneity of electron density  $\rho_e$  relative to that of water.  $P$  is the point of dose calculation.

Geometrical factors, such as the inverse square law and field size divergence  $A_d$ , would still be based on the actual distance  $SSD + d$ . Thus, care needs to be taken not to use PDD calculation methods directly with this effective depth correction.

This method is reasonably accurate when the calculation point is well beyond the boundary of the inhomogeneity. At short distances from the boundary, and within the inhomogeneous volume, however, the equivalent path correction is no longer valid because of the importance of the modification of scattered radiation for the lower energies, and because of the perturbations of the secondary electron transport for the higher energies. More sophisticated computer based methods (see [Section 26.2.3.2](#)) are then required to obtain accurate results.

## 24.1 INTRODUCTION

The electron beams most commonly available in radiotherapy departments have energies of between 4 MeV and 25 MeV as produced by standard clinical linear accelerators, although some microtrons provide higher energies. Electron beams have advantages for a variety of clinical situations due to the characteristics of their depth-dose curves (Figure 24.1). They deliver acceptably uniform doses to a relatively well-defined region extending from the surface to the therapeutic range (taken as the distal 85% or 90%), which can be altered to fit the clinical situation by varying the beam energy, followed by a steep fall in relative dose that spares underlying structures. The general approach to electron-beam measurement and dosimetry is similar to that for megavoltage x-ray beams. However, there are a number of significant differences:

- Electrons, being charged particles, lose energy continuously as they pass through matter. Therefore, the mean energy decreases continuously with depth in the phantom.
- Electrons are light particles and undergo significant scatter. Therefore, the angular distribution of an electron beam also changes with its passage through matter. Scatter effects cause large perturbations around patient surface irregularities and inhomogeneities. Beam characteristics change when scatter equilibrium is lost. Scatter from collimators and other structures in the accelerator head has a marked effect on the detail of the dose distribution in the region around the surface and extending at least to  $d_{\max}$  and also on the link between dose and monitor units(MU). As a consequence, some of the detail of beam properties can depend much more strongly on the design of the machine head than is the case for megavoltage x-ray beams.

The basic physics relating to electron interactions has been discussed previously ([Chapter 3](#)) and additional material can be found in ICRU (1984) and Klevenhagen (1985, 1993). In this chapter, the characteristics of clinical electron beams are described.

**FIGURE 24.1**

An electron beam depth-dose curve in water illustrating the significant characteristic parameters. Depending on local practice either the distal 90% ( $R_{90}$ ) or the distal 85% ( $R_{85}$ ) is taken to be the therapeutic range.  $R_{100}$  is the depth of maximum,  $R_{50}$  is the 50% depth,  $D_x$  is the bremsstrahlung tail percentage and  $R_p$  is the extrapolated range. (From ICRU, Report 35, International Commission on Radiation Units and Measurements, Bethesda, MD, 1984. With permission.)

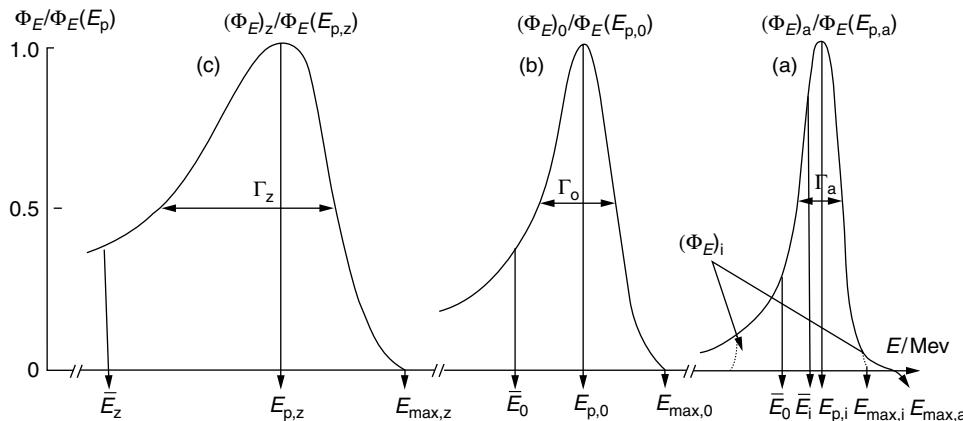

[Section 11.4.5](#) describes how electron beams are generated. [Chapter 18](#) and [Section 19.3](#) present the methods for dose measurement in electron beams considering the absolute dose calibration and the experimental determination of the relative dose distribution respectively. [Chapter 27](#) and [Chapter 28](#) describe electron treatment planning algorithms and Monte Carlo approaches to electron-beam modelling, whereas [Chapter 34](#) deals with the techniques that make use of these beams in clinical situations.

## 24.2 DEPTH–DOSE CHARACTERISTICS OF ELECTRON BEAMS

### 24.2.1 SPECTRUM AT THE PATIENT SURFACE

The electron-beam spectrum at the patient or phantom surface will be reduced in energy and broadened as compared to that emerging from the vacuum window, with a more significant skewing towards lower energies (Figure 24.2), due to the cumulative effect of the interactions experienced in passing through scattering foils, monitor chamber, air, etc. It is characterised by a *most probable energy at the surface*,  $E_{p,0}$ , and a lower *mean energy at the surface*,  $\bar{E}_0$ , where the former is used to characterise the dose distribution and should approximately coincide with the energy stated by the manufacturer and the latter has generally been used in selecting appropriate correction coefficients for dose measurements. Both are determined practically by measuring depth-dose characteristics.

As the beam travels through the patient or phantom, all of the electrons undergo scattering and energy-loss interactions. The spectrum gradually shifts to lower energies and continues to broaden (Figure 24.2), until the electrons have lost all their energy. It is

**FIGURE 24.2**

Illustrative representation of electron-beam spectra for 3 different locations on the beam path: (a) the *initial beam exiting the accelerator* (right-hand side: the subscript *a* represents the intrinsic accelerator beam, whereas *i* represents the initial electron beam; any difference is due to energy-defining slits); (b) the *beam incident at the surface of the phantom* (middle: represented by the subscript *0*); and (c) at *depth z* (left-hand side, represented by *z*). The abscissa represents nominal energies and illustrates the maximum (subscript *max*), most probable (subscript *p*) and mean energy ( $\bar{E}$ ) for each case; the ordinate is the electron fluence differential in energy, normalised to the peak value. (From ICRU, Report 35, International Commission on Radiation Units and Measurements, Bethesda, MD, 1984. With permission.)

characterised by the mean energy at depth  $z$ ,  $\bar{E}_z$ . As a rough estimate of this, the mean energy loss is approximately 2 MeV/cm in tissue or water.

#### 24.2.2 GENERAL SHAPE OF DEPTH–DOSE CURVE

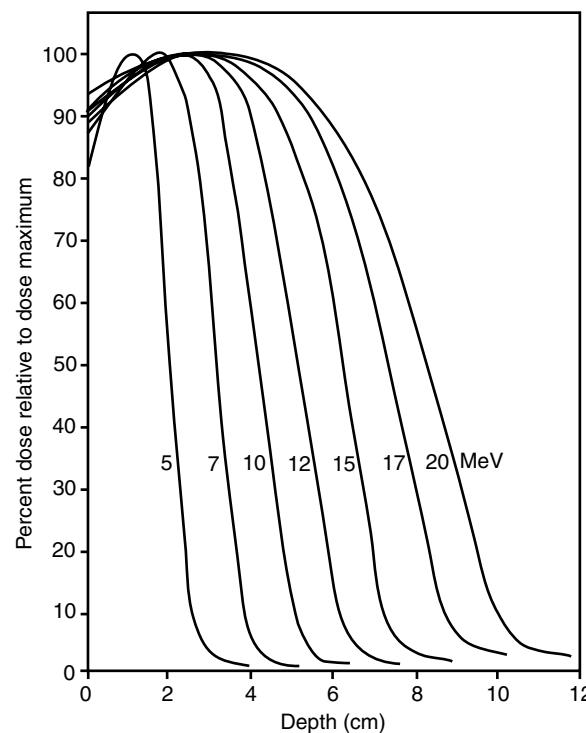

Figure 24.1 shows the general shape of an electron beam depth-dose curve in a reasonably large field. It illustrates the relatively uniform dose region from surface to *therapeutic range*, typically taken to be the depth of the distal 90% or 85% dose depending on local practice, and the rapidly falling part of the curve beyond that. The therapeutic range can be roughly estimated in cm of water or soft tissue as one-third of the beam energy in MeV.

The *surface dose* ( $D_s$ ), conventionally stated at 0.5 mm depth, generally lies between around 75% or 80% for lower-energy beams (4 MeV to 6 MeV) and between 90% and 100% for higher-energy beams (20 MeV to 25 MeV). The rise in relative dose from the surface is due to the increasing obliquity of the electron paths as a result of scatter as the electrons penetrate the material. The electron paths are deflected through increasing mean angles from the original incident direction. This, in turn, increases the mean pathlength travelled for fixed increments of depth into the material and increases the electron fluence with depth (see Section 6.3.5). Thus, the energy deposited in successive layers of the material increases (see Figure 6.5). This continues until the beam is essentially fully diffused, i.e. the mean scattering angle does not increase further, in which case the depth-dose curve becomes flat. At increasing depths, it continues until electrons begin to be lost from the beam, in which case the depth-dose curve begins to fall. The depth of dose maximum ( $R_{100}$ ) and the shape of the peak of the depth-dose curve is governed by the balance of these scatter effects with eventual loss of electrons from the beam. It therefore depends not only on beam energy, but also on the details of the accelerator head design because this determines the angular distribution of the incident electrons. The difference in relative value between  $D_s$  and 100% at  $R_{100}$  is governed by the scatter properties of the beam and is therefore larger for lower energies where scatter is more significant, i.e.  $D_s$  is lower at lower energies.

The fall-off of the curve at depth is described by the dose *gradient*, which becomes less steep as energy increases, significantly so for beams having initial energies above approximately 20 MeV, but also depending on machine design. Scanning beam machines generally produce deeper therapeutic range and steeper fall-off than scattering foil machines. A *bremsstrahlung (x-ray) tail* is observed beyond the region where primary electrons are directly depositing energy, typically being around 1% of maximum dose for lower-energy beams to around 5% for 20 MeV to 25 MeV beams. Most of this originates in the machine head, with around half that contribution from the scattering foils where they are present. The *practical range*,  $R_p^*$ , representing those electrons that have travelled through the material with the minimum of scatter deviations from the original direction producing a straight or almost straight path, is obtained from the intersection of the extrapolated x-ray tail with the tangent to the steepest part of the falling curve. It can be estimated in cm of water or soft tissue as roughly half the beam energy in MeV. The *50% depth*,  $R_{50}$ , is the depth at which the relative dose falls to half the maximum value and lies approximately midway between therapeutic range and practical range.

Figure 24.1 also illustrates an alternative general rule for estimating the depth of significant doses on the central axis of electron beams. This is called the *2, 3, 4, 5 rule* and it is used to find the central-axis depth (in mm) of the 100%, 90% and 50% doses and the practical range by multiplying the incident beam energy (in MeV) by 2, 3, 4 and 5, respectively. Although it is only an approximate rule, particularly with regard to the depth of 100%

\* Although the subscript p is always used in the symbol, the same quantity is also frequently called *extrapolated range* because it is obtained by extrapolation from the depth-dose curve.

**FIGURE 24.3**

Typical central axis percentage depth-dose curves for beam energies from 5 MeV to 20 MeV.

dose, which breaks down above about 15 MeV, it is nevertheless a convenient, practical aid in the clinic.

#### 24.2.3 VARIATION WITH BEAM ENERGY

Figure 24.3 shows some representative electron-beam depth-dose curves for a range of energies from 5 MeV to 20 MeV. General features of these curves are that, as energy increases:

- The relative surface dose increases.
- The depth of dose maximum\* increases over the lower energies, but less strongly, if at all, at higher energies. This characteristic can vary with machine and does not necessarily vary in a monotonic way with energy.
- The penetration increases, as reflected in the values of therapeutic range,  $R_{50}$ , and practical range,  $R_p$ .
- The steepness of the falling part of the curve is roughly constant at the lower energies, but decreases at the higher energies.
- The x-ray tail increases.

Three energy values are used to specify an electron beam spectrum, two of them being used mostly for the purposes of dose measurements (see [Section 18.5.5](#)). They are obtained from

\* The depth of maximum dose,  $R_{100}$ , is not always well defined in electron beams since, except for the lower energies, the depth-dose curve is rather flat in this region. Therefore it could be more relevant to define  $R_{100}$  as the mid-depth between distal and proximal 99% or 98%.

empirical relationships between energy (expressed in MeV) and the measured values of particular characteristics of the depth-attenuation curves in water (expressed in cm).

1. The mean energy at the surface,  $\bar{E}_0$ , is obtained from the 50% depth. A number of different approaches have been employed. The most common relation is:

$$\bar{E}_0 = 2.33 R_{50} \quad (24.1)$$

which is taken to be valid from 5 MeV to 35 MeV. Strictly, this applies to the  $R_{50}$  from depth-dose curves for monoenergetic broad parallel beams. However, it is often more convenient to use values from depth-dose curves obtained at fixed Source Skin Distance. Various dosimetry protocols give data linking  $\bar{E}_0$  with  $R_{50}$  obtained in different ways (e.g. IPEMB 1996b; IAEA 1997b).

2. The most probable energy at the surface,  $E_{p,0}$ , is obtained from the practical range. There are a number of empirical expressions in the literature linking  $E_{p,0}$  and  $R_p$ . The most widely used relation is

$$E_{p,0} = 0.22 + 1.98R_p + 0.0025R_p^2 \quad (24.2)$$

3. The mean energy at depth  $z$ ,  $\bar{E}_z$ . A widely used relation for beams having a mean surface energy of  $\bar{E}_0$  is

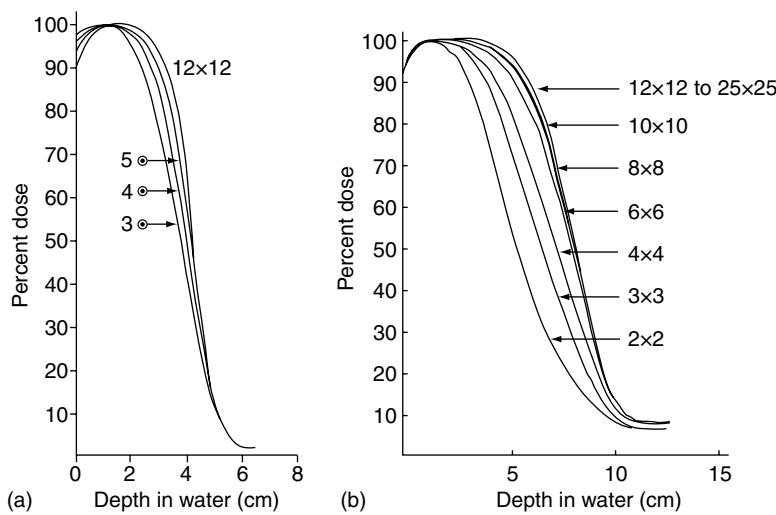

$$\bar{E}_z = \bar{E}_0(1 - z/R_p) \quad (24.3)$$

where  $z$  and  $R_p$  are measured for the same material. This approximation is close to more accurate values only for lower energy beams or for higher energies at depths close to the surface and close to  $R_p$ .

For any of the above, the determination of  $R_{50}$  and  $R_p$  must be carried out in a sufficiently large field, such that the values obtained are independent of field size, i.e. scatter equilibrium is obtained. The energies obtained are then the appropriate value to be used for any irradiation conditions in that beam, including smaller field sizes. Up to 15 MeV, at least 12 cm  $\times$  12 cm fields are preferable. Larger field sizes, e.g. 20 cm  $\times$  20 cm, are appropriate at higher energies. All the energy relationships given above are only approximations to the true values due to the simplifications involved that are not applicable to the whole range of possible clinical beam spectra.

#### 24.2.4 VARIATION WITH FIELD SIZE

At medium and large field sizes, central-axis depth doses do not vary significantly in their basic characteristics, although the exact value of surface dose and the detail of the depth-dose curve between the surface and dose maximum may vary. This is the case as long as the field is large enough to produce scatter equilibrium at the central axis. Below these dimensions, more electrons are scattered away from the central axis, reducing the fluence and the dose deposited, than are scattered inward. This imbalance results in the high-value depth doses moving progressively towards the surface as the field size reduces, with an increase in the surface dose relative to maximum dose. The maximum penetration of electrons stays the same, as it must because it essentially represents the electron range. Thus the practical range is hardly changed. Therefore, the steepness of the depth-dose curve is progressively reduced. This is illustrated in [Figure 24.4](#) for two electron energies. This loss of side-scatter equilibrium occurs for field dimensions that are less than some critical value that is dependent on electron energy, but is also affected by machine design. In practice, it is often found to be approximately the same as  $R_p$ .

**FIGURE 24.4**

Typical variation of the central axis percentage depth-dose curves with field size at 100 cm Source Skin Distance for (a) a 10 MeV (3 cm, 4 cm, and 5 cm circles and 12 cm square) and (b) a 20 MeV electron beam. Square field sizes expressed in cm × cm.

#### 24.2.5 VARIATION WITH FIELD SHAPE

Where the field shape has all dimensions greater than the scatter equilibrium value, the depth-dose characteristics will be the same as for medium to large square fields. Where any dimension is smaller than the critical value, the depth dose will be modified in a similar way to that discussed above. The exact depth dose will depend on the shape and the sizes involved. Various methods have been proposed for finding equivalent fields. For example, for rectangular fields of sides  $a \times b$  it has been suggested (Hogstrom et al. 1981) that the percentage depth dose (PDD) at a given depth can be estimated from square field information, using:

$$\text{PDD}(a,b) = [\text{PDD}(a,a) \cdot \text{PDD}(b,b)]^{1/2} \quad (24.4)$$

provided that the variation in collimator scatter is negligible. However, the concept of a single equivalent field has limited application and will vary with the specific machine and irradiation situation; therefore, any such simple models should be checked experimentally for the particular beams in use. More sophisticated models, such as pencil-beam approaches (see [Section 27.2](#)), are required to describe the real situation, particularly when the shape is irregular.

#### 24.2.6 VARIATION WITH SOURCE SKIN DISTANCE (SSD)

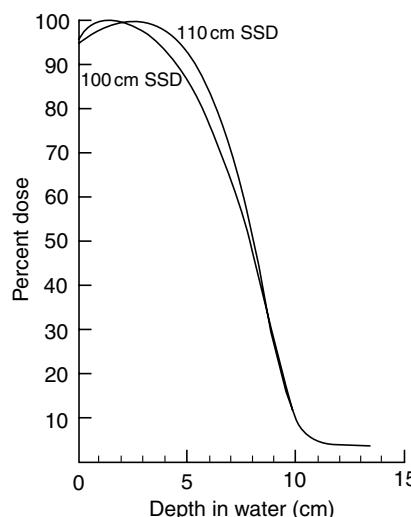

In general, electron treatments are carried out at SSDs close to the nominal value. Except in special cases, shorter SSDs are not possible because of the applicator. Longer SSDs are dictated where surface shape prevents the applicator being positioned close to the surface. To deal with this situation, a virtual source may be defined as the point that is closest to the intersection of the back projections of the mean directions of electrons passing through the plane perpendicular to the central axis at the isocentre. This point will be different for different beam energies and can also vary with field size. It can be determined by taking measurements at different distances and plotting the reciprocal of the square root of the readings against distance (see [Figure 23.10](#)). The virtual source position is determined either by the distance-intercept of the resulting line (see [Section 19.3.1](#) and [Section 23.2.1.16](#)) or by the inverse of the gradient of the line (Khan 1978; AAPM

1991). An alternative method is to plot field widths measured at various distances against distance and again examine the intercept of the resulting line. ICRU (1984) and AAPM (1991) give further discussion of these methods. The virtual source position defines the effective SSD that can be used in conjunction with an inverse square law correction for that beam energy and applicator size. In general, the effective SSD is shorter for smaller field sizes for a given energy, as the contribution of scattered electrons to the central axis from x-ray collimators and applicator is more significant. For very small field sizes, this can be quite marked. It also tends to be shorter at lower energies where scatter is more important.

After the virtual source position is determined, corrections can be made to the depth-dose curve. In general, because the penetration of electron beams is not very large, an Inverse Square Law correction to depth-dose curves is not very significant, particularly for changes in SSD of up to 10 cm, which is often the limit met in practice. Changes might be expected close to the surface and possibly extending to around the depth of therapeutic range. This is particularly marked if collimator scatter is used to significantly flatten the beam. Relative doses close to the surface decrease, but the depth of therapeutic range increases (Figure 24.5). The main problem with increased SSD is that of flatness and penumbra (see [Section 24.3.5](#)).

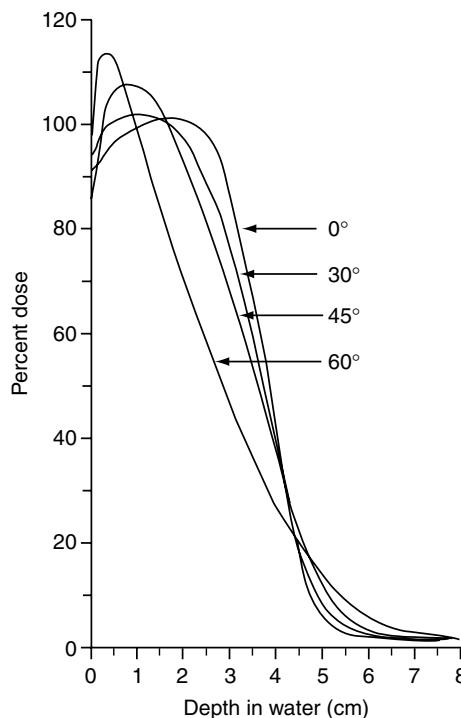

#### 24.2.7 VARIATION WITH OBLIQUE INCIDENCE

Oblique incidence has an effect on the depth-dose distribution due to changes in the effective penetration of the electrons and changes in scatter. A simplistic approach to correct for this is to apply the inverse square law to calculate the change of dose due to changing distance from the source at oblique angles. This approach assumes that at a point where the SSD is increased compared to the SSD on the central axis, the dose rate is reduced in proportion to the inverse square of the ratio of the SSDs and vice versa for a reduced SSD. (ICRU 1984). However, in 1979, McKenzie divided the field into elemental beams to show that scatter effects can work in the opposite direction, i.e. near to an oblique surface that is increasing in distance from the normal FSD; the spreading of the elemental beams due to scatter can result in an increase in dose at larger distances. This increase is at shallower depths, with a lower dose beneath this at greater depths. Later work confirmed these findings

**FIGURE 24.5**

The effect of extended SSD on the percentage depth-dose curve for a 6 cm × 6 cm 20 MeV electron beam. Both curves are normalised to the maximum dose.

**FIGURE 24.6**

Variation of central axis depth doses with angle of incidence, for a 10 MeV electron beam. All the curves are normalised to the maximum dose for a normal incidence.

(Ekstrand and Dixon 1982; Khan et al. 1985). In clinical practice, this increase in dose close to the surface commonly compensates or even overcompensates for the reduction due to inverse-square effects.

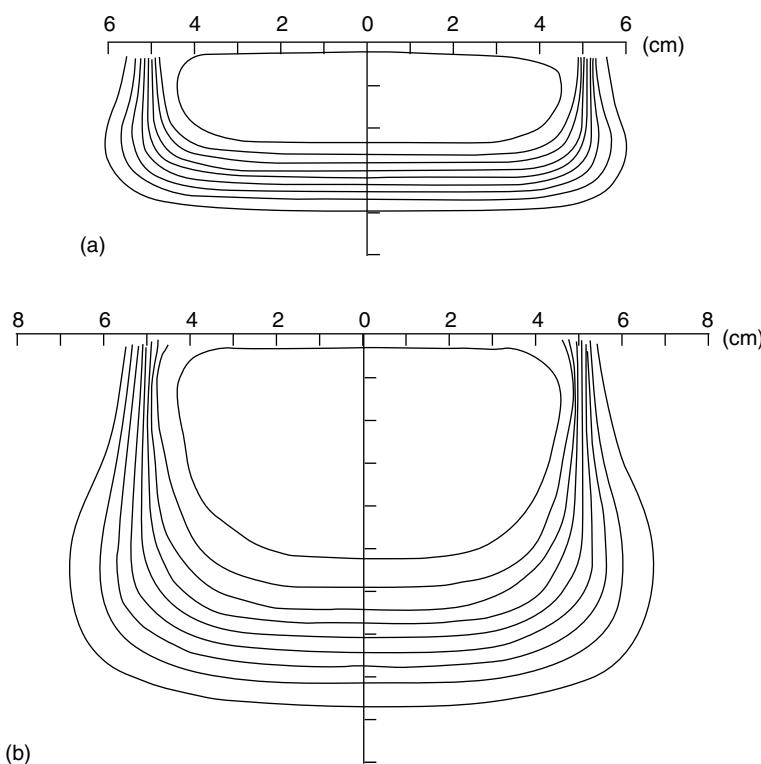

Thus, as the angle between the electron-beam central axis and a perpendicular to the surface increases, the depth-dose curve pulls towards the surface in the region of the therapeutic range. The dose at the depth of maximum dose increases and becomes greater than the zero angle maximum when the angle becomes steep, due to scatter from upstream excess of tissue. Conversely, scatter from downstream missing tissue penetrates to depths larger than the practical range, increasing the residual dose. Figure 24.6 illustrates this with depth doses measured along the central axis with increasing angle of incidence.

---

## 24.3 ISODOSES

### 24.3.1 GENERAL CHARACTERISTICS

Typical isodose distributions are presented in [Figure 24.7](#) for the same field size for both a low energy and a high energy electron beam, showing the isodose lines from 90% to 10% of the maximum central axis dose. These distributions illustrate the typical features. The relatively uniform dose region between the surface and the therapeutic range and the rapid fall-off with depth beyond this are evident, with only minor changes across the central part of the field. However there are significant changes towards the field edges due to scatter. At the surface, the penumbra is narrow, as the field is sharply defined by the applicator close to the surface. As the beam penetrates to increasing depths, the 50% isodose line initially approximately follows

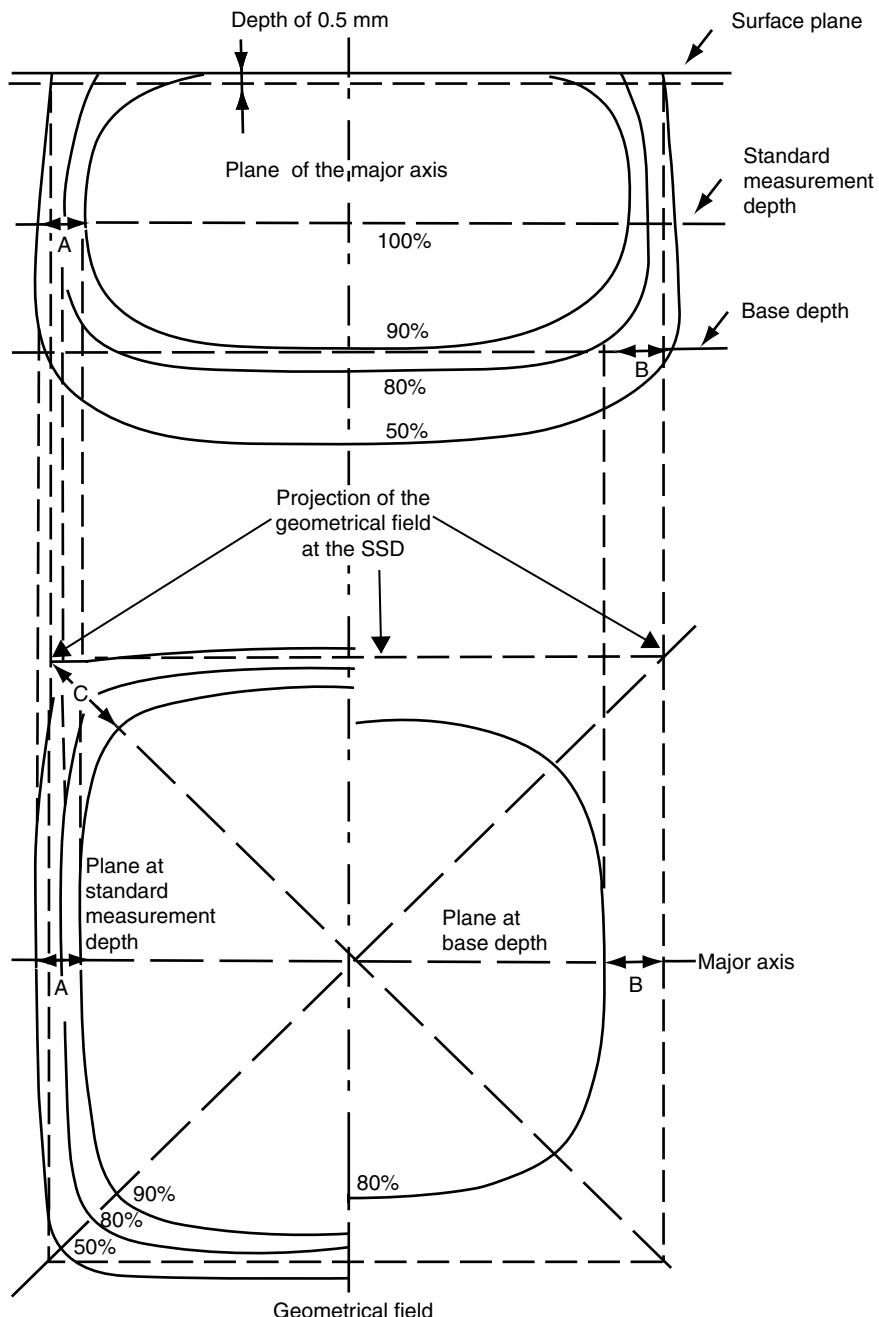

**FIGURE 24.7**

Typical central plane electron isodose curves in water for (a) a 7.5 MeV and (b) a 17 MeV beam for a 10 cm  $\times$  10 cm applicator placed in contact with the surface. The isodose lines are ranging from 90% to 10% of the maximum central axis dose value with a 10% increment.

the geometric beam edge. This defines the field size and corresponds to the dimensions of the applicator projected downwards. Lower value isodose lines bulge significantly outwards due to scatter, producing significant dose outside the field edge. Correspondingly, the higher-value isodose lines are pulled in at depth, reflecting the loss of dose from the out-scattered electrons. This has the consequence that the high-dose volume, e.g. that encompassed by the 90% isodose, is reduced in width as depth increases and can be considerably narrower at the depth corresponding to the therapeutic range than at the surface. The width of the 90% isodose will depend on beam energy, field size and machine design, and will increase towards the diagonal positions at the field corners. The clinical consequences of these characteristics are discussed in [Section 34.3](#).

#### 24.3.2 ELECTRON BEAM FLATNESS AND SYMMETRY

Field flatness and symmetry are specified over some stated central region either in terms of particular beam profiles at particular depths or in planes at stated reference depths. The specified central region may be defined in terms of a proportion of the field width, e.g. within the central 80% of the beam, or in terms of fixed distances from the geometric beam edge or the 50% isodose line on the principal and diagonal axes. For electron beams, the International Electrotechnical Commission (IEC 1989) defines the *standard measurement depth* as half the depth of the distal 80% dose on the central axis; and the *base depth* as the depth of the 90% dose on the central axis. [Figure 24.8](#) illustrates the general shapes and the position of these planes. For flatness and symmetry criteria, measurements are required at these

**FIGURE 24.8**

Schematic electron isodose distributions to illustrate the general form, the specified measurement planes and the International Electrotechnical Commission (IEC)-specified flatness-defining distances. (From IEC, *Medical Electrical Equipment—Medical Electron Accelerators in the Range 1 to 50 MeV—Functional Performance Characteristics*, IEC No 976, International Electrotechnical Commission, Geneva, 1989.)

depths and also at 0.5 mm depth and at the depth of dose maximum. The IEC specification includes:

1. The maximum distance between the 90% isodose contour and the edge of the projection of the geometric field (from the surface and parallel to the beam radiation axis) on both major axes at the standard measurement depth should not exceed 10 mm (Figure 24.8, distance *A*).
2. The maximum distance between the 80% contour and the edge of the projection of the geometric field on both major axes at the base depth should not exceed 15 mm (Figure 24.8, distance *B*).
3. The maximum distance between the 90% contour and the corner of the geometric field (diagonal axes) at the standard measurement depth should not exceed 20 mm (Figure 24.8, distance *C*).
4. The ratio of the highest absorbed dose anywhere in the beam at the standard measurement depth to the dose on the central axis at depth of dose maximum should not exceed 1.03\*.
5. In an area 1 cm inside the 90% isodose contour at the standard measurement depth, the ratio of doses at any two points equidistant from the central axis should not exceed 1.05.

#### 24.3.3 ELECTRON-BEAM PENUMBRA

The penumbra for electron beams is defined either in terms of the distance between two isodose values on a beam profile at the depth of maximum dose (or at the standard measurement depth), or indirectly in terms of distances between specified isodoses and the geometric field edge under stated conditions as above. If the former, then generally the 20%–80% width is expected to be 10 mm to 12 mm for electron beams below 10 MeV, and 8 mm to 10 mm for electron beams between 10 MeV and 20 MeV. These values apply for applicators with the final collimation stage at 5 cm or less from the skin, but for greater separation between the applicator and the skin the penumbra will increase.

#### 24.3.4 VARIATION OF ISODOSES WITH FIELD SIZE

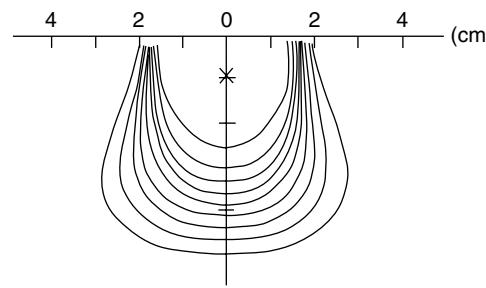

As the field size reduces, the central uniform portion of the isodose distribution reduces in width, until for small field sizes the isodoses become essentially two penumbral regions and the high-dose volume is very constricted in width at depth (Figure 24.9). The central axis distribution reflects the small-field depth dose behaviour, as discussed above.

Similar constrictions occur in any regions where the dimensions are small enough, e.g. small applicators, small shaped fields and larger fields where one dimension, or part of the irradiated area, is sufficiently small (Figure 24.10).

#### 24.3.5 VARIATION OF ISODOSES WITH SSD

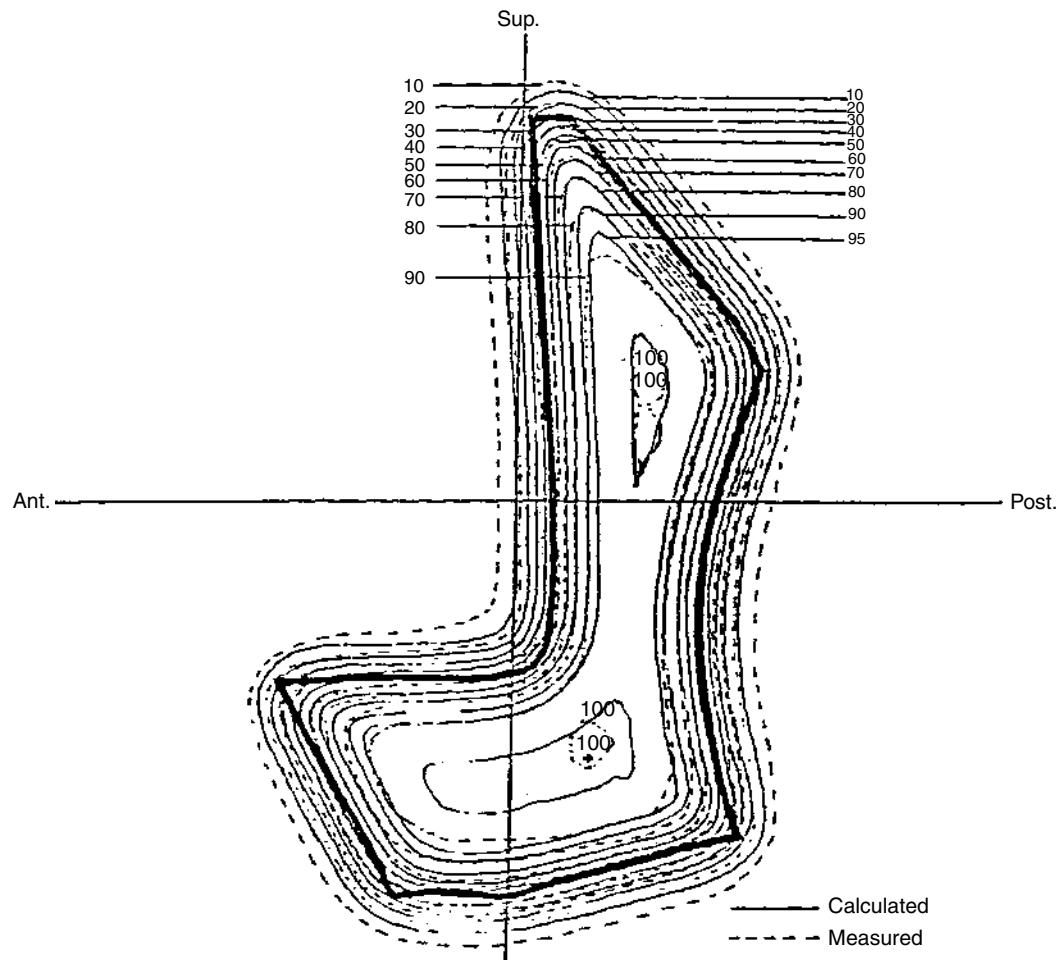

The variation of depth dose with SSD was discussed above. In addition, the distribution across the beam can be altered significantly. In particular, larger gaps result in greater penumbra widths, as head-scattered electrons are allowed to diverge more before being incident on the patient or phantom surface. Hence, increasing SSD does not generally produce wider high-dose regions; instead, these may remain approximately constant or even be reduced in width. Beam flatness may also be altered by increased SSD, particularly in those linac designs in which electron scatter off the collimator system is used to improve

\* It may be noted that this specification does not preclude *cold spots* within the treatment field at, or close to, the depth of dose maximum being as low as 90% of the maximum dose. IPEM have proposed an additional specification to address this issue (IPEM 1999).

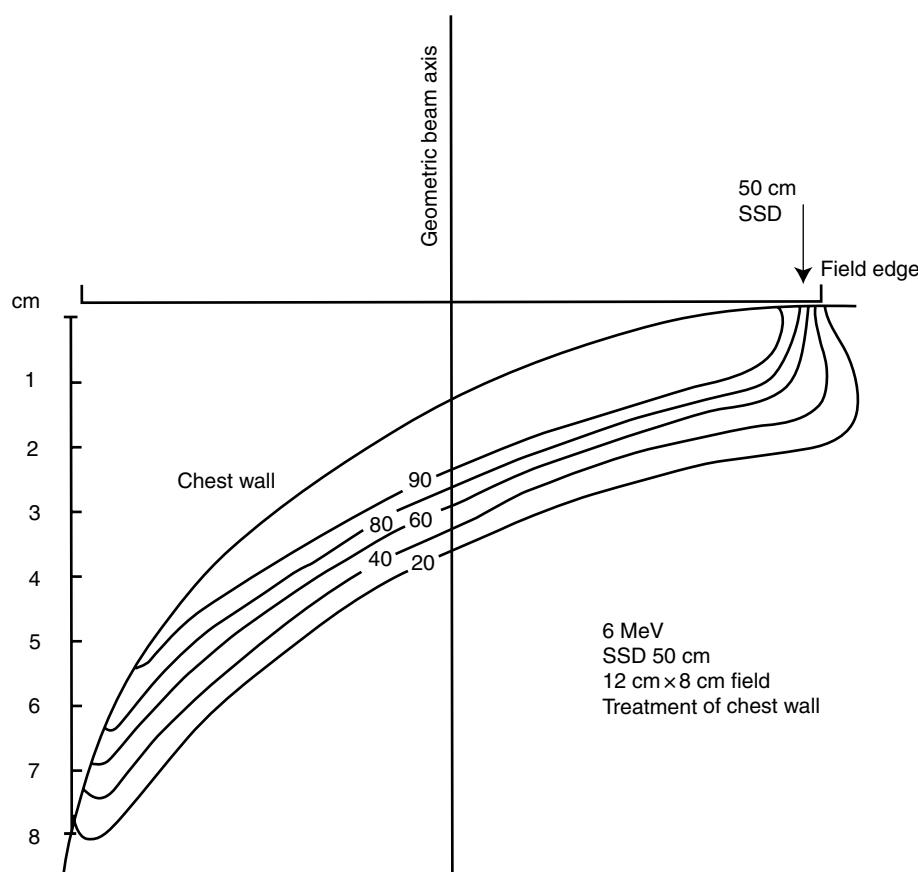

**FIGURE 24.9**

Effect of small beam area on electron isodose curves: a 3.5 cm circular applicator on a 10 MeV beam, at close distance from the distal end of the cone.

flatness. A sharp penumbra can be regained by using field shaping at the patient surface, but the maximum field size for acceptably uniform dose is still determined by the scatter behaviour. Thus, unlike photons, extending SSD does not usually allow larger areas to be treated uniformly.

**FIGURE 24.10**

Typical dose distribution perpendicular to the beam axis, at depth of dose maximum, for an irregular-field 9-MeV electron beam.

**FIGURE 24.11**

A 6 MeV electron beam incident on a chest wall illustrating the changing effects on isodose as the obliquity increases. This irradiation would not be ideal as the beam is not in best apposition. However, the beam direction may be dictated by adjacent treatment.

#### 24.3.6 VARIATION OF ISODOSES WITH OBLIQUE INCIDENCE

Isodose lines generally tend to roughly follow surface shape up to incident angles of around 30°. As obliquity increases above this, the electron paths become more tangential, air gaps increase and scatter changes become more significant. The isodoses move increasingly closer to the surface and the penumbral region becomes increasingly wide (Figure 24.11). At larger angles, scatter effects, as discussed for oblique incidence depth doses, can produce increased dose hot-spots (see [Section 24.6](#)).

---

## 24.4 FIELD SHAPING/SHIELDING

### 24.4.1 FIELD SHAPING

Most accelerators have a set range of electron applicators (or cones) that allow limited flexibility in modifying field shape. For other sizes, or for irregular fields, shaping can be achieved relatively simply using cut-outs of lead or low-melting-point alloy attached to, or close to, the end of the applicator (cone) or on the patient surface. As a rule of thumb, the minimum thickness of lead, in mm, is about half the nominal beam energy, in MeV, e.g. 10 mm for 20 MeV. These thicknesses should be increased by a factor of 1.2 for standard low-melting-point alloy.

Generally, these give adequate shielding with less than 5% bremsstrahlung residual dose at low energies which increases to about 10% at 20 MeV. The highest doses under the shielding are on the skin. If excessively thin shielding is used, this can result in skin dose being increased as compared to the open-field values due to the production of forward-scattered electrons and bremsstrahlung. Sharp field definition can be maintained by using shielding in close proximity to the patient surface. However, some compromise may be necessary, depending on the weight, the applicator design and the standard air gap. Normal electron field edge effects occur at a shielding edge; therefore, scatter outside the shielding should be taken into consideration.

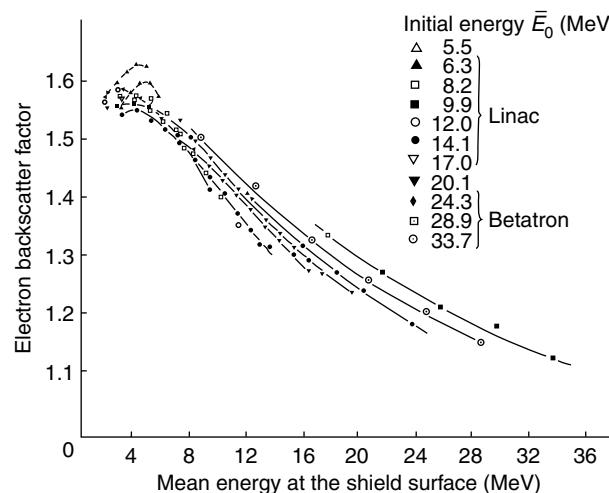

#### 24.4.2 INTERNAL SHIELDING/BACKSCATTERED ELECTRONS

One particular specialised application is to position shielding material inside anatomical structures to spare tissues lying below the target volume, for example in treatments involving eyelids, lip, or cheek. Given space restrictions, the minimum thickness to provide the required shielding should be used for the field size and depth involved. Any shielding material will produce backscatter that can significantly increase the dose at the tissue/shield interface. This excess dose increases as the atomic number of the scattering material increases and as the mean energy at the position of the shield ( $\bar{E}_s$ ) decreases (Figure 24.12). For the specific example of lead, Kleivenhagen et al. (1982) give the empirical relationship

$$\text{EBF} = 1 + 0.735 \exp(-0.052\bar{E}_s) \quad (24.5)$$

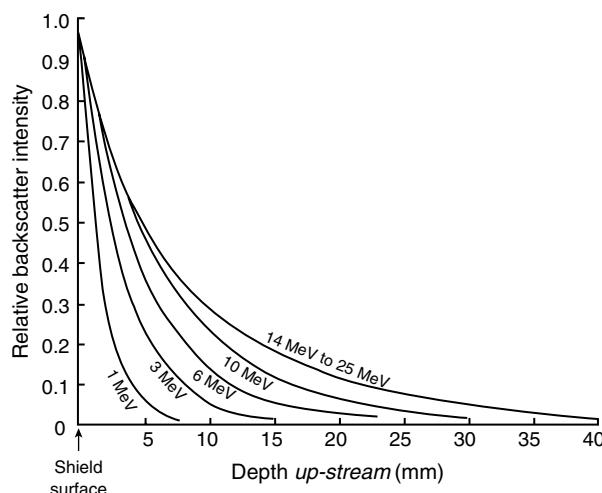

where the electron backscatter factor (EBF) gives the relative increase in dose at the surface of the backscattering shield compared to the dose without shield. Dose enhancement can be up to approximately 60% for  $\bar{E}_s$  of 3 MeV or 4 MeV.

Lambert and Kleivenhagen (1982) have reported the transmission of backscattered electrons through tissue or water substitute materials, with exponential fits to the data (Figure 24.13). Acceptable dose distributions can be achieved by using appropriate layers of such low-Z material between the shield and the overlying tissue to attenuate the backscatter. More details and a clinical example are given in [Section 34.4.2](#).

**FIGURE 24.12**

Variation of electron backscatter factor (EBF) with beam energy  $\bar{E}_s$  at the shield surface, for lead of sufficient thickness to provide shielding of underlying tissue. Each curve is for one beam of initial energy  $E_0$ . As the depth of the shield changes, the beam energy at the shield surface changes. (From Kleivenhagen, S. C. et al., *Phys. Med. Biol.*, 27, 363–373, 1982. With permission.)

**FIGURE 24.13**

Penetration of electrons (backscattered from underlying lead) in polystyrene in the *up-stream* direction of the primary beam. The energies indicated on the curves are the mean energies of the primary electrons incident on the lead. As the energy increases, a thicker layer of polystyrene is required to stop most of the backscattered electrons. (From Lambert, G. D. and Klevenhagen, S. C., *Phys. Med. Biol.*, 27, 721–725, 1982.)

## 24.5 BOLUS/ENERGY DEGRADERS

In various clinical situations (see Section 34.4), it is necessary to add tissue-similar material at the base of the applicator and/or in contact with the patient's skin. One particular situation is the modification of the depth dose to reduce the therapeutic range to match a specific clinically required depth that is not achievable with a standard beam energy. Alternatively, for superficial target volumes, low-energy beams may give excessively low surface doses and a higher energy beam may be selected in conjunction with an energy degrader whose thickness is chosen to bring the therapeutic range back to the desired depth, but with the low dose part of the build-up occurring in the degrader such that by the time the beam is incident on the skin the patient surface dose is higher. Suitable materials include wax or commercial flexible tissue substitutes. Alternatively, sheets of plastic, e.g. polymethyl methacrylate (PMMA, known as Perspex or Lucite), can be used, provided that any air gaps are not too large. The thicknesses should be chosen taking into account the electron density differences between the material used and water or soft tissue. Lambert et al. (1999), and others, have explored the use of higher-*Z* materials to increase surface doses.

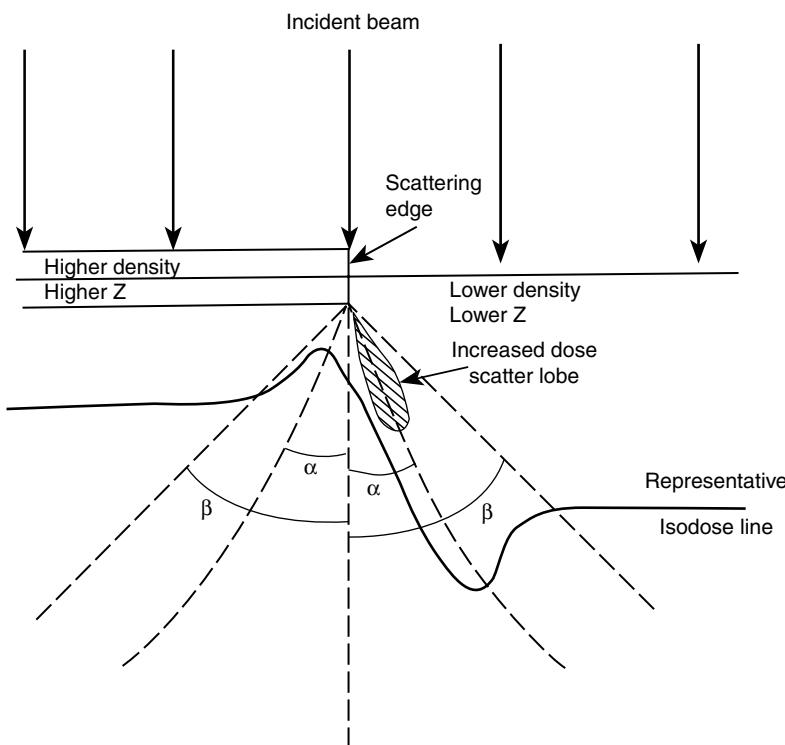

## 24.6 ELECTRON SCATTER EFFECTS

Electrons scatter very easily and strong scatter effects are observed in all electron-beam situations. The fundamental physics of the electron scatter processes has been described in Section 3.5. Scatter perturbations cause significant effects in dose measurements and scatter determines a number of the unique characteristics of electron-beam distributions, as discussed above. Scatter perturbations also produce significant effects in clinical dose distributions, some of which will be discussed in Chapter 34.

A scatter perturbation is produced when the junction of two materials of different composition is struck tangentially, or at a large oblique angle, by an electron beam. More electrons are scattered away from the higher density or higher-atomic-number material towards a lower

density or lower-atomic-number material than are scattered back. This imbalance gives rise to increased electron fluence and therefore increased dose (hot-spot) scatter lobes into or under the lower-density or lower-Z medium. There are correspondingly lower fluences and lower dose areas in or under the higher-density or higher-Z region, reflecting the relative loss of the out-scattered electrons. As an extreme example, if an electron field overlaps the edge of a phantom that is parallel to the beam axis, then the distribution at the edge of the phantom will be qualitatively similar to that at the edge of a normal electron isodose distribution, with high-dose isodose lines curving inwards due to loss of electrons scattered out into the adjacent air. Such situations arise clinically where fields overlap the edges of normal or abnormal body structures (which may then require added side-scatter to achieve the required distribution), at surface irregularities, at edges of energy degraders (bolus) in the field if they are not tapered, at edges of shielding or collimation, or at internal interfaces between tissues (e.g. tissue/lung, tissue/bone, tissue/air cavity, etc.) that are lying roughly in the same direction as the beam. These can give large local changes in dose distribution. Where small inhomogeneities or irregularities are present, the effects may be reinforced by scatter perturbations from more than one interface overlapping. Similar effects occur around dosimeters, e.g. the fluence perturbation around ion chambers (see [Section D.2.4](#) and [Figure D.10](#)).

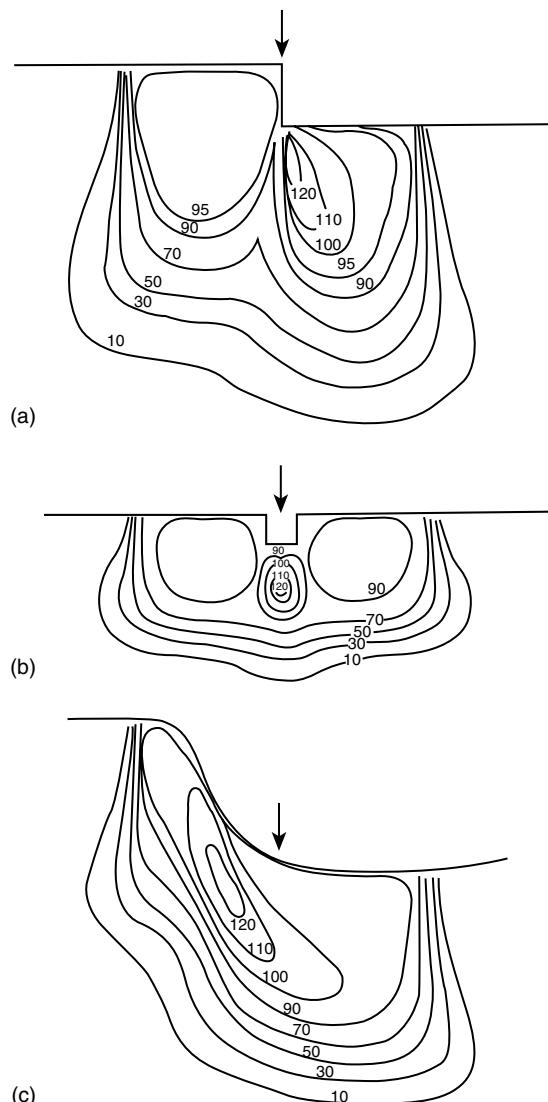

Sophisticated methods are required to deal with these effects in detail, i.e. at least the use of pencil-beam methods ([Section 27.2](#)) and ideally Monte Carlo modeling ([Section 28.4](#)). However, simple methods can be used as a means of providing a quick estimate of the magnitude of effects. For example, Pohlit and Manegold (1976) showed experimentally that the effects are maximum at an angle  $\alpha$  ([Figure 24.14](#)), which is approximately 60° at 5 MeV, 30° at 10 MeV and 15° at 20 MeV, where the energies are mean values at the depth of the interface.

**FIGURE 24.14**

The general form of the scatter perturbation effect on dose distributions beneath an interface. (After Pohlit, W. and Manegold, K. H., *High-Energy Photons and Electrons*, Wiley, London, 1976. With permission.)

The effects decrease with lateral distance from the interface to become negligible at a second angle  $\beta$ , beyond which interface or edge effects are not significant and the distribution is only influenced by differences in absorption of the electrons passing through the different materials.  $\beta$  is approximately 2.2 to 2.5 times  $\alpha$  in the energy range from 10 MeV to 30 MeV. Maximum changes in dose, whether reductions or increases as compared to the dose at the equivalent point in a homogeneous water phantom, may be estimated along either line at angle  $\alpha$ . They are found to increase with increasing energy at the depth of the interface, for example varying from approximately 4% at 5 MeV to 8% at 10 MeV and 14% at 20 MeV for a bone/water interface. For air/water or lead/water interfaces, the figures are approximately 1.8 times these values. Thus, air cavities give rise to greater effects than similar-sized bone cavities. Figure 24.15 provides some examples of the general form and magnitude of the scatter perturbation effects in a few typical situations (Thwaites 2000).

**FIGURE 24.15**

Illustrative examples of scatter perturbation effects on dose distributions. (a) A 20 MeV beam incident on a sharp irregularity; (b) a 10 MeV beam incident on a narrow air cavity, (c) a 17 MeV beam incident on a neck/chin contour. (From Thwaites, D. I., *Radiotherapy Physics in Practice*, 2nd Ed., Williams J. R. and Thwaites, D. I., Eds., Oxford University Press, Oxford, p. 332, 2000. With permission.)

In addition to side-scatter from interfaces parallel to, or at shallow angles to, the beam, backscatter will also occur where an interface between materials of different density and atomic number lies across an electron beam. Some information on the dependence on energy and atomic number of the material is presented above as it relates to backscatter from internal shielding (see [Section 24.4.2](#)). However, similar effects will increase doses upstream from any higher atomic number material, e.g. bone, metallic implants, etc. and the information presented in [Figure 24.12](#) can be used to estimate the magnitude of effects, although absolute values will be lower for lower-atomic-number back-scattering materials. Similarly, backscatter is reduced upstream from an interface with lung or air.

---

## 24.7 OUTPUT FACTORS AND MONITOR UNIT CALCULATIONS

The output factors, in dose/MU, are a function of applicator size and SSD. For the nominal SSD, applicator (cone) factors relative to a standard applicator size (usually 10 cm × 10 cm) should be measured at depth of dose maximum for each field size. The depth of dose maximum will vary for smaller field sizes and the output factor is not simply a ratio of ion chamber readings in this case, but is a ratio of reading times stopping power ratio, as the stopping power ratios vary with depth (see also [Section D.1.2](#)). If the machine is an older design that uses a fixed side-scattering cone mount or a fixed x-ray collimator setting, with a range of add-on field-defining applicators, the factors usually vary relatively smoothly with field size at a given energy. For machines that have differing pre-set x-ray collimator positions for each combination of applicator and energy, the variation of dose/MU with field size may be less predictable. For variable trimmer systems, the output varies relatively smoothly with field size so that a limited set of measurements allows interpolation to intermediate settings.

The dose/MU at dose maximum on the central axis varies with the electrons scattered off the x-ray collimators and those scattered off the applicator, as well as phantom scatter. If further field shaping is used, there may be additional scatter from the edges of the shield. The relative contributions of these components may vary with: the beam energy, the depth of dose maximum (itself energy and field size dependent), the particular standard applicator involved, the x-ray collimator position and the overall size and shape of any modified field, including the distance from the central axis of shaping material. This represents a complex combination and  $R_{100}$  and output factors must be determined for a sufficiently wide range of fields and cut-outs. Output factors for cut-outs must relate to the dose maximum of the modified field; they may be expressed relative to the output of the open applicator at its dose maximum or relative to a reference output for a standard applicator. Measurements should be carried out under the conditions to be used clinically. Thus, in the event that the applicator design and the position of field shaping material require changes in the nominal treatment distance, this is included in the factor. If any field dimension is less than the range of the electrons, side scatter equilibrium at the central axis will be lost and the dose per monitor unit will be less. This effect is more pronounced for lower energies. Similar effects will also be present for fields where shielding is used to reduce the size of one dimension to within this range. However, provided that there is no change in SSD and the field shaping does not reduce any dimensions below that necessary for scatter equilibrium on the central axis, the output factor will not differ significantly from the unshaped field output factor. For shaped fields, various methods have been applied to predicting output factors, including equivalent area, scatter integration, pencil beam and Monte Carlo. Because of the various components contributing to output when cut-outs are used, the relative output factors may not be smooth or monotonic in behaviour and prediction for unmeasured fields must be carried out with care and verified by measurement.

Electron-beam treatments are most commonly carried out at the standard treatment distance defined by the applicator end, usually with a short stand-off distance. As discussed

above, extending the SSD generally worsens the dose distribution; however, some clinical situations dictate longer SSD due to problems in positioning, surface shapes, etc. In these cases, the dose/MU will be reduced with increased distance. The calculation of the dose/MU for a SSD change could then be based on the inverse square law relative to the *virtual*, or *effective*, point source location, which will generally be variable with both energy and field size (see [Section 24.2.6](#)).

## INTRODUCTION

Calculation of the dose at a single point on the central axis of a beam under well-defined conditions can be performed using beam data tables and a calculator (see [Chapter 23](#) for photons and [Chapter 24](#) for electrons). Calculating the distribution of dose in a patient is not so straightforward. Before computerized treatment planning systems became widely available, dose distributions were calculated manually by the addition of percentages estimated from the superposition of isodose charts (such as those shown in [Figure 22.11](#)). The methods used involved empirically derived corrections to account for patient shape and inhomogeneities (see [Section 22.4](#)). So-called *hand planning* was time consuming and relied heavily on the experience of the planner; even so, complex planning methods were attempted at many centres. Modern computer technology has allowed increasingly sophisticated techniques to be routinely applied to treatment planning and has widened the aims and scope of treatment planning itself.

In the 1970s and 1980s, treatment planning algorithms were developed by individuals or groups working in, or attached to radiotherapy institutions. Commercial systems based on published algorithms or collaboration with research institutes are now widely used, and the number of one-off hospital-based systems is relatively small. As the power of computers has grown, so has the complexity of the planning algorithms. Some insight into the impressive development that took place during the last 40 years can be obtained from browsing through the series of proceedings of the International Conference on the Use of Computers in Radiation Therapy (ICCR); these meetings typically have been held every three years since 1961 (see references).

Although photon and electron algorithms have much in common ([Chapter 25](#)), there are significant differences which will be addressed separately in [Chapter 26](#) and [Chapter 27](#). Also, the general approach of dose computation principles covers a wide range from models that are mostly a representation of the experimental dose distribution to physically based models that model the transport of elementary particles from their production to their energy deposition in the patient. The Monte Carlo algorithms that can be used for photons as well as for electrons belong to the latter category, and they will be presented separately in [Chapter 28](#).

## 25.1 GENERAL REQUIREMENTS

The dose calculation algorithms, as discussed here, primarily are intended to be integrated into clinically used treatment planning software. Their ultimate goal is to predict accurately the dose delivered at any single point in the patient in order to decide if a given treatment plan is acceptable or to choose the best plan from several alternative ones. The corresponding requirements are therefore to obtain rapidly an accurate and comprehensive result in all situations with a maximum of flexibility. The issues related to comprehensiveness and flexibility are dependent mostly on the practical implementation of the algorithm within the treatment planning software. They are discussed in Chapter 39. Other issues are essentially algorithm dependent and are discussed in what follows.

### 25.1.1 ACCURACY

There has been extensive discussion in the literature on the accuracy required when treating a patient. This is covered in detail in [Section 37.4](#) and [Section 37.5](#). Since the dose computation is only one element of a complex chain (see [Figure 43.1](#)), the general principle is that it should not add a significant uncertainty to the final outcome. An interesting analysis based on this principle has been made by Ahnesjö and Aspradakis (1999) and is illustrated in Table 25.1. This table lists the uncertainty attached to each link of the chain starting from the absolute dose determination (see [Chapter 18](#)) and ending with the patient dose calculation. Two situations are considered the *present* technique (i.e. in 1999) and the future development. Several hypothetical levels of dose calculation uncertainty (from 0.5% to 5%) are considered. For each level the overall uncertainty is calculated from quadratic combination of individual uncertainties and compared to the overall uncertainty excluding dose calculation. It turns out that a dose calculation uncertainty of about 2% or 3% does not lead to a significant increase in the overall uncertainty at *present*, whereas 1% calculation accuracy might be required in the future.

Some indications on how to assess the accuracy of a dose planning algorithm are given later (see [Section 39.3.4.2](#)), but it must be recognised that it is very difficult to state the accuracy range for a given dose computation algorithm independently of the context in which it is used. The reasons are twofold: (i) the parameters used by the algorithm (basic data) have a huge influence on the result itself and hence on the corresponding accuracy, and (ii) the accuracy can be very good for some situations (e.g. a water medium) and very poor for others (e.g. inhomogeneous media). For these reasons, simple models can turn out to be more accurate than *sophisticated* models, at least in some instances. The important point is to be aware of the cases where the error is outside acceptable limits.

### 25.1.2 SPEED

The increase in the speed of computers has made life much easier than before when planning a patient's treatment. However, with more powerful computers has come an increase in the demands placed upon them; a full 3D dose distribution (i.e. in the whole treated area) for a large number of complex beams is often demanded, together with

**TABLE 25.1**

Determination of the Accuracy Required for Dose Calculation

	Present Technique $100 \times \Delta D(1\sigma)/D$	Future Development $100 \times \Delta D(1\sigma)/D$
Absorbed dose determination at the calibration point	2.0	1.0
Additional uncertainty for other points	1.1	0.5
Monitor stability	1.0	0.5
Beam flatness	1.5	0.8
Patient data uncertainties	1.5	1.0
Beam and patient set-up	2.5	1.6
<b>Overall excluding dose calculation</b>	<b>4.1</b>	<b>2.4</b>
Dose calculation	1.0 <b>2.0</b> <b>3.0</b> 4.0 5.0	0.5 <b>1.0</b> 2.0 3.0 4.0
<b>Resulting overall uncertainty</b>	<b>4.2</b> <b>4.6</b> <b>5.1</b> 5.7 6.5	2.4 <b>2.6</b> 3.1 3.8 4.7

Uncertainties are expressed as percentages. The *present* technique refers to 1999.

Source: From Ahnesjö, A. and Aspradakis, M. M., *Phys. Med. Biol.*, 44, R99–R155, 1999.

searching for the best plan through an interactive trial-and-error procedure\*. Typically, for such cases where the planner uses the graphical display to look at the dose changes resulting from beam modifications, the overall response time should not be more than 10 s to 20 s. With the advent of intensity modulated radiotherapy (IMRT) the speed problem is even more crucial since the inverse planning approach requires that the dose computation be repeated for many beams, many times at many points, as part of an automated iterative process (see Chapter 43).

It is easily understood that speeding up the calculation generally means a decrease in accuracy (for given computer hardware). Therefore, the choice of the dose calculation algorithm on a given occasion is largely a compromise which should take into account the clinical impact of a greater inaccuracy in dose. Although somewhat difficult to organise in practice, a good solution is to have access to several algorithms and make the appropriate choice depending on the circumstances (e.g. have a faster algorithm for inverse planning and then confirm the dose distribution with a slower but more accurate one before the start of treatment). However, if used for inverse planning, the fast algorithm must have sufficient accuracy to ensure that its limitations do not have a significant effect on the outcome of optimisation.

### 25.1.3 GENERAL ASPECTS

The calculation of the dose distribution in a patient implies that relevant beam data are combined with individualised patient data. In this process, it is therefore essential that the dose calculation algorithm takes into account the characteristics both of the patient anatomy and of the clinical beam. As seen in Part E, factors affecting the delivered dose are quite complex, and they include the influence of all accessories (i.e. wedge filters, compensators, blocks, etc.). They are even more complex when special techniques are being used (see Part I).

As far as the patient anatomy is concerned, the most effective representation is a 3D matrix of voxels derived from a CT scan of the patient in the treatment position (Chapter 30). Ideally, the exact tissue density and composition of each of these voxels should be taken into account.

In practice, however, many simplifications have to be made for both the patient representation and the beam description. Again this is mostly a trade-off between the current possibilities of the algorithm, ease of access to the relevant beam and patient data, speed of calculation and accuracy.

---

## 25.2 COORDINATE SYSTEMS AND GEOMETRICAL ISSUES

In order to compute the dose at any point within the patient it is necessary to know the corresponding geometry. As a first approximation, it could be sufficient to calculate the overlying thickness of tissue along the line joining the source to the calculation point. This would typically allow an accurate calculation of the primary component. This thickness  $z$ , generally referred to as the *depth* of the calculation point, can be expressed as a geometrical distance (as if the patient were entirely made of water) or be corrected for tissue inhomogeneity, using the concept of *equivalent path length* (sometimes called *radiological* or *water equivalent* thickness). This concept is rather intuitive (Figure 25.1). It is based on the fact that the product  $(t_m \times \rho_m)$  of a given thickness  $t_m$  of material m and the *density*  $\rho_m$  of this material gives approximately the same attenuation for photons (and the same penetration for electrons) as the product  $(t_w \times \rho_w)$ , where w stands for water ( $\rho_w = 1$ ). It can be demonstrated that this equivalence is perfect for the primary component of a polyenergetic photon beam, provided that density is expressed as

---

\* Such a trial-and-error procedure has also become known as *forward planning* in contrast to *inverse planning* (see Chapter 43).

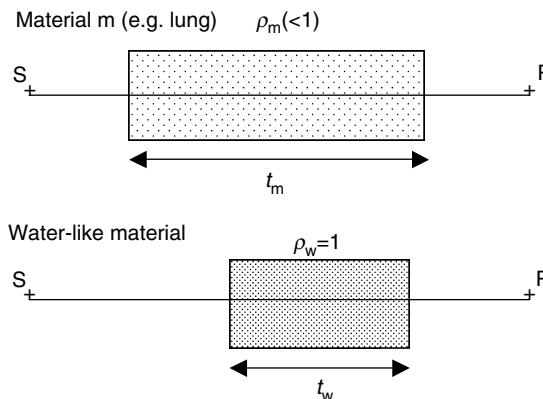

**FIGURE 25.1**

Illustration of the equivalent path length method: the attenuation at point P for a thickness  $t_m$  of a material of electronic density relative to water  $\rho_m$  is assumed to be the same as for a scaled thickness  $t_w$  of water where  $t_w = t_m \cdot \rho_m$ . This is rigorous for primary photons when only Compton interactions with peripheral electrons are considered (same total number of electrons/cm<sup>2</sup> interposed between the source and point P).

electronic density relative to water and that the Compton effect is the only interaction process to be considered (see also [Section 22.4](#) and [Section 23.3.4.5](#)). For a given photon spectrum, whatever interaction process of the primary component is considered, this equivalence is also rigorous using the mass density under the assumption that the *mass* attenuation coefficient is independent of the material (see [Section 4.4.1](#)).

In order to achieve a higher accuracy, it is necessary to consider also the influence of the scattered photons and secondary electrons. As far as photons are concerned, the equivalent path length method can be extended to the lateral dimensions by application of the O'Connor theorem (O'Connor 1957). With this theorem it can be shown that, when considering two media of different densities but the same atomic composition exposed to the same beam, the dose at corresponding points in the two media will be the same provided that all geometric distances in the two media, including field sizes, are scaled inversely with density (Figure 25.2) (Bjärngard 1987; Ahnesjö and Aspradakis 1999).

The practical application of the O'Connor theorem is not straightforward. In general, however, understanding some of the fundamentals and some of their related principles is very useful in gaining an insight into the possibilities and limitations of the various dose

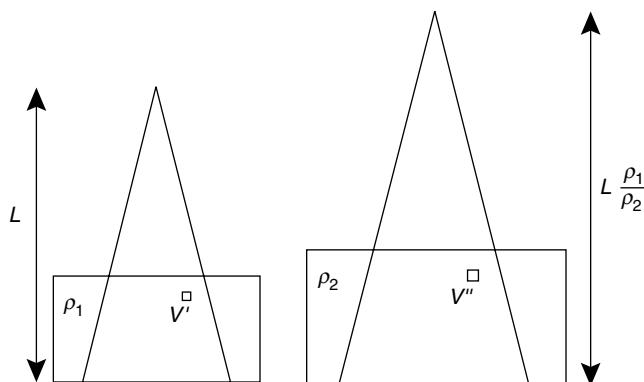

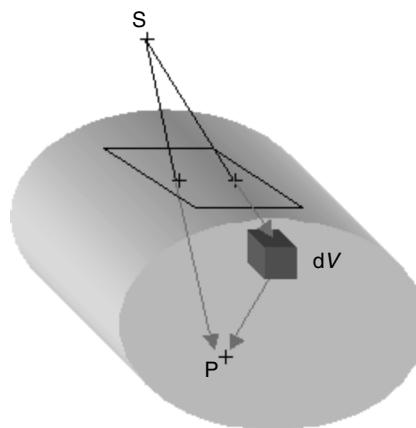

**FIGURE 25.2**

Illustration of the conditions required for O'Connor theorem to be valid. The figure illustrates a situation where  $\rho_1$  is larger than  $\rho_2$ . (From Ahnesjö, A. and Aspradakis, M. M., *Phys. Med. Biol.*, 44, R99–R155, 1999. With permission.)

**FIGURE 25.3**

Schematic drawing of a beam incident on a patient. The dose at point P is influenced principally by the tissues lying between the source S and P but also by the scattered radiation from the rest of the patient volume.

calculation algorithms. Although some simplifications are often acceptable, it should always be remembered that the problem is a 3D problem and that one should take into account not only what happens along the line joining the source to the calculation point but also the contributions to the dose at that point from the scattered radiation (both photons and electrons) arising in the rest of the medium (see Figure 25.3).

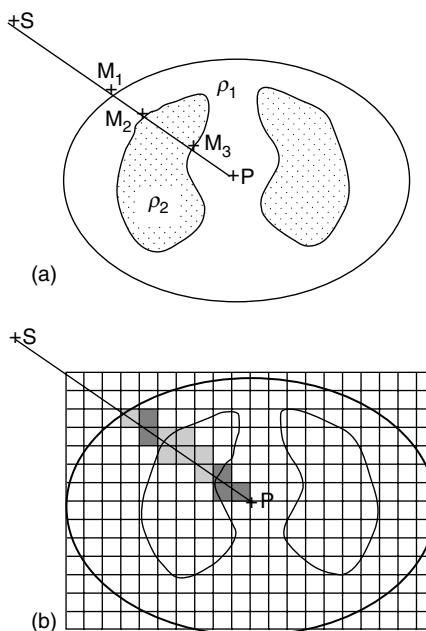

**FIGURE 25.4**

Illustration of two methods for the calculation of equivalent path length  $t_{eq}$ : (a) For *contour-based* patient representation,  $t_{eq}$  is calculated from the (3D) intersections of a line joining the source S to the calculation point P with the external body surface (at  $M_1$ ) and with internal structures such as lung (at  $M_2$  and  $M_3$ ):  $t_{eq} = M_1 M_2 \cdot \rho_1 + M_2 M_3 \cdot \rho_2 + M_3 P \cdot \rho_1$ . (b) For *voxel-based* patient representation,  $t_{eq}$  is calculated from the sum of the elementary path lengths through each individual image voxel:  $t_{eq} = \sum t_i \rho_i$  where  $t_i$  is the geometrical distance through voxel  $i$  and  $\rho_i$  the density of voxel  $i$ .

For electron beams (and for the secondary electrons generated in photon beams), similar scaling considerations can be useful and provide an often acceptable approximation (see also the description of Fano's theorem in [Section 6.7.3](#)).

In practice, the implementation of clinical dose calculation methods requires the definition of unambiguous coordinate systems. It also generally requires dealing simultaneously or sequentially with *vector-based* (i.e. contours) and *image-based* representations (i.e. pixels and voxels) of the patient, with algorithms for transforming one representation into the other. The depth calculations could be handled in either of these two modes ([Figure 25.4](#)) and thus may require, as a first step, a coordinate transformation in which a point linked to the patient would be expressed in relation to a Cartesian coordinate system linked to the beam. Thanks to this transformation which takes into account the beam geometrical characteristics such as 3D position, orientation and divergence, the geometrical problem is very much simplified (Siddon 1985), and the source-to-point distances and point depths become directly available. In subsequent chapters, a coordinate system with the  $z$  axis coincident with the beam axis and the  $x$  and  $y$  directions, parallel to the width and length of the field, respectively, will be considered. The depth of the point will be referred to as  $d$  or  $z$  and the source-to-point distance as  $f$ . We will use the quantities and symbols defined in [Section 23.2.1](#).

## 25.3 ABSOLUTE AND RELATIVE DOSE

The dose calculation algorithm ought to be able to yield the absolute dose distribution (i.e. in Gy) within the patient, for a given number of monitor units (MU). However, the current practice is to calculate relative dose distributions, which is relative to the dose at a given arbitrary point in the open part of the beam. This point, called the *weight point* or *beam normalisation point*, is frequently coincident with some reference point used for patient set-up or for dose prescription (i.e. the isocentre, the ICRU reference point or the depth of maximum dose  $d_{\max}$ ). Though often overlooked in the past, the link between relative and absolute dose is now recognised as fundamental (Ahnesjö et al. 1992a; Mackie et al. 1995, 1996; Fraas et al. 1998; Ahnesjö and Aspradakis 1999; Liu et al. 2000; Jiang et al. 2001; Mijnheer et al. 2004).

The point is that one should take full advantage of the sophistication of modern algorithms to assess precisely the relationship between the dose at a given reference point and the number of monitor units. The need for such an approach is even more evident when special techniques are used, e.g. intensity modulated radiation therapy (see [Chapter 43](#)), where traditional methods of calculating monitor units, such as those described in [Chapter 23](#), are not applicable. The solution to the above problem is far from evident. It depends very much on the type of algorithm and on its clinical implementation. However, the general principle can be described.

Whatever kind of dose modelling is being used, the dose at any point is directly or indirectly linked to an internal quantity  $Q_0$  used as a reference (i.e. used for beam normalisation purposes). If, for instance, the dose is simply obtained from storage and retrieval of dose measurements performed on a Cartesian grid for different field sizes at a given SSD, then  $Q_0$  could be the dose at the normalisation point of each grid (e.g. at constant depth) and it could therefore be field-size and depth dependent. As seen later,  $Q_0$  could also be the dose in air  $D_{\text{air}} = D(\text{air}, A, \text{SAD})$  (or in a mini-phantom) as defined in Chapter 23.  $D_{\text{air}}$  is independent of the phantom and is easily calculated at different distances. At a given distance  $f$  it depends almost exclusively upon the collimator opening  $A$ . The collimator opening  $A$  is also the only significant *uncontrolled*\* parameter of influence if  $Q_0$  represents the primary photon energy

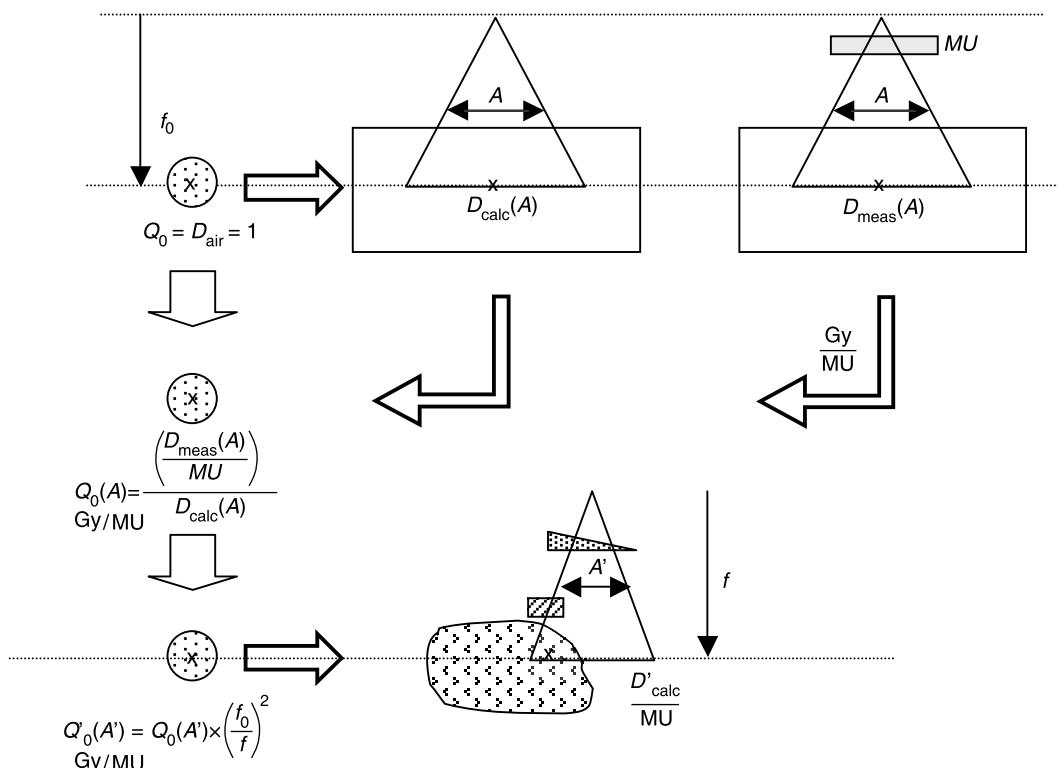

\* We use the term *uncontrolled* to characterize the parameters for which the influence on  $Q_0$  is not predictable by the calculation algorithm. The variation of  $Q_0$  as a function of such parameters should be measured instead.

fluence at a reference distance in the so-called kernel-based convolution/superposition method (see [Section 26.3](#)). For methods such as Monte-Carlo simulation, where the particles emitted from the source (photons or electrons) are transported through the treatment head and through the patient,  $Q_0$  could be the number of primary particles used for simulation (see [Section 28.6.1](#)).

In all cases, once the *uncontrolled* parameter(s) of influence of  $Q_0$  is (are) clearly identified, a reference set-up is decided arbitrarily with a simple geometrical phantom (i.e. used for beam calibration). For this set-up, the parameter(s) *param* is (are) varied systematically and both dose *measurements* (for a given number of MU) and dose *calculations* (for given value of  $Q_0$ ) are performed. In principle one could then derive the quantity of interest  $(Q_0/MU)(param)$  using the following equation:

$$\frac{Q_0}{MU}(param) = \frac{\frac{D_{\text{meas}}(param)}{MU}}{\frac{D_{\text{calc}}(param)}{Q_0}} \quad (25.1)$$

where  $D_{\text{meas}}(param)$  and  $D_{\text{calc}}(param)$  are the measured and calculated doses for a particular value of the parameter(s) *param* respectively.

**FIGURE 25.5**

The principle of the *internal calibration* of a dose calculation algorithm allowing the calculation of the absolute dose ( $D_{\text{calc}}$ ) per MU at any point and for any situation when  $D_{\text{air}}$  is the reference quantity  $Q_0$  (left column of the figure), the field size  $A$  being the *uncontrolled* parameter. The upper part of the figure describes the reference set-up (both measurements and calculation).  $D_{\text{calc}}(A)$  is first calculated keeping  $Q_0$  equal to unity.  $D_{\text{calc}}(A)$  is then used as a normalisation factor of the measured dose  $D_{\text{meas}}(A)$  to derive the quantity  $Q_0(A)$  that must be used in all subsequent calculations. The lower part of the figure corresponds to calculation for the clinical situation (field size  $A'$ , distance  $f$ , including beam modifiers and patient characteristics). In this example, the calculated quantity  $Q_0(A)$  is proportional to the collimator-scatter factor  $S_c$  (see [Section 23.2.1.12](#)) but it is related to the absolute dose and directly derived from in-phantom measurements performed in reference conditions.

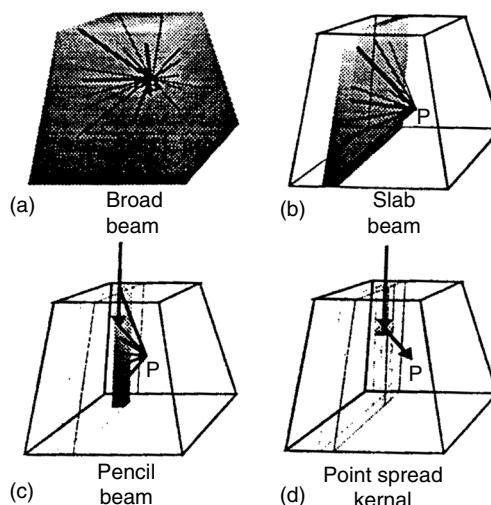

It is then easy to calculate the *absolute dose per MU* at any point and under any conditions, provided that the algorithm makes use of the quantity  $(Q_0/MU)(\text{param})$  instead of  $Q_0$ .

This overall procedure can be considered as an *internal calibration* of the dose calculation algorithm. It is illustrated in [Figure 25.5](#) when the dose is calculated from the reference quantity  $Q_0 = D_{\text{air}}$ , using the Clarkson–Cunningham integration of the scatter component (see [Section 26.3.2](#)). The detail of the method for other formalisms can be found in (Ahnesjö and Aspradakis 1999) and in [Section 28.6.1](#).

Another point of discussion is the definition of the dose in a non-water like medium. Actually, for a given photon energy fluence the local dose is dependent on the surrounding medium (see [Chapter 6](#)). For instance for low energy x-rays the absorbed dose in bone is much higher than in soft tissue. In the current algorithms used for clinical planning, this is not considered and even if the photon (and/or electron) fluence is corrected for the influence of inhomogeneities, the local dose is always referred to a water-like medium. This may change as Monte-Carlo methods come into clinical use (du Plessis et al. 1998; Siebers et al. 2000b; and [Section 28.6.2](#)). It is therefore important to state clearly to which medium the calculated dose is related.

## 25.4 ALGORITHM CLASSIFICATION

There is no current consensus on a classification methodology for dose calculation algorithms. ICRU (1987) distinguished between tabular (or matrix) formats, beam generating functions, separation of primary and scattered radiation and representations using basic principles. Mackie et al. (1995, 1996) suggested distinguishing between correction-based and model-based methods. This was related mostly to the handling of beam modifiers and inhomogeneity corrections; in the former case the open-beam dose distribution in water is computed and then corrected for the beam modifiers and patient characteristics, whereas in the latter case the interaction in the patient is computed directly. The former approach could be considered as based principally on correction factors extracted from measurement and the latter on more physical modelling of beam interactions. However, this conceptual distinction is

**FIGURE 25.6**

Integration of scatter from various types of kernels. (From Battista, J. J. et al., in *XIIth International Conference on Computers in Radiotherapy*; Leavitt, D. D. and Starkshall, G., Eds., Medical Physics Publishing, Salt Lake City, UT, pp. 29–42, 1997. With permission.)

difficult to apply strictly since there is a wide range of possibilities between measurement-oriented and fundamental methods.

Another suggestion was made by Battista et al. (1997), who referred to the fact that most modern methods used clinically make use of some integration or superposition of elementary *kernels* throughout the patient volume ([Figure 25.6](#)) (see [Section 26.3](#)). They made a distinction according to the number of dimensions over which the integration is carried out: the absence of integration was referred to as the *broad-beam* approach, because the beam is treated as a whole rather than being broken up into its component segments. The Monte-Carlo approach (see [Chapter 5](#) and [Chapter 28](#)), where each particle is tracked in 3D, does not fit exactly with this scheme. It could be considered as the ultimate form of the 3D integration and treated separately.

This provides a systematic approach to the frequent classification into 1D, 2D or 3D (or 2.5D, etc.) models. However, as explained by Battista et al., one must also consider how the anatomical dimensions are taken into account in the implementation of the model. Typically for a 1D algorithm the dose at a point P depends only on the accessories and patient characteristics found on the line joining the source to P; a 2D algorithm takes into account the modifications in the transverse plane, excluding the changes in the cranio-caudal direction, whereas a 3D algorithm accounts for any change in the whole volume (see also Figure 11 and Table 7 in AAPM 2004). This classification of dose algorithms should be differentiated from the classification of Treatment Planning Systems where the possibilities of 3D beam orientation and 3D display must also be considered (see [Chapter 39](#)).

Although discussed in the literature mostly with reference to photons, all the previous considerations are very similar for electrons. In fact the methods for dose calculation, which originally were quite different, have certain unifying features (Bloch 1988). In what follows, nevertheless they have been kept separate. Photon beam are dealt with in [Chapter 26](#) and electron beams in [Chapter 27](#). The application of the Monte-Carlo method, which is common to both photons and electrons, and which is just starting to be used for clinical planning, is covered in [Chapter 28](#).

It should be noted that, whatever method is used, some empirical tuning of the model with respect to the actual beam characteristics is needed to a greater or lesser extent. Such tuning is of the utmost importance for the validity of the results (see [Section 39.3.6](#)).

## 26.1 PHYSICAL BACKGROUND

As seen in [Part A](#) and [Part E](#), the mechanisms of dose deposition in the patient by a clinical photon beam are quite complex. They are summarised in Figure 26.1. Note that we refer in this chapter implicitly to megavoltage photon beams which were dealt with in [Chapter 22](#); detailed dose computation in patients is not generally carried out for kilovoltage x-ray beams which were dealt with in [Chapter 21](#).

In this figure, four main dose components have been identified:

- The primary dose dominates and represents generally more than 70% of the total dose
- The phantom scatter dose is the second-largest contribution, and can represent up to 30% of the total dose

**FIGURE 26.1**

Schematic representation of the main interactions and dose components for clinical photon beams. (From Ahnesjö, A. and Aspradakis, M. M., *Phys. Med. Biol.*, 44, R99–R155, 1999. With permission.)

- The head scatter dose is of less importance but it can amount to 5% to 10% of the total dose
- The contaminant charged-particle energy deposition has a large influence, especially for high-energy photons, but only at small depths (typically less than 4 cm, i.e. only in the buildup region; externally incident electrons cannot reach any further).

Depending on the sophistication of the model, these components, although always implicitly taken into account in contributing to the total dose, may or may not be considered explicitly. In the following distinction between models, we will consider separately the *broad beam* methods (also referred to as *empirical* methods), which do not make any distinction between these components and the *superposition* methods, which have many variants according to the type of components taken into account and to the integration order of these components. Excellent general descriptions of photon beam dose calculations methods have been given by Mackie et al. (1996) and Ahnesjö and Aspradakis (1999). These have been drawn from extensively in what follows.

## 26.2 BROAD-BEAM (EMPIRICAL) METHODS

### 26.2.1 SIMPLE BEAMS IN WATER

The dose representation of *simple beams* (i.e. rectangular fields limited by the main collimator without any accessories) in water can be further subdivided into two types:

- Representations that use *tabulated beam data* dose distributions for a number of beams measured under reference conditions are stored in tabular form and are interpolated by the treatment planning system (TPS) during calculation.
- Representations that use an *analytical approach* (beam generating functions): depth-dose and profile characteristics are modelled using mathematical functions. Some of these approaches are purely mathematical, while others more closely reflect the physics of broad beam interactions.

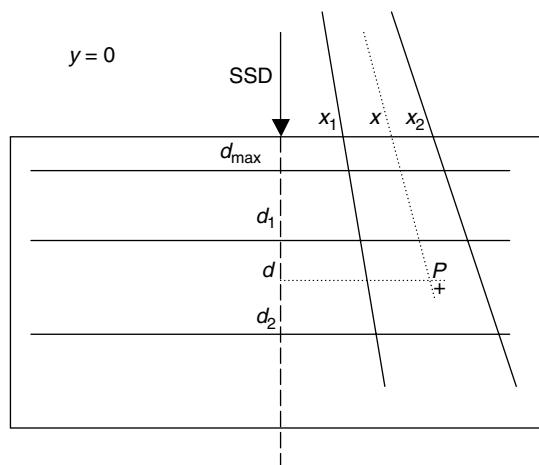

#### 26.2.1.1 Tabulated Beam Data Representations

Many early dose calculation algorithms were based on this principle (see ICRU 1987). For the sake of simplicity only the most frequently implemented one is described here.

In the 1970s Bentley and Milan developed a small digital computer system for radiotherapy treatment planning (Bentley and Milan 1971). This was a forerunner of the modern TPSs. The need for a fast and accurate system had a strong influence on the model they developed and the Bentley–Milan model, as it is now known, was still commonly used until recently. The beam data are stored in a tabular form as central axis depth-dose data and off-axis ratios (Milan and Bentley 1974).

Depth-dose data depend on the width and length of the field under consideration. It would have been impractical to store depth-dose curves for all possible open and wedge fields so *equivalent squares* (see Section 23.2.1.8) were used to reduce the required data to square fields only. Each square field had depth-dose data stored at 17 depths, equally spaced, starting at the depth of dose maximum and extending as far as the user decides is necessary. This is usually to a depth of between 30 cm and 35 cm. The dose in the build-up region was modelled very crudely considering that the dose at a depth,  $d$ , smaller than the depth of maximum dose,  $d_{\max}$ , could be calculated from a linear interpolation between the surface dose and the maximum dose assigned to a modified depth,  $d_B$ , calculated as

$$d_B = d_{\max} - \frac{(d_{\max} - d)^3}{d_{\max}^2} \quad (26.1)$$

**FIGURE 26.2**

Tabular method for dose calculation at a point  $P$  located in the central patient cross-section ( $y=0$ ) at depth  $d$  (parallel to the beam axis) and at a distance  $x$  from the central axis (defined at the patient surface). The dose at  $P$  can be obtained from linear interpolation between the four closest points of the grid (lines  $x_1$ ,  $x_2$ ,  $d_1$ ,  $d_2$ ).

Off-axis ratios depend mainly on the width of the field. The effect of the length of the field on the profile can be ignored, so only square field profiles need to be stored. The off-axis ratios will also depend on depth but if the effect of divergence is removed the shape of the profile only changes slowly. This is due to the different amounts of scatter present at different depths. Therefore, by adopting a system of fan lines that diverge from the radiation source, the off-axis ratios need only be stored at 5 depths. The depths were chosen to correspond to measurement points 1, 5, 9, 13 and 17 on the depth-dose curve. Each profile was covered by 47 fan lines, divided up so that number 24 lies on the central axis of the beam with 23 others on either side. The spacing of the fan lines was originally constant but could also depend on the field size and be non-uniform so that more fan lines could be placed in the penumbra region where the dose is changing rapidly. The off-axis ratio on the central fan line was unity by definition.

The dose at any point in the central cross-section of a patient (i.e. in a transverse plane passing through the beam axis) is then calculated after co-ordinate transformation by linear interpolation as a function of depth  $d$  and off-axis distance  $x$  (see Figure 26.2). In upper and lower patient cross-sections, the dose can also be interpolated as a function of  $y$ , assuming that the behaviour is the same as that in the  $x$  direction.

### 26.2.1.2 Analytical Beam Representations

A wide variety of mathematical functions has been developed over the years to model beams (see Appendix A in ICRU 1987). Generally the mathematical representation of the beam is split into two parts: central axis depth-dose values, and off-axis ratios. Each part is approximated by an analytical function. The dose is found by multiplying the two parts together. The range of energies and field sizes for which the expressions hold must be determined and their use restricted to this range.

One analytical approach that was used in many centres and also in at least one commercial TPS was that of van de Geijn (1965). Over a number of years he published analytical models and refinements that provided means of fitting depth dose and profile data over a wide range of energies (van de Geijn 1970, 1972). One advantage of this method was that depth-dose tables for a particular beam energy could be characterised by taking only seven measurements. Each of the parameters used in the fitting process was linked to the physical properties of broad beams.

## 26.2.2 IMPROVEMENT OF OFF-AXIS CALCULATIONS AND CORRECTIONS FOR WEDGE FILTERS

Tabular or analytical beam representations, may be used for points located not only off-centre (in the  $x$  direction), but also off-plane (in the  $y$  direction). The more straightforward approach consists in assuming that, for a flat homogeneous medium, the dose at any  $(x,y,z)$  point can be obtained from the dose at  $(0,0,z)$  by multiplying it by two off-axis functions,  $\mathcal{g}(x)$   $\mathcal{g}(y)$ . However, some corrections are required, especially for megavoltage radiation where a flattening filter is present, to account for the radial changes of the off-axis curves as a function of depth in case of both symmetric and asymmetric fields (Chui and Mohan 1986; Storchi and Woudstra 1995).

With the broad-beam representation, the wedge filters could be treated as part of the initial beam description or as an additional accessory requiring specific correction. The first approach simply involves including a number of dose distributions with wedge filters in the original experimental data set. The second approach requires a dose profile for a large field to be acquired in the wedge direction with and without the wedge filter. Then a *transmission* profile is derived from these two curves, tabulated for computing purposes and used as a correction factor. Alternatively this transmission profile can be calculated from the physical dimensions and composition of the filter using the appropriate attenuation coefficient. It must then be verified experimentally that this coefficient, which is slightly dependent upon the wedge thickness, gives acceptable results.

The concept of a wedge transmission profile is not restricted to the broad beam approach and has been implemented in more recent algorithms. As discussed in [Section 22.6.1.2](#), although correction factors may be added (Yao and Ranganathan 1994; Myler and Szabo 2002), considering only the effect of the wedge on the fluence incident on the surface contains several simplifications since it implicitly assumes that the beam quality does not change as a function of off-axis position and that the scatter component behaves in the same way as the primary one.

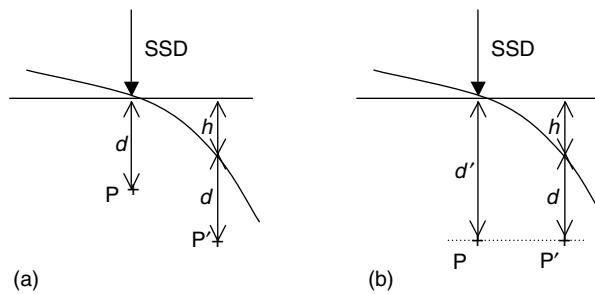

## 26.2.3 CORRECTION FOR PATIENT SHAPE AND INHOMOGENEITIES

In the discussion so far it has been implicitly assumed that the measurements and beam models have dealt with the *reference situation*, i.e. a beam incident normally on a flat surface of homogeneous, water-equivalent material. Needless to say, the human body is not like this; therefore dose calculations in a patient must include correction factors to account for the shape of the patient and the shape and position of inhomogeneities. The accuracy and complexity of the correction method employed depend on circumstances but it should be remembered that the more complex (and presumably therefore more accurate) the correction the longer it takes to compute. Correction factors are normally expressed as a ratio of the corrected dose to the uncorrected dose.

### 26.2.3.1 Patient Shape

One method of correcting for the patient shape in regions not too far from the central axis (i.e. ignoring off-axis correction) is the effective source-skin distance (SSD) method ([Figure 26.3a](#)). This applies an inverse square law correction to the measured depth-dose data. If the SSD on the central axis is represented by  $SSD$ , the increase in SSD for a particular off-axis point is  $b$ , and the corresponding point is at a depth  $d$ , then the dose at the same depth on the central axis must be multiplied by the correction factor  $C$ , defined by

$$C = \left( \frac{SSD + d}{SSD + b + d} \right)^2 \quad (26.2)$$

**FIGURE 26.3**

Correction for patient surface obliquity using either the effective SSD method (a) or the TAR/TPR ratio method (b). In (a), the dose at  $P'$  can be obtained from the dose at  $P$  by correcting for the increase in distance from  $(SSD + d)$  to  $(SSD + h + d)$  keeping the same attenuation (for depth  $d$ ). In (b),  $P$  and  $P'$  are at the same distance  $(SSD + d')$  from the source but the depth is decreased from  $d'$ , or  $d + h$ , to  $d$ . In both cases, the beam divergence and off-axis corrections have been omitted for simplicity (see also ICRU 1976).

Bentley and Milan used this method to correct for patient shape. However in practice, in order to make it more general and usable at any SSD, they modified the stored beam data so that it was effectively *infinite* SSD data by multiplying it by

$$\left( \frac{SSD + d}{SSD} \right)^2$$

The correction applied by the algorithm to the dose on the beam axis at a depth  $d$  and at *infinite* SSD is then simplified to

$$\left( \frac{SSD}{SSD + h + d} \right)^2$$

The tissue-air ratio or tissue-phantom ratio (TAR or TPR) method (see [Section 23.2.1](#) for definitions) is an alternative way of correcting for shape (Figure 26.3b). As the name suggests the correction factor can either be a ratio of two TARs or two TPRs. The ratios are a function both of depth and of field size at that depth. They are not dependent on SSD. If the increase in SSD is  $h$  and the depth of the point under consideration is  $d$ , as before, then the dose at the point of interest is the dose on the central axis at a depth of  $d + h$  (i.e. at the same distance from the source) multiplied by the correction factor

$$C = \frac{T(d, A_d)}{T(d + h, A_d)} \quad (26.3)$$

where  $T$  is the TAR or TPR at depth  $d$  with the field size at that depth being  $A_d$ .

### 26.2.3.2 Patient Inhomogeneities

Up to this point, it has been assumed that the patient is composed of water-equivalent tissue and thus that depths in the patient correspond to the same depths in water. This is never exactly the case and in practice, especially for lung treatments, corrections are needed to take into account changes in attenuation and scatter due to the presence of an inhomogeneity (see AAPM 2004 for a complete review of the inhomogeneity corrections methods).

**Effective-Depth or Equivalent Path Length Method:** The simplest method to correct for an inhomogeneity is the equivalent path length method (see [Section 25.2](#)). The *effective depth* to a calculation point  $P$  is the thickness of water-equivalent tissue that would attenuate the radiation by the same amount as the actual tissue along a fan line between the surface and point  $P$ . It is a one dimensional correction that ignores changes in scatter. If the radiation passes through  $n$  different tissues, each of thickness  $t_i$  and density  $\rho_i$  to reach the calculation point then

the *effective* (or *radiological*) depth  $d_{\text{eff}}$  is

$$d_{\text{eff}} = \sum_{i=1}^n t_i \rho_i \quad (26.4)$$

The dose at a point below the inhomogeneity can be obtained from the uncorrected dose by applying a correction factor,  $C$ , given by

$$C = \frac{\text{PDD}(d_{\text{eff}})}{\text{PDD}(d)} \times \left( \frac{SSD + d_{\text{eff}}}{SSD + d} \right)^2 \quad (26.5)$$

where  $\text{PDD}(d_{\text{eff}})$  is the percentage depth dose for the corrected depth,  $\text{PDD}(d)$  is the percentage depth dose for the actual depth and the SSD is  $SSD$ .

Note that the inverse square law correction is also needed. This is needed because  $\text{PDD}(d_{\text{eff}})$  assumes the distance from the radiation source to the point under consideration is  $SSD + d_{\text{eff}}$  when it is actually  $SSD + d$ .

*TAR Ratio (or TPR Ratio) Method:* The TAR ratio method is a slightly more precise implementation of the equivalent path length approach. The correction factor is calculated as a ratio of TARs or TPRs. The correction factor to be applied to the uncorrected dose is

$$C = \frac{T(d_{\text{eff}}, A_d)}{T(d, A_d)} \quad (26.6)$$

where  $T$  is the TAR or TPR and  $A_d$  is the field size at depth  $d$ .

Again, this correction is strictly true only for the primary radiation and does not apply to scatter. In some situations, especially at some distance from inhomogeneities, both corrections (i.e. Equation 26.5 and Equation 26.6) are equivalent and will give an acceptable estimate of the dose. In others, more sophisticated corrections are needed that account for size and position of the inhomogeneity.

*Power-Law Correction (Batho Correction):* The power-law correction is again a ratio of two TARs (or TPRs) but in this instance they are raised to a power that depends on the density of the surrounding material (Batho 1964) as shown in Equation 26.7. For a point located in a slab of density  $\rho_1$  overlaid by a slab of density  $\rho_2$ , the correction factor is

$$C = \frac{\text{TAR}(l_2, A_d)^{(\rho_2 - \rho_1)}}{\text{TAR}(l_1, A_d)^{(1 - \rho_1)}} \quad (26.7)$$

where  $l_1$  and  $l_2$  are the distances from the point to the upper (i.e. closest to the source) boundaries of inhomogeneities 1 and 2, respectively (Figure 26.4). The distances,  $l$ , are distances from the boundaries of the inhomogeneity, so this correction accounts for the position of the inhomogeneity but not for its overall size and shape. It produces better agreement with measurements than the effective depth or TAR ratio methods. However, it predicts dose discontinuities at interfaces between the normal tissue and the inhomogeneity.

Batho's original suggestion to use TAR has been shown to exaggerate the correction for a point lying in a low density inhomogeneity since it ignores the backscatter from underlying material; the accuracy was improved by using Tissue Maximum Ratio (TMR) or TPR instead (El-Khatib and Battista 1984; Kappas and Rosenwald 1985).

For a series of superimposed inhomogeneous slabs a more general form for this correction (Sontag and Cunningham 1977; Parker et al. 1980) can be written as

$$C = \prod_{i=1}^n \text{TPR}(l_i, A_d)^{(\rho_i - \rho_{i-1})} \quad (26.8)$$

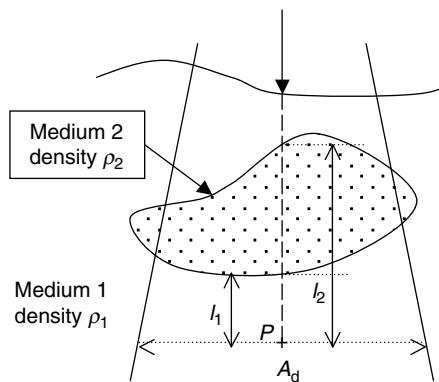

**FIGURE 26.4**

Illustration of the power law correction method applied at point  $P$  located in a medium of density  $\rho_1$  below an inhomogeneity of density  $\rho_2$ : assuming a slab geometry, the correction factor at point  $P$  can be calculated from Equation 26.7.

where  $l_i$  is the distance from the dose calculation point to the anterior part of the  $i$ th inhomogeneity (starting from inhomogeneity 1, where the point lies),  $\rho_i$  is the relative electron density of the  $i$ th inhomogeneity and  $\rho_0 = 1$ .

*Beam Subtraction Method:* The power-law correction, which indirectly accounts for (first) scatter modification (Wong and Henkelman 1982), fails to give accurate results when the lateral dimensions of the inhomogeneity are smaller than the field size. The beam subtraction method makes use of a smaller *virtual* beam which exactly covers the inhomogeneity (Lulu and Bjängard 1982; Kappas and Rosenwald 1982, 1985) (see Figure 26.5). For this virtual beam, the power law correction is satisfactory. The additional scatter from the outer part of the original beam is generated in water-equivalent material. It can therefore be calculated by subtracting the dose due to the virtual beam from that due to the original beam to yield a correction factor

$$C = 1 + \frac{T(d, A_d^*)}{T(d, A_d)} \times (C^* - 1) \quad (26.9)$$

where  $T$  is the TAR or TPR,  $A_d$  is the field size at depth  $d$ ,  $A_d^*$  is the virtual field size at depth  $d$  and  $C^*$  is the power law correction factor for the virtual field size.

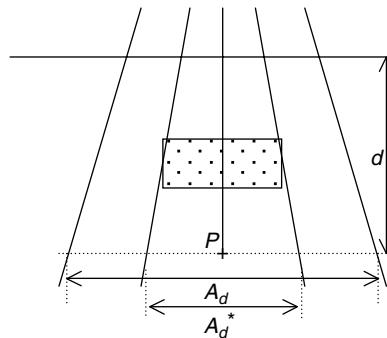

**FIGURE 26.5**

Illustration of the beam-subtraction method for an inhomogeneity smaller than the beam size: The Batho correction factor is applied to the beam  $A_d^*$  that has the same dimensions as the inhomogeneity whereas the scatter from the outer part is generated in water and calculated by subtracting the dose in water for the virtual beam  $A_d^*$  from the dose in water for the whole beam  $A_d$ .

After experimental verification, the 3D version of this method has been implemented in some clinical planning systems (Kappas and Rosenwald 1986a).

*Equivalent Tissue Air Ratio (ETAR) Correction:* The ETAR method is another way to account for the 3D shape of the inhomogeneity. It was developed by Sontag and Cunningham (1978), who suggested that the TAR ratio method described above (Equation 26.6) could be improved by scaling not only the depth, but also the field size. The general expression for the correction factor is then

$$C = \frac{T(d_{\text{eff}}, A'_d)}{T(d, A_d)} \quad (26.10)$$

where  $A_d$  in the numerator has been replaced by  $A'_d$  obtained by scaling  $A_d$  (actually the radius of the equivalent circular field) according to the density of the surrounding inhomogeneities. In practice, Sontag and Cunningham scaled the field size using an effective density,  $\tilde{\rho}$  different from the one used for scaling the depth  $d_{\text{eff}}$  (see Equation 26.4). The quantity  $\tilde{\rho}$  is calculated as

$$\tilde{\rho} = \frac{\sum_i \sum_j \sum_k \rho_{ijk} W_{ijk}}{\sum_i \sum_j \sum_k W_{ijk}} \quad (26.11)$$

using the densities  $\rho_{ijk}$  for each voxel  $ijk$  of a series of CT images, where the  $W_{ijk}$  are weighting factors describing the relative contribution of each voxel to the effective density at the calculation point. These weighting factors are different for each calculation point.

Although the theory behind this method appears to be reasonable, in practice it takes too long to perform a full summation over the entire irradiated volume. To overcome this limitation imposed by the calculation time the three dimensional density array (from CT) is reduced to two dimensions by coalescing pixels with the same  $x,y$  coordinates into a single slice at a distance  $Z_{\text{eff}}$  from the central slice.  $Z_{\text{eff}}$  is calculated from the weighted sum of the  $Z$  values of individual slices, where each weighting factor, which represents the scatter contribution of each slice to the calculation point, is calculated from the circular beam scatter-air ratio difference for two different radii depending upon the field size and slice position. After this simplification the  $W_{ij}$  (replacing  $W_{ijk}$ ) are calculated from the probability of scattered photons from the density element  $\rho_{ij}$  reaching the point of calculation. Although this method was implemented on clinically used TPSs, the associated simplifications have been shown to cause some inconsistencies (Wong and Henkelman 1983; Carrasco et al. 2004). The main inherent limitation of this method is that the scatter is considered as a whole, without explicit ray tracing for calculation of the scatter dose (Wong and Purdy 1990). Further refinements in the calculation of the correction factor, are out of the scope of the *broad beam* methods. They are discussed briefly in the last paragraph of [Section 26.3.2.2](#).

Of the above methods for inhomogeneity correction, the effective depth, the TAR (or TPR) ratio and the standard power law methods can be carried out by hand or using a computer. The more advanced application of power law, beam subtraction and ETAR methods can only be implemented with a computer. For all these methods, the density information can be obtained either from contours or from voxels (see [Figure 25.4](#)). However, using methods designed for relatively large inhomogeneities (such as the power-law correction) in situations involving voxel-sized inhomogeneities is likely to be significantly inaccurate and should be avoided.

## 26.2.4 LIMITATIONS AND DRAWBACKS OF BROAD-BEAM METHODS

Beginning with the dose calculation under reference conditions, we have seen how it is necessary to apply many corrections to the original measured data in order for it to be accurate in real situations involving patients. Although the corrections applied are only approximations,

they give reasonable results in the vast majority of clinical situations. However this broad-beam approach, which nevertheless requires a lot of experimental effort or somewhat arbitrary curve-fitting procedures, is inadequate as soon as the situation is more complex or when greater accuracy is required. This is, for instance, the case for non-rectangular or intensity-modulated fields (see [Chapter 43](#) and [Chapter 44](#)) or when dose-escalation protocols are implemented. Because the speed of computers has increased dramatically since the start of computerized treatment planning, the broad-beam approach has now been superseded in clinical treatment planning by more sophisticated and computer-resource intensive algorithms based on the superposition principle.

## 26.3 SUPERPOSITION METHODS

### 26.3.1 THE SUPERPOSITION PRINCIPLE

The superposition principle is summarised in Figure 26.6.

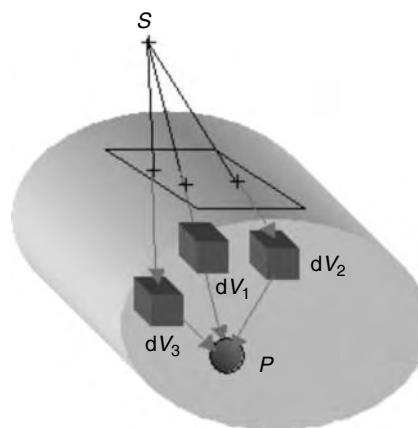

If we consider separately the primary photons and the secondary particles (photons and/or electrons), the dose at a point  $P(x, y, z)$  can be considered as the sum of the contributions of the energy *launched* at a distance from  $P$ , in volume elements  $dV(x', y', z')$ . This elementary energy originates from the energy fluence  $p(x', y', z')$  of the *primary* photons impinging on  $dV$ . Let  $s(x, x', y, y', z, z')$  be the scatter energy per unit primary photon fluence launched at  $dV$  and reaching  $P$ . Then the dose at  $P$  is

$$D_P(x, y, z) = \iiint_V p(x', y', z') s(x, x', y, y', z, z') dV \quad (26.12)$$

where the limits of integration  $V$  correspond to the limits of the actual scattering volume.

As discussed previously (see [Figure 25.6](#)) there are several alternative ways of performing this 3D integration, including reducing it to 1D or 2D integration in order to speed up the calculations. These possibilities, which imply different levels of underlying assumptions, have been extensively exploited in clinical treatment planning algorithms. Some of them will be discussed in what follows.

Referring to [Figure 26.1](#) above, the dose at  $P$  is the sum of several components which involve photon and electron interactions and these could be treated separately. These interactions take place at a distance from point  $P$ . The electrons travel only a short path and

**FIGURE 26.6**

The superposition principle: the dose at  $P$  can be considered as the sum of the contributions of energy deposited in a small volume surrounding  $P$  by particles (electrons, photons) originating from primary photon interactions in distant volume elements  $dV_i$ .

therefore contribute to the dose at points which are typically at a maximum distance of a few mm (for  $^{60}\text{Co}$   $\gamma$ -rays), to between 3 cm and 4 cm (for 25 MV photons). By contrast, photons travel large distances without interacting and must therefore be considered, whether or not they are close to point  $P$ . In a homogeneous medium (i.e. water equivalent), even for high primary photon energy, electronic (or charged-particle) equilibrium is achieved for most of the points and the dose is, to a good approximation, only dependent on the local photon fluence (or kerma) (see [Section 6.5](#)). This is no longer true at tissue interfaces (e.g. patient skin, edges of inhomogeneities) where, especially at high energy, electron disequilibrium occurs and should be taken into account. It is also not true when the lateral dimensions of the beam are smaller than the range of the secondary electrons in the medium, e.g. for 25 MV photons in the lung ( $\rho \approx 0.3 \text{ g/cm}^3$ ) for field sizes smaller than  $\approx 10 \text{ cm} \times 10 \text{ cm}$ . If electron transport is faithfully modelled, however, then the effects of the lack of charged-particle equilibrium are automatically taken into account.

The three methods presented below are currently in fairly widespread use. They can be seen as different ways of combining the dose components on the one hand and the order of integration on the other hand. They all require some means to calculate the fluence (or the dose) for the primary photons. Although they are all largely based on experimental data, the nature and use of these data varies significantly according to the method and its practical implementation.

### 26.3.2 PRIMARY-SCATTER SEPARATION

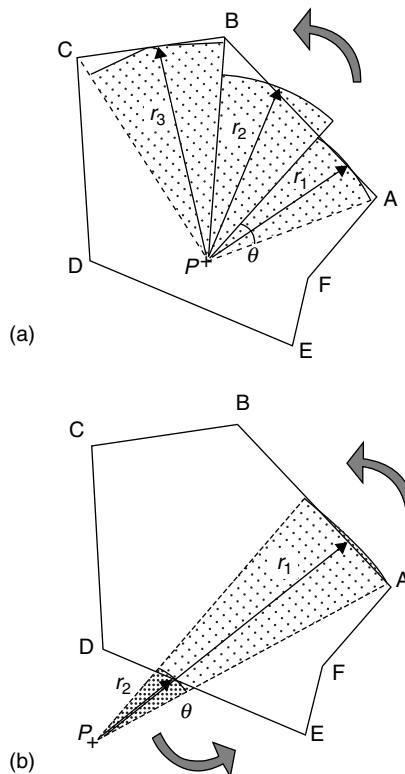

#### 26.3.2.1 Principle of the Method

The primary-scatter separation method as applied to computerised treatment planning was originally developed by Cunningham to solve the problem of dose calculation in irregular fields such as mantle fields (Cunningham et al. 1972). This idea originated from Clarkson's scatter integration method presented in [Section 23.2.1.8](#). As seen in that section, the method makes use of the Scatter-Air Ratio, defined as the ratio of the *dose at a point due to the scattered radiation only to the dose in free space at the same point* (Cunningham 1972).

$$\text{SAR}(z, A_z) = \text{TAR}(z, A_z) - \text{TAR}_0(z) \quad (26.13)$$

where  $\text{TAR}(z, A_z)$  is the tissue-air ratio at a depth  $z$  in the field of size  $A_z$  and  $\text{TAR}_0(z)$  is the tissue-air ratio at the same depth but in a field of zero area.  $\text{TAR}_0(z)$  is taken to represent the primary radiation. The reason for this is that, as the irradiated area is reduced, the scattering volume approaches zero and if there is no scattering volume there can be no scattered radiation, only primary radiation. The zero-area TAR is a mathematical abstraction\*; it cannot be measured directly but it can be obtained by extrapolating TARs for small field sizes back to zero field size. Beyond the build-up region,  $\text{TAR}_0(z)$  can also be obtained by performing measurements in scatter-free conditions, typically using large distances between source and detector, placing in-between variable thicknesses of water equivalent material and collimating the beam both on the source side and on the detector side to reduce scatter as much as possible. In megavoltage beams, qualitative changes occur for off-axis points (see [Section 22.3.3.2](#)) and therefore,  $\text{TAR}_0(z)$  may have to be corrected, either selecting different tables according to the off-axis radius or applying a radial correction factor (Zefkili et al. 1994; Lee 1997).

\* Strictly, the dose in free space or the dose in zero field size would be zero as there would be no charged-particle equilibrium (CPE); one has to imagine that in both these situations there is enough phantom-like material surrounding the point to establish CPE.

**FIGURE 26.7**

Clarkson's scatter-integration method: For a field such as ABCDEF, and a calculation point  $P$ , the assumption is made that the scatter from the whole area can be calculated by addition of the scatter contributions of angular sectors of angle  $\theta$  and radii such as  $r_1$ ,  $r_2$ , etc. The contribution from each of these sectors,  $i$ , to the total scatter dose at  $P$  is a fraction  $\theta/2\pi$  of the scatter  $S(z, r_i)$  at the centre of a circular field of radius  $r_i$ . If  $P$  is outside the field (as in b) a similar summation is possible, but in this case the contribution that would have arisen from the parts of the sectors that are outside the field must be subtracted from the total. This is achieved by proceeding around the edge of the contour as before, but assigning a positive sign to sectors for which the direction of rotation is anticlockwise (i.e. from A to B) and a negative sign to those for which it is clockwise (i.e. from D to E) so that the contribution of the small sector ( $r_2$ ) is subtracted from the large sector ( $r_1$ ) leaving the contribution from inside the field area.

The scatter component for any field can be calculated using Clarkson's method (Figure 26.7). This method uses sector integration; so the field must be divided up into  $n$  sectors centred on the point  $(x, y, z)$  at which the dose is required. If the  $i$ th sector has an angular width  $\Delta\theta_i$  and radius  $r_i$  and the SARs are tabulated as functions of depth and field radius at that depth then its SAR can be found by interpolating from the tables and weighting it according to its angular width. The total scatter dose,  $D_S(x, y, z)$  is found by summing over all sectors and is given by

$$D_S(x, y, z) = D_A(z) \times \sum_i S(z, r_i) \frac{\Delta\theta_i}{2\pi} \quad (26.14)$$

where  $D_A(z)$  is dose in air\* (i.e. without attenuation) at position  $(0, 0, z)$ ,  $S(z, r_i)$  is the scatter-air ratio for a depth  $z$  in a circular beam of radius,  $r_i$ .

\*  $D_A(z)$  at the distance  $f$  from the source and for the actual collimator opening  $A$  is easily calculated from the dose in air  $D(\text{air}, A_{\text{ref}}, \text{SAD})$  at the isocentre distance SAD and for the reference field  $A_{\text{ref}}$  by multiplying this quantity by  $(\text{SAD}/f)^2$  and by the collimator scatter factor (or air output factor)  $S_c(A)$  (see Table 23.1 and Table 23.2).

The dose,  $D_p(x, y, z)$  due to the primary radiation is

$$D_p(x, y, z) = D_A(z) \times T(z, 0) \times f(x, y) \quad (26.15)$$

where  $T(z, 0)$  is the zero area TAR at depth  $z$  and  $f(x, y)$  is an off axis factor in air that corrects for the beam profile.

The total dose at the point is then

$$D(x, y, z) = D_p(x, y, z) + D_S(x, y, z) \quad (26.16)$$

### 26.3.2.2 Application to Cobalt-60 and Medium-Energy X-Ray Beams

*In-Phantom Basic Measurements:* The application of primary-scatter separation for  $^{60}\text{Co}$   $\gamma$ -ray beams or medium energy x-ray beams (typically  $< 6$  MV) is relatively straightforward. TAR tables for square fields, including TAR0, are easily obtained from published tables or preferably from measurements. The *in air* reference dose  $D_A$  is obtained with an ionisation chamber with a 5 mm thick build-up cap for cobalt-60 (or thicker at higher energy).  $S(z, r)$  tables are then derived using Equation 26.13 and the equivalence between a circular and a square field (see [Section 23.2.1.8](#)):

$$r = \frac{1}{\sqrt{\pi}} \times a \quad (26.17)$$

where  $r$  is the radius of the circular field equivalent to the square field  $a \times a$ .

*In-Air Beam Profiles:* The *in air* primary component must account for the beam profile as described by the correction factor  $f(x, y)$  (see Equation 26.15). This factor is close to unity in the central region, decreases slowly for off-axis points as the oblique distance to the source increases, and decreases sharply at the edge of the collimator in the penumbra region. For rectangular beams ( $2X \times 2Y$ ), Cunningham (Johns and Cunningham 1983) has suggested computing  $f(x, y)$  as  $g(x) \times g(y)$  where:

$$\begin{aligned} g(x) &= 0.5e^{(-\alpha_{\text{ext}}(x - X))} && \text{if } x > X \\ g(x) &= 1 - 0.5e^{(-\alpha_{\text{int}}(X - x))} && \text{if } x < X \end{aligned} \quad (26.18)$$

a similar expression being used for  $g(y)$ , replacing  $x$  with  $y$  and  $X$  with  $Y$ .

$\alpha_{\text{int}}$  and  $\alpha_{\text{ext}}$  are two *collimation* coefficients, characteristic of the penumbra width for the interior and the exterior of the beam respectively. The higher these coefficients, the sharper is the profile in the penumbra region. They can be adjusted according to the experimental in-air off-axis curves and shown to be practically proportional to the inverse of the width of the geometrical penumbra. A further correction to the above equation is required to account for the residual collimator transmission.

For x-ray beams, it may be necessary to account for the influence of the flattening filter which usually produces a profile in free air or at a shallow depth that is higher towards the edges than at the centre. This is necessary to produce a flat profile at larger depths (see [Section 22.3.3.2](#)). This is easily performed by introducing an additional correction with a multiplicative radial function representing the in-air measurement, normalised to the value on beam axis and measured along the diagonal of the largest field.

For irregular fields, Equation 26.18 cannot be applied as such. A modification (Cunningham et al. 1972) consists in assuming that the source is represented by an *intensity function* which can be imagined as a large radioactive disk seen through the collimator opening, with a local *density* which is infinite on the beam axis and decreases exponentially from the

centre to the periphery. The detailed expression is given as a footnote\*. In this expression,  $\beta$  is a collimation coefficient very similar to the  $\alpha$  coefficient defined for rectangular fields. Within the Clarkson integration process, the  $\beta$  value may be different for the various field-delimiting segments. This offers the possibility of accounting for the differences in the penumbra, depending on whether it is generated by the main jaws or by blocks at a given point. Because  $\beta$  (or  $\alpha$ ) is directly correlated with the width of the computed penumbra, it is easy to adjust these to match experimental in-air profiles.

**Intensity Modulation:** Up to now we have implicitly assumed that the primary fluence (i.e. the dose in air) was uniform over the field area and that the patient surface was flat and normal to the beam axis, so that the scatter from an angular sector could be considered as a fraction of the scatter from a circular field at the depth of the calculation point (Figure 26.8a).

However, if the surface is oblique or irregular or if the primary beam is non-uniform (i.e. modulated by insertion of a wedge filter or compensator), it is possible, using the same  $S(z,r)$  tables, to replace the 1D angular Clarkson integration by a 2D integration of elementary *pencil-like* scatter elements.

$$\Delta S_{ij}(z_{ij}, \theta_i) = \frac{\Delta\theta_i}{2\pi} \times (S(z_{ij}, r_{ij} + \Delta r) - S(z_{ij}, r_{ij})) \quad (26.19)$$

where the scattering pencil beam is referenced to a polar co-ordinate system centred on the calculation point  $P$ , located at a distance  $r_{ij}$  along the radius defined by angle  $\theta_i$ , and  $z_{ij}$  is the thickness of tissue above  $P$  as calculated along the pencil beam (see Figure 26.8b). In addition, when performing the integration over the field area, each scattering pencil beam must be weighted according to the primary fluence at point  $ij$ . When extended to higher energy photons (see below), this method gives satisfactory results for intensity modulated radiotherapy performed with multileaf collimators (Papatheodorou et al. 2000).

Figure 26.8c illustrates the so-called *differential scatter-air ratio* (dSAR) method (in a polar coordinate system) that is an extension of the Clarkson method to a 3D integration of scatter (Beaudoin 1968; Cunningham 1972).

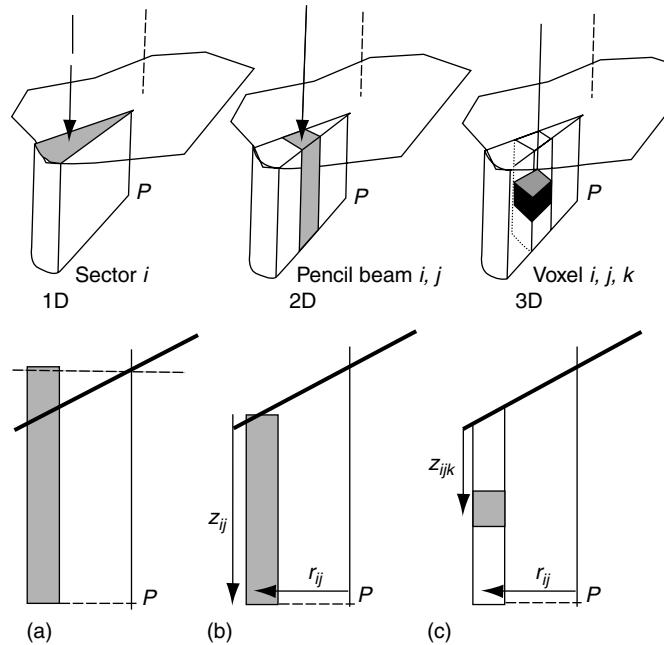

**Inhomogeneities:** Separation of the medium into elementary volumes makes it possible to refine the corrections for inhomogeneities described previously in Section 26.2.3.2, provided that the primary-beam intensity reaching a voxel accounts for the transmission through the inhomogeneous medium and that the scatter from a voxel is weighted by its electronic density and also corrected by the presence of adjacent inhomogeneities. This was the basis of the dSAR method. However, due to the complex behaviour of multiple scatter, this method turned out to be inaccurate and had to be improved. This was attempted with the delta volume method (DV) proposed by Wong and Henkelman (1983) and with the dTAR method proposed by Kappas and Rosenwald (1986b). The ETAR method described by Sontag and Cunningham (1978) which also considers primary and scatter components separately, but which has been shown to be inaccurate in some situations (see Section 26.2.3.2) has been significantly improved by Redpath and Thwaites (1991). They allowed for the effective depth above the inhomogeneities and made a slight change to the method by which the equivalent density,  $\tilde{\rho}$ , was calculated, taking into account the scatter changes with respect to depth. They also optimised the calculation time and obtained quite good results for several benchmark examples.

\* For a circular field and a calculation point on the beam axis, the normalised apparent *density* seen through the projected opening of radius  $R$  is:

$$Dens(R) = \frac{\beta^2}{2\pi} \int_0^{2\pi} \int_0^R e^{-\beta r} r dr d\theta = 1 - (1 + \beta R)e^{-\beta R}$$

The Clarkson integration method is then applied to this expression for any point  $x,y$ :

$$f(x,y) = \frac{\Delta\theta}{2\pi} \sum_{i=0}^n Dens(r_i)$$

**FIGURE 26.8**

Some of the possibilities for medium decomposition to obtain the total scatter at point  $P$  for an irregular field. The upper views are 3D representations of the elementary volumes. The lower views are 2D cuts through the angular sectors in the case of surface obliquity. (a) Conventional Clarkson's 1D angular integration; the scatter at  $P$  is calculated assuming that the depth of all scattering elements is the same as  $P$  (shaded scattering column or *pencil*). (b) Pencil-like, 2D angular + radial integration; the scatter from each scattering pencil ( $\theta_i, r_{ij}$ ) is calculated taking into account the surface obliquity, with the possibility of weighting the scatter according to the primary-beam intensity at  $(\theta_i, r_{ij})$ . (c) Voxel-based, 3D integration (dSAR method) which requires the calculation of the attenuation of the primary before reaching the voxel element  $i,j,k$ .

### 26.3.2.3 Extension to Higher Energies

As the photon energy increases, the quantities related to the *in-air* reference become irrelevant because of the need for large build-up caps to ensure electronic equilibrium and because of the importance of the attenuation and scatter contribution in such caps. The TAR must therefore be replaced by other quantities (see [Section 23.2.1](#)). However, the same general approach is still possible with the introduction of the mini-phantom concept (see [Section 23.2.1.12](#); Drouard et al. 1986; van Gasteren et al. 1991; Dutreix et al. 1997). The attenuation of the *primary* component is then represented by the tissue-phantom ratio in the mini-phantom,  $\text{TPR}(z, \text{ESQ}_m)$ , where  $\text{ESQ}_m$  is the equivalent square corresponding to the mini-phantom geometry<sup>†</sup>. By extension of Equation 26.13, the scatter air ratio used in the Clarkson integration is replaced by SAR\* calculated from the following equation at depth  $z$  for the field  $A_z$ :

$$\text{SAR}^*(z, A_z) = \text{TAR}^*(z, A_z) - \text{TPR}(z, \text{ESQ}_m) \quad (26.20)$$

where  $\text{TAR}^*$ , the replacement quantity for TAR, can be written as:

$$\text{TAR}^*(z, A_z) = \text{TPR}(z, A_z) \times \frac{S_p(z_{\text{ref}}, A_z)}{S_p(z_{\text{ref}}, \text{ESQ}_m)} \quad (26.21)$$

<sup>†</sup> To obtain a quantity that accurately represents the primary component, one should correct the TPR for the scatter from the mini-phantom (Zefkili et al. 1994). This could be necessary for accurate calculation of the dose under small blocks.

In this expression,  $S_p$  is the phantom scatter factor defined in [Section 23.2.1.10](#). In addition, the *in-air* reference dose  $D_A$  of Equation 26.14 and Equation 26.15 has to be replaced by the dose in the mini-phantom at depth  $z_{\text{ref}}$  for the current collimator opening  $A$ .

This method provides accurate results for rectangular or irregular fields of dimensions larger than  $\text{ESQ}_m$ . However, it implicitly assumes that the path length of secondary electrons is negligible and that the *primary* penumbra can be accurately modelled by adjustment of the collimation coefficients described above, independently of depth and field size. Nevertheless, at higher photon energies, secondary electron path lengths cannot be ignored and specific adaptations must be performed to account properly for electron transport in water-equivalent media (Rosenwald et al. 1987; Woo et al. 1990).

The advantage of the primary-scatter separation is that it allows one to account accurately for the influence of beam modifiers (modulation of the primary and even of the scatter component) and for the volume of tissues included within the beam limits. Its main limitation is related to the accuracy of inhomogeneity corrections which are normally performed according to one of the methods described above (see [Section 26.2.3.2](#) and [Section 26.3.2.2](#)). In particular, these methods cannot accurately handle the situations where there is a lack of electronic equilibrium at the beam edge or on the axis of small fields, e.g. high energy photon beams through lungs (Mohan and Chui 1985; Mackie et al. 1985; AAPM 2004).

### 26.3.3 PENCIL-BEAM APPROACH

#### 26.3.3.1 General

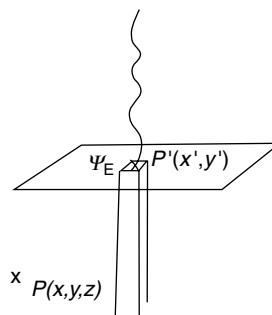

The first mention of using the pencil-beam approach for photon beams can be ascribed to Schoknecht (1971). The method was in fact developed first for electron beams (see [Chapter 27](#)). A detailed model for photon beams was first described by Mohan and Chui (1987). Since that time, the literature has grown and one can mention papers by Ahnesjö et al. (1992b), Bourland and Chaney (1992), and Bortfeld et al. (1993), that deal with implementation aspects, and other papers that discuss the limitations of the pencil-beam method (e.g. Knöös et al. 1995) in certain inhomogeneous situations.

In essence, convolving a pencil beam over the field area defined by the final collimator is similar to performing the 2D integration described in [Figure 26.8b](#). For example, one can easily model any variation in incident beam intensity, due, say, to a wedge or compensator. This approach is also suited to modelling complex treatments such as dynamic wedges or intensity-modulated radiation therapy, where the incident fluence is modulated over time. Furthermore, the beam spectrum variations, either off-axis or due to filtration by a wedge or any arbitrary compensator can, in principle, be taken into account by changing the pencil-beam quality according to its entrance position. The main difference between the two approaches is the following: In the primary-scatter separation, the scatter component is the only one which is scanned over the field area whereas in the pencil-beam approach described below, the *pencil* is made of the total energy (from secondary electrons and scattered photons) generated by the primary photons and deposited at a distance. This energy is characterised by a *pencil-beam convolution kernel*,  $K_{\text{PB}}$ , which represents the energy distribution released from the pencil beam and normalised to unit fluence at the penetration point on the patient surface (see [Figure 26.9](#)).

The general expression for the dose computed from pencil-beam *kernels* is therefore:

$$D(x, y, z) = \iint \frac{\mu}{\rho} \Psi_E(x', y') K_{\text{PB}}(x - x', y - y', z) dx' dy' \quad (26.22)$$

where the 2D integration is restricted to the field area;  $\Psi_E(x', y')$  is the *entrance* energy fluence at point  $P'$  ( $\text{J m}^{-2}$ );  $\frac{\mu}{\rho} \Psi_E(x', y')$  is the total energy (secondary electrons and scattered photons) per unit mass released from  $P'$ , known as *terma* ( $\text{J kg}^{-1}$  or Gy),  $\mu/\rho$  being the mass attenuation

**FIGURE 26.9**

Principle of the pencil-beam approach. The dose at point  $P$  is computed from the integration over the field area of pencil kernels weighted by the primary fluence impinging on the patient surface.

coefficient ( $\text{m}^2 \text{ kg}^{-1}$ ) for medium at  $P'$  (see [Chapter 4](#));  $K_{\text{PB}}(x-x',y-y',z)$  is the value of the kernel at point  $P(x, y, z)$  for a pencil beam impinging on the patient at point  $P'(x', y')$ ; it represents the fractional energy deposition per unit mass at  $P$  due to primary energy fluence entering the patient at  $P'$ .

In the above expression, the pencil-beam kernels are in principle unique for each position of both  $P$  and  $P'$ . However, in a homogeneous water-like medium, one can consider that, at a given depth  $z$  and distance between  $P$  and the pencil-beam axis, they are as a first approximation independent of the pencil-beam position  $(x', y')$ . In that case Equation 26.22 is actually a convolution between the incident energy fluence and the pencil-beam convolution kernels. In this case, as discussed in [Section 26.3.3.4](#), the computation can be speeded up by means of fast Fourier transform (FFT) convolution algorithms. If this assumption is considered as unacceptable (e.g. because of off-axis spectral variations due to the flattening filter) or if inhomogeneities are considered, then the kernel is no longer spatially invariant and the mathematical solution is a *superposition* where the FFT approach is no longer applicable.

In both cases, the dose calculation problem involves the determination of the entrance energy fluence on the one hand and of pencil-beam kernels on the other hand.

### *26.3.3.2 Determination of $\Psi_E$ , the Entrance Primary Energy Fluence*

In the absence of beam modifiers, the primary fluence is basically uniform within the field aperture and drops to a small residual value outside. The method of calculation is generally based on geometrical considerations complemented by calculation of transmission through the main collimator or convolution with a source function, to account for the finite size of the source (Mohan and Chui 1987). As seen in [Section 26.3.2.2](#), the influence of the flattening filter can be further accounted for by application of a radial function derived from dose profile measurements along the diagonal of the largest field, performed at shallow depth (just large enough to avoid electron contamination) (Storchi and Woustra 1995). The extrafocal radiation (i.e. radiation not originating in the x-ray target) generated as scatter mainly in the primary collimator and in the flattening filter should be included (Ahnesjö and Trepp 1991; Jaffray et al. 1993; Papanikolaou et al. 1993). A frequent approach, which can be used also for irregular fields, consists in calculating the scattered dose from the head by integration of an extended source model over the parts of the head visible from the point of calculation (Ahnesjö 1994; Sharpe et al. 1995; Liu et al. 1997a).

The dose at the edge of collimating blocks can be calculated with the same method as for the main collimator (Mohan and Chui 1987; Storchi and Woustra 1996). When additional beam modifiers are used (wedges, compensators), the primary beam is attenuated but also some scatter is generated which can be accounted for by performing scatter integration over the

modifying device (Ahnesjö et al. 1995; Islam and Van Dyk 1995; Castellanos and Rosenwald 1998).

Altogether, the methods for calculation of the primary fluence distribution are very similar to the methods described in the [Section 26.3.2.2](#) (*in air* profiles). They can also be thought of as the product of correction matrices, each of them representing the beam attenuation or modulation due to each specific beam limiting or modifying device. Ideally, such calculations should also account for the spectral modifications while passing through the modifiers, e.g. wedges, compensators (Liu et al. 1997b). It should be realised that with the development of intensity-modulated radiotherapy, it is becoming very important to include an accurate value for the transmission of the individual leaves of multileaf collimators.

Another issue is the fact that, in principle, for each position of  $P'$  the local pencil-beam kernel should be modified to compensate for the changes in the energy spectrum owing to off-axis *softening* as the flattening filter gets thinner and to beam filtration from additional beam modifiers (Tailor et al. 1998). This is generally ignored.

### 26.3.3.3 Determination of $K_{PB}$ , the Pencil-Beam Kernels

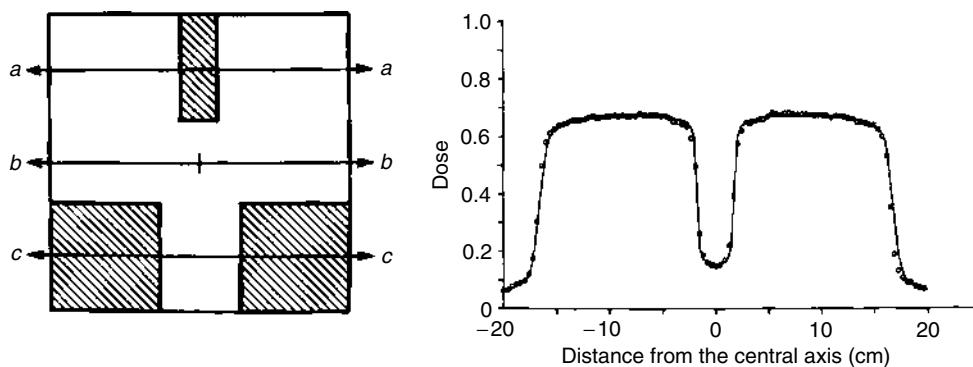

There are several methods of obtaining the relevant pencil-beam kernels. Mohan and Chui (1987) performed direct Monte Carlo (MC) calculations, for a number of monoenergetic pencil beams as well as for polyenergetic linear-accelerator pencil beams. In practice, polyenergetic kernels can be computed by simple addition of monoenergetic kernels, each of them being weighted according to the local x-ray spectrum. However, such an approach requires the spectrum of the photons emitted by the accelerator to be known (ideally at any point on the patient surface). This spectrum cannot be easily measured in a clinical environment. It can, however, be computed by the Monte Carlo method from the characteristics of electrons hitting the target and details of the head characteristics (Mohan et al. 1985; Lovelock et al. 1995; Liu et al. 1997a) (see also [Section 28.3](#)). It can also be derived from attenuation measurements (Huang et al. 1983; François et al. 1997; Nisbet et al. 1998) or adjusted empirically to minimise the deviations between computed and measured depth-dose distributions (Ahnesjö and Andreo 1989; Starkschall et al. 2000).

Other approaches for pencil-beam kernel determination include integration of pre-calculated point kernels (see [Section 26.3.4](#)), deconvolution from broad beam measurements (Chui and Mohan 1988), or experimental estimation using scatter-factor differentiation (Ceberg et al. 1996; Storchi and Woustra 1996).

In what follows, we will describe some examples of application of the pencil-beam method, including short descriptions of different *tricks* which have been used for clinical implementations.

### 26.3.3.4 Some Practical Implementations

As indicated previously, under certain circumstances, the fast Fourier transform can speed up the computation enormously (e.g. Boyer 1984). This was successfully exploited by Mohan and Chui (1987). They demonstrated the power of the pencil-beam method in predicting dose distributions for irregular fields in a uniform medium with a flat incident surface ([Figure 26.10](#)). They obtained their elementary pencil beams for cobalt-60, 6 MV and 18 MV qualities by running the EGS4 Monte Carlo code. They used the FFT method assuming that the pencil-beam *kernel* was invariant with respect to its position (i.e. they neglected the consequences of their off-axis spectral variations). Nevertheless, Mohan and Chui (1987) made the point that their method relied only on basic principles of physics, without resorting to empirical assumptions or employing arbitrary analytical functions to describe the source distribution or the shape of the boundary. They stated that the reason for this was that the Monte Carlo generated pencil beams automatically took into account the transport (in water) of scattered photons and secondary electrons.

**FIGURE 26.10**

Pencil-beam FFT convolutions vs. measurements for a blocked 6 MV beam. The right-hand side figure shows a profile at level (a) of the irregular field displayed on the left-hand side taken at 10 cm deep. On the graph the points represent measurements and the line represents the convolution calculation. (From Mohan, R. and Chui, C.-S., *Medical Phys.*, 14, 70–77, 1987. With permission.)

Bortfeld et al. (1993) maximised the efficiency of the pencil-beam method by decomposing the pencil-beam kernel into three separate terms and thereby managed to reduce the required number of 2D convolutions; they also employed the fast Hartley transform. They reported a calculation time for the three convolutions of less than 10 s, out of a total time of only 40 s, for a 3D dose calculation of a 10 cm × 10 cm field (using a DEC VAXstation 3100). For the 15 MV beam, excellent agreement with measurement was demonstrated for the case of various irregular fields in a uniform water medium.

Ahnesjö et al. (1992b) presented a complete pencil-beam model for clinical use. They employed polyenergetic pencil-beam kernels, obtained from in-depth convolution of Monte Carlo-derived energy deposition point kernels (see Section 26.3.4.3) with the fluence variation of the primary photons (Ahnesjö and Andreo 1989). They found that these pencil beams could be represented analytically with high accuracy by a sum of two exponentials over the radius:

$$K_{PB}(r,z) = \frac{A_z e^{-a_z r}}{r} + \frac{B_z e^{-b_z r}}{r} \quad (26.23)$$

where  $r$  is the cylindrical radius from the pencil-beam axis and the four coefficients are fitting parameters which depend on the depth,  $z$ .

In the Ahnesjö et al. (1992b) pencil-beam model, for all dose components except (photon) scatter, the effects of tissue variations and patient contour are modelled by depth scaling, i.e. by calculating the dose using pencil-beam parameters taken at the radiological depth (i.e. the equivalent depth in water). For the scatter dose, the pencil-beam parameters at the geometrical depth are used and the kernel integration is followed by the application of a special scatter correction factor described in their paper. Knöös et al. (1994) reported on a dosimetric verification of the Ahnesjö et al. (1992b) pencil-beam model as implemented at that time in the TMS/HELAX TPS but this study was confined to homogeneous water phantoms, where its performance was found to be excellent.

Another pencil-beam algorithm implementation was performed by Storchi and Woustra (1996) who based their model parametrisation on a limited number of experimental data and introduced both *scatter* and *boundary* kernels. The comparison between measurements and calculations was performed for rectangular and irregular fields, with and without wedge filters, yielding deviations less than 2% except for 45° wedges or under blocks where it could be between 4% and 5%. This algorithm was incorporated into the Cadplan (Dosetek–Varian) TPS and migrated more recently into the Eclipse (Varian) system.

### 26.3.3.5 Inhomogeneities and Other Limitations

Bortfeld et al. (1993) stressed the inherent limitations of the pencil-beam approach: that high accuracy is in principle only achievable for homogeneous phantoms with flat surfaces. The very same point was made by Mohan and Chui (1987). Nor do Ahnesjö et al. (1992b) make any exaggerated claims for the performance of their particular pencil-beam model in inhomogeneous situations.

Knöös et al. (1995) made a detailed study of the limitations of the pencil-beam approach in the case of lung tissue. They investigated the effects of scaling operations for heterogeneity corrections, such as the method described in Ahnesjö et al. (1992b), by comparisons of the pencil-beam model in the *TMS/HELAX* system with Monte Carlo calculations in the admittedly difficult geometry of the mediastinum. Deviations in low-density volumes were found to increase with increasing beam energy from around 3% at 4 MV to 14% at 18 MV; this was ascribed to electron disequilibrium. They concluded that the magnitude of this limitation of the pencil-beam model in heterogeneous situations was similar to that found in *conventional* inhomogeneity correction models (see [Section 26.2.3.2](#) and [Section 26.3.2.2](#)).

The pencil-beam approach has been quite extensively implemented in commercial planning systems. One reason for this is that it represents an acceptable compromise between speed and accuracy for most of the clinical situations and that it is particularly well suited for intensity modulation techniques (including inverse planning: see [Chapter 43](#)). However, the principle of the method is very similar to primary-scatter double decomposition; its quality depends strongly of the detailed implementation and it suffers inherently from serious limitations in handling inhomogeneity corrections properly since the pencil beam is generally treated as a whole, i.e. not separated into primary and scatter components. For more accurate results in the presence of inhomogeneities, so-called *differential* pencil-beam approaches, usually referred to as *point-kernel convolution/superposition methods*, are preferable. These are covered in the following section.

## 26.3.4 POINT KERNEL CONVOLUTION/SUPERPOSITION

### 26.3.4.1 General

The idea of the point kernel convolution/superposition\* approach to dose calculation for treatment planning was put forward by several independent groups in 1984 (Ahnesjö 1984; Boyer and Mok 1984; Chui and Mohan 1984; Mackie and Scrimger 1984). This was prior to the first attempts to use pencil-beam kernels for photons (see [Section 26.3.3](#)). Actually, in contrast to what happened with electron beams (see [Chapter 27](#)), the photon pencil-beam approach was developed essentially as a subset of the more general photon point-kernel approach. Although much of the material pertaining to pencil-beam kernels holds also for point kernels, a full description is justifiable for a method which has been implemented in several commercial planning systems and represents a good compromise between the limitations of the other superposition methods and the potentially highly accurate but computer-resource intensive Monte Carlo computations (see [Chapter 28](#)).

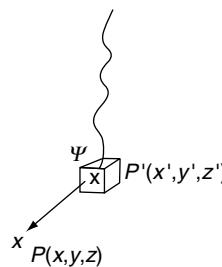

The principle of the method is illustrated in [Figure 26.11](#).

For an homogeneous medium, this can be expressed by the following equation:

$$D(x, y, z) = \iiint \frac{\mu}{\rho} \Psi(x', y', z') K(x-x', y-y', z-z') dV' \quad (26.24)$$

---

\* The fundamental mathematical operation is *superposition*, but if the kernel is spatially invariant, *convolution* can be used as a means of rapid calculation of the superposition (see [Section 26.3.4.6](#)).

**FIGURE 26.11**

Principle of point kernel convolution: the dose at  $P$  is calculated from 3D integration of the energy released from voxels such as  $dV'$  centred on  $P'$  (see also [Figure 26.6](#)).

The 3D integration is performed over the patient volume;  $\Psi(x',y',z')$  is the energy fluence at point  $P'$  ( $J\ m^{-2}$ );  $dV' = dx'dy'dz'$  is an elementary volume (approximated by a voxel) around  $P'$ ;  $\frac{\mu}{\rho} \Psi(x',y',z')$  is the total energy (secondary electrons and scattered photons) per mass released from  $dV'$ , known as *terma* ( $J\ kg^{-1}$  or Gy),  $\mu/\rho$  being the mass attenuation coefficient ( $m^2\ kg^{-1}$ ) for the medium at  $P'$ ;  $K(x-x',y-y',z-z')$  is the *energy deposition point kernel* (sometimes called *dose-spread array* or *point spread function* or *differential pencil-beam kernel*) which represents the fraction of energy released from  $dV'$  that is deposited at  $P$ , when primary photons interact at  $P'$ .

A more general form of the above equation for a clinical polyenergetic beam consists in performing an overall integration of the expression according to the energy bins of the local beam spectrum, where  $\Psi$  should be replaced by the energy fluence differential in energy,  $\mu/\rho$  and  $K$  being both energy dependent. Simplifying the expression by the use of an equivalent mean energy is not accurate enough but a limited number of bins can be used as demonstrated by Boyer et al. (1989) and Zhu and Van Dyk (1995). Some other practical solutions will be discussed below.

In common with the pencil-beam approach, the dose computation requires that the energy fluence (or the terma) and the point kernels are first determined.

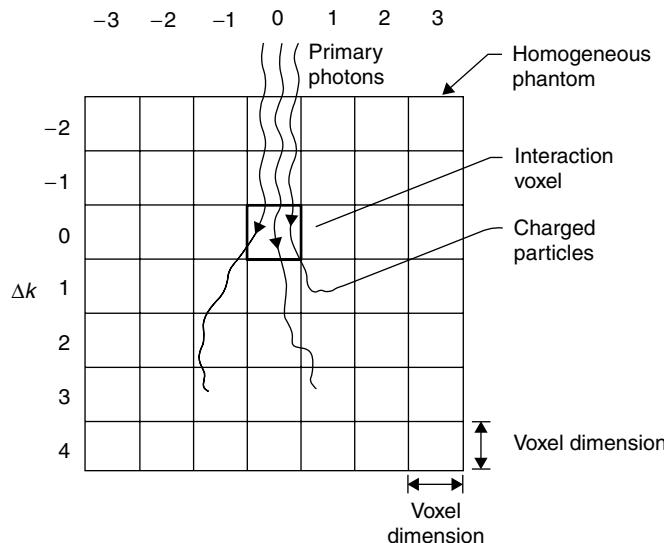

#### *26.3.4.2 Determination of the Energy Fluence and Terma*

The determination of the 2D energy fluence at the patient surface has been discussed above as part of the pencil-beam approach. This fluence is then transported through the patient by ray tracing along paths diverging from the source position, applying the inverse square-law correction and a tissue attenuation correction according to the patient composition integrated between the patient surface and  $P'$ . For extra-focal radiation this is an approximation; however it is acceptable as long as this contribution is small. In principle the attenuation calculation should account for the depth-hardening effect on the primary beam as well as the off-axis softening due to the influence of the flattening filter (Zefkili et al. 1994; Lee 1997).

The terma at any point is then obtained by multiplication of the energy fluence and the mass attenuation coefficient, the latter depending on the local energy spectrum and tissue composition (Metcalfe et al. 1990; Papanikolaou et al. 1993).

#### *26.3.4.3 Determination of the Energy Deposition Point Kernels, K*

The standard method for determination of  $K$  for monoenergetic beams in water is Monte Carlo computation in a phantom made of small, adjacent voxels, where the primary photons are forced to interact at the voxel at the origin ([Figure 26.12](#)).

**FIGURE 26.12**

Generation of an energy deposition kernel in a homogeneous phantom by Monte Carlo computation. (From Mackie, T. R. et. al., *Med. Phys.*, 12, 188–195, 1985. With permission.)

Spherical geometry is usually chosen, using polar coordinates with set radial and angular intervals in order to obtain an accurate representation of energy deposition at any distance from the interaction point (Mackie et al. 1988; Mohan et al. 1986; Ahnesjö et al. 1987). The graphical representation of the kernels for various energies either as isolevels or profiles is illustrative of the energy-deposition processes and helps in understanding the principle of the method (Figure 26.13).

Figure 26.13 also illustrates the possibility of computing separately *primary* kernels (related to the energy deposited by the charged particles set in motion by primary photons) and *scatter* kernels (related to the energy deposited by all charged particles set in motion by scattered photons). Such a decomposition could be further extended to different orders of scatter, bremsstrahlung and annihilation radiation and may prove to be useful for simplification and/or acceleration of computation. In addition, the decrease in the contribution of scattered photons and the increase in the importance of electron transport as the energy increases are clearly seen in the figure, as well as the directional behaviour.

Although other possibilities for normalisation have been suggested (Ahnesjö and Aspradakis 1999), the kernel  $K$  in Equation 26.24 is the fraction of incident energy per unit volume. It can be therefore expressed as  $\text{cm}^{-3}$  and should be consistent with the equation

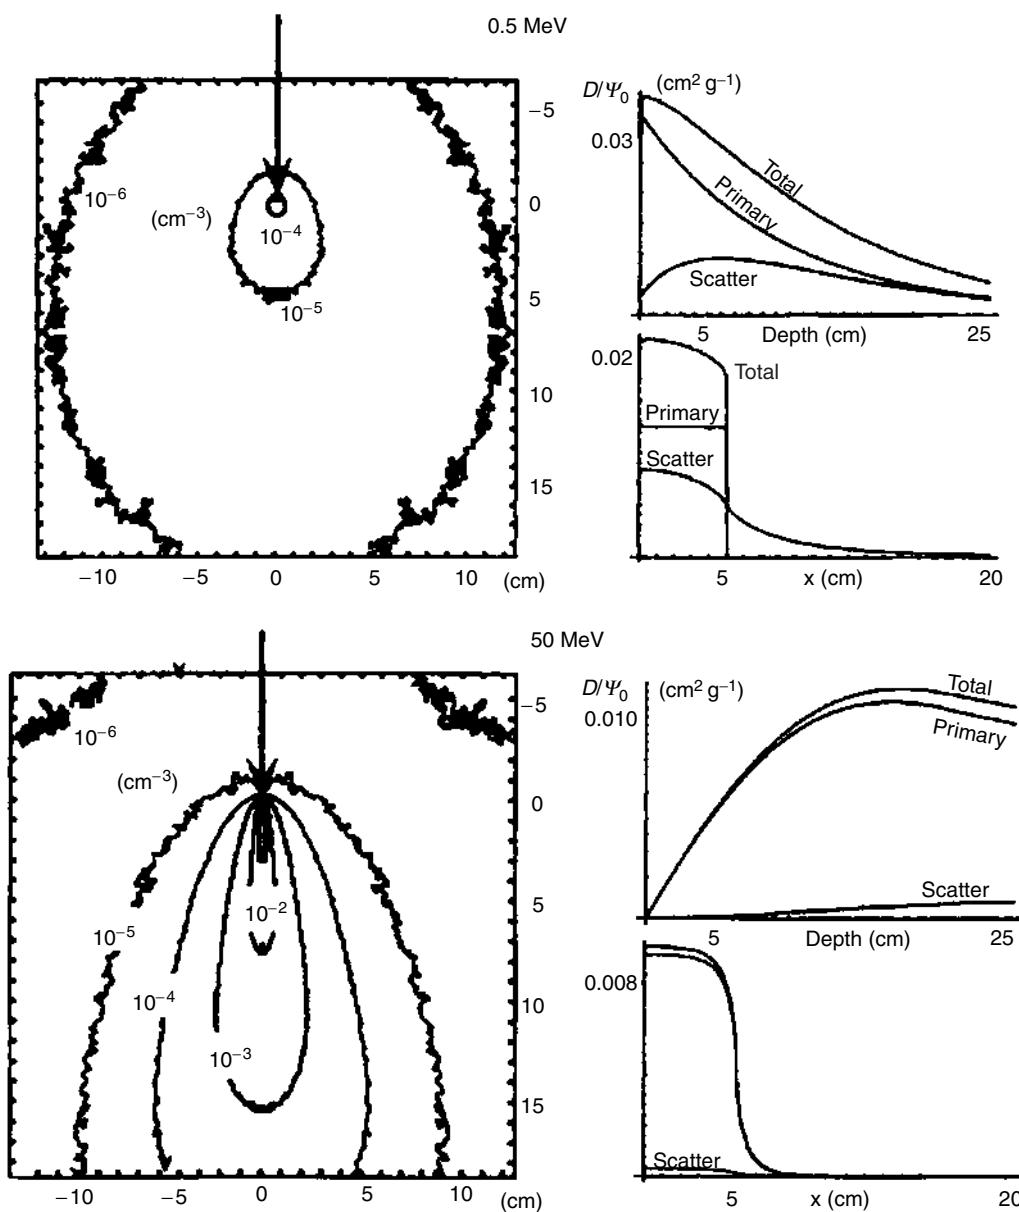

$$\iiint_{\infty} K(x,y,z) dV \equiv 1$$

As pointed out by Mackie et al. (1988) and Boyer (1988):

$$\iiint_{\infty} K_p(x,y,z) dV = \frac{\mu_{\text{en}}}{\mu} \quad \text{and} \quad \iiint_{\infty} K_s(x,y,z) dV = \frac{\mu - \mu_{\text{en}}}{\mu} \quad (26.25)$$

where  $K_p$  is the *primary* kernel;  $K_s$  the *scatter* kernel;  $\mu$  is the linear attenuation coefficient; and  $\mu_{\text{en}}$  is the linear energy-absorption coefficient (see Chapter 4).

This turns out to be useful for verification of the generated kernels and for the application of relevant corrections for beam-quality variations.

**FIGURE 26.13**

Graphical representation of energy deposition kernels for 0.5 MeV (top) and 50 MeV photons (bottom), both in isolevel format (left) and profiles format (right). (From Ahnesjö, A. and Aspradakis, M. M., *Phys. Med. Biol.*, 44, R99–R155, 1999. With permission.)

When modelling clinical beams, it is important to account as faithfully as possible for their spectral composition and the spatial variations thereof. The most straightforward method is to generate polyenergetic kernels by weighted addition of precalculated monoenergetic kernels according to the normalised incident fluence spectrum. This spectrum must first be obtained by one of the methods explained above for the pencil-beam approach. However, the fluence spectrum changes with depth and lateral position. Because it is impractical to use different kernels for different positions of  $P$  and because the overall dose per unit fluence does not change much, it has been considered as acceptable to make corrections according to Equation 26.25. Thus the primary kernel is multiplied by a factor equal to the ratio between  $\mu_{\text{en}}$  at point  $P'$  and

$\mu_{en}$  at the surface and the scatter kernel is multiplied by a similar ratio of energy-scatter coefficients ( $\mu - \mu_{en}$ ) (Metcalfe et al. 1990; Papanikolaou et al. 1993; Hoban 1995).

Instead of using tables of precalculated kernels, Ahnesjo and Mackie (1987) have suggested an analytical fit of the form:

$$K(r) = \frac{A_\theta e^{-a_\theta} + B_\theta e^{-b_\theta}}{r^2} \quad (26.26)$$

where  $r$  is the distance between  $P$  and  $P'$ ;  $A_\theta$ ,  $a_\theta$ ,  $B_\theta$  and  $b_\theta$  are fitting parameters depending on the scattering angle,  $\theta$ .

In this formulation, the first term mainly describes the primary and the second one mainly the scatter-energy deposition fraction.

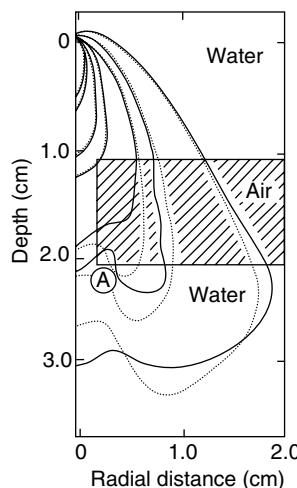

#### 26.3.4.4 Beam Divergence and Tilting of the Kernels

In addition to a modification of the photon fluence, the beam divergence introduces a modification of the kernel directions which are *tilted* accordingly. Therefore the same kernel should strictly not be used for different off-axis distances. In practice, it has been found acceptable in most clinical cases to neglect this effect (Sharpe and Battista 1993), especially if it is compensated for by applying the inverse square-law correction at dose calculation sites instead of at each primary interaction site (Papanikolaou et al. 1993). This issue has also been addressed by Liu et al. (1997c).

#### 26.3.4.5 Kernel Scaling according to Tissue Density and Tissue Inhomogeneities

If the density of the medium is different from unity, then according to the O'Connor theorem the same dose distribution would be obtained by scaling appropriately all phantom dimensions (see [Section 25.2](#)). This is equivalent to using a scaled distance for fluence computation at  $P'$  and scaling the kernels in all directions according to the inverse of the density. This is, in turn equivalent to replacing all distances in [Figure 26.11](#) and Equation 26.24 by the equivalent radiological distances. In Figure 26.11 we have to consider separately the density  $\rho_1$  of the medium between surface and  $P'$  which modifies  $\Psi(x', y', z')$ , the density  $\rho$  of the medium surrounding  $P'$  which modifies the *terma* term according to  $\mu/\rho$  and the density of  $\rho_2$  of the medium between  $P'$  and  $P$  which changes the kernel value to  $K[\rho_2(x-x'), \rho_2(y-y'), \rho_2(z-z')]$ . This leads to a generalisation of Equation 26.24 for an inhomogeneous medium where all the distances can be scaled according to the relevant radiological equivalent path lengths with respect to the voxel-density distribution and the positions of  $P$  and  $P'$ .

It is clear however that, as soon as the kernel  $K$  can no longer be considered as spatially invariant, Equation 26.24 is no longer a convolution and the integration must be conducted by the superposition method instead. Therefore, one expects much longer computation time if inhomogeneities are taken into account. Zhu and Boyer (1990) have presented an alternative way to compute the dose in 3D for inhomogeneous materials. The kernels remain spatially invariant but the fluence is computed by ray tracing through the 3D CT matrix of inhomogeneous densities; In this way the possibility of using Fourier space with its attendant speed advantages is retained. Zhu and Boyer (1990) show that the method compares well with measurements for fairly simple inhomogeneous phantoms. Obviously it will fail in the region of large mismatches at interfaces where there is no electronic equilibrium, i.e. in exactly those situations where one might expect significant advantages from the point-kernel approach compared to the pencil-beam approach. Even when the kernels are scaled, Equation 26.24 in an inhomogeneous medium is only approximate. In particular, the densities to be considered should include not only the voxels between  $P'$  and  $P$  but also the other surrounding voxels. Another approximation comes from the fact that rectilinear scaling is not exact with respect to multiple scattering of secondary electrons in an inhomogeneous medium. Therefore

**FIGURE 26.14**

Graphical comparison of a density scaled kernel (dotted line) and a Monte Carlo kernel (full line) in the presence of an air ring; it can be assumed that the Monte Carlo-derived kernel correctly shows the effect of the inhomogeneities. (From Woo, M. K. and Cunningham, J. R., *Med. Phys.*, 17, 187–194, 1990. With permission.)

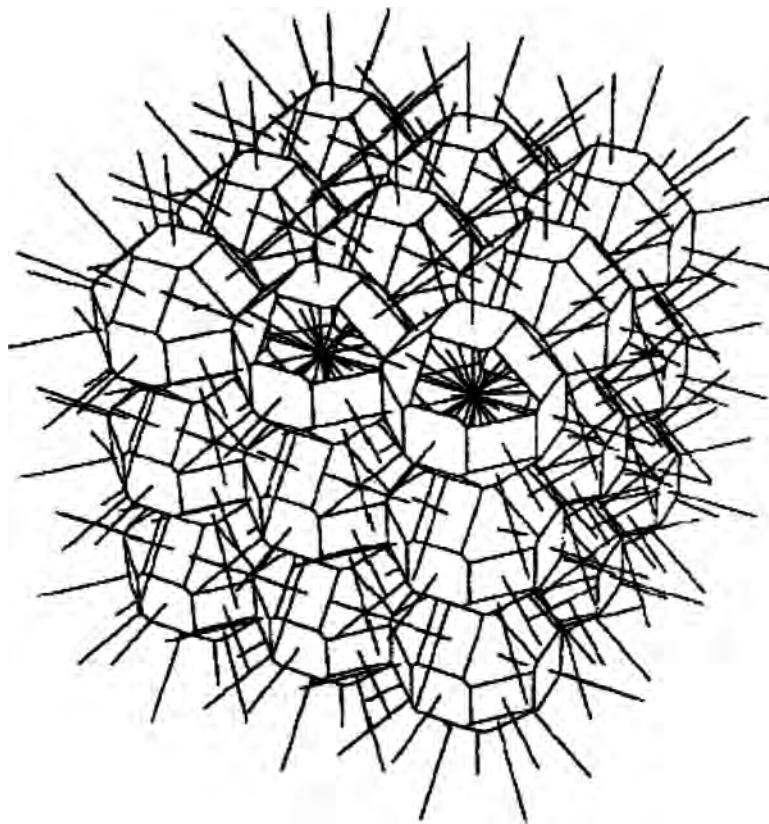

a number of refinements have been suggested, which inevitably lead to an increase in computation time (Keall and Hoban 1995; Sauer 1995; Yu et al. 1995). In spite of the inherent limitations and approximations of the scaling method, it seems that in most situations there is an *averaging* effect of the surrounding kernels which gives acceptable results (Woo and Cunningham 1990) (Figure 26.14). Significant discrepancies occur only in extreme situations according to Arnfield et al. (2000). It should also be remembered that the results can be very different depending on the practical implementation of the method.

#### 26.3.4.6 Practical Implementation

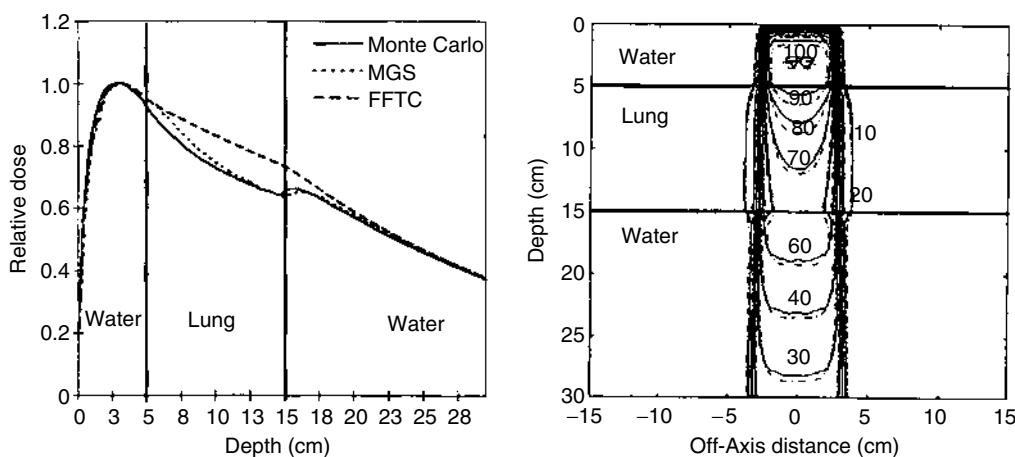

Direct summation (superposition) of the dose using an equation such as Equation 26.24, implies repeating the elementary computation at  $n^3$  deposition voxels from  $n^3$  interaction voxels. The resulting order of calculation is  $n^6$ . If we apply a scaling with respect to the positions of  $P$  and  $P'$ , this is likely to further increase the order to  $n^7$ . This is very demanding and efforts have been made to reduce the computation time.

When convolution is possible (i.e. for homogeneous medium), the use of FFT drastically reduces the number of operations. Instead of  $n^6$  operations for full superposition, a 3D FFT algorithm would generate a number of operations proportional to  $n^3 \log_2 n$  (Ahnesjö and Aspradakis 1999).

Another method for reducing the computation time consists of avoiding having to account systematically for all  $n^3$  voxels which theoretically contribute to the dose at any specific single point. This has been done in the so called *collapsed cone convolution* (CCC) method which takes advantage of the fact that at large distances the kernel values fall off rapidly (Mackie et al. 1987; Ahnesjö 1989). Consequently, if we draw in 3D a set of  $m$  lines (say for instance 3 orthogonal and 6+4 diagonal) from the deposition site, they will intersect the neighbouring voxels preferentially and avoid more distant voxels (see Figure 26.15). If we calculate only the contribution from the voxels along these  $m$  lines, there will be  $n \cdot m$  voxels sampled for each of the  $n^3$  deposition voxels and the number of operations is reduced to the order  $n^4 m$ . (instead of  $n^6$ ). It is however necessary to make sure that the total transported energy remains the same as if all voxels were sampled. Therefore some normalising procedure is required which *collapses* the energy emitted from all neighbouring voxels onto the average direction defined by the sampling lines. This is where the name “collapsed cone” comes from.

**FIGURE 26.15**

Schematic representation of 26 possible discrete directions of particle transport (13 cone axes) from each interaction voxel of a lattice made of  $3 \times 3 \times 3$  voxels. (Reproduced from Ahnesjö, A. and Aspradakis, M. M., *Phys. Med. Biol.*, 44, R99–R155, 1999. With permission.)

**FIGURE 26.16**

Comparison between a full Monte Carlo calculation (solid line) and a derivation of the CCC method called MGS (dashed line) for a  $5 \text{ cm} \times 5 \text{ cm}$  15 MV beam with a lung slab (density 0.31) 10 cm thick. (From Miften, M. et al., *Phys. Med. Biol.*, 45, 817–833, 2000. With permission.)

The CCC method or other methods derived from it have been successfully implemented in several clinical treatment planning systems: Philips-Pinnacle (Mackie et al. 1985; Bedford et al. 2003), Helax-TMS which has become Oncentra Masterplan (Ahnesjö et al. 2005), CMS Focus which is now called XiO (Miften et al. 2000), and the DKFZ system (Scholz et al. 2003). These implementations account, for example, with reasonable accuracy for both the observed penumbra broadening and dose reduction on the axis of a high energy photon beam passing through lung (i.e. a low-density inhomogeneity) ([Figure 26.16](#)). Both of these effects are due to secondary electron transport and cannot be accounted for by any of the simpler superposition methods discussed in [Section 26.3.2](#) and [Section 26.3.3](#).

---

## 26.4 CONCLUDING REMARKS

A very wide variety of methods for photon dose computation in external-beam therapy has been implemented in treatment planning systems. These range from very basic dose representation methods ([Section 26.2](#)) to sophisticated methods involving convolution/superposition of precalculated kernels ([Section 26.3](#)). Although most of them perform well in simple clinical situations, there are still many cases where approximations have to be made for some or all of the different algorithms. These include the dose representation in the build-up region, under blocks, at beam edges and in the presence of inhomogeneities. The superposition methods with all their variants are the most promising. Nevertheless, it is necessary to find a compromise between speed and accuracy and to recognise the limitations of the various algorithms, especially for situations where a lack of electronic equilibrium can be of clinical importance such as in the lung particularly at high photon energies. It is emphasised that there is no completely correct way of scaling the water-based point kernels/spread functions to account for the effect of inhomogeneities ([Figure 26.14](#)) short of using Monte Carlo simulation ([Chapter 28](#)).

## 27.1 INTRODUCTION

Methods of calculating the dose distribution in patients undergoing external-beam radiotherapy have gradually evolved over the years. The emphasis has justifiably been on photon beams (see [Chapter 25](#) and [Chapter 26](#)). The division of a *broad* beam into a large number of narrow beams, or *pencils*, would seem to be a natural line of attack, given that this corresponds to the way the particles, either photons or electrons, are incident on the phantom or patient. However, it was not until the early 1980s that pencil-beam methods were first exploited, and the first models were developed for electrons (Brahme et al. 1981; Hogstrom et al. 1981; Lax et al. 1983) rather than for photons. This was possibly due to the fact that the inadequacies of so-called *broad-beam* approaches (see [Section 26.2](#)) in modelling irregular fields and inhomogeneities are more dramatic for electrons than for photons (e.g. [Figure 27.1](#)).

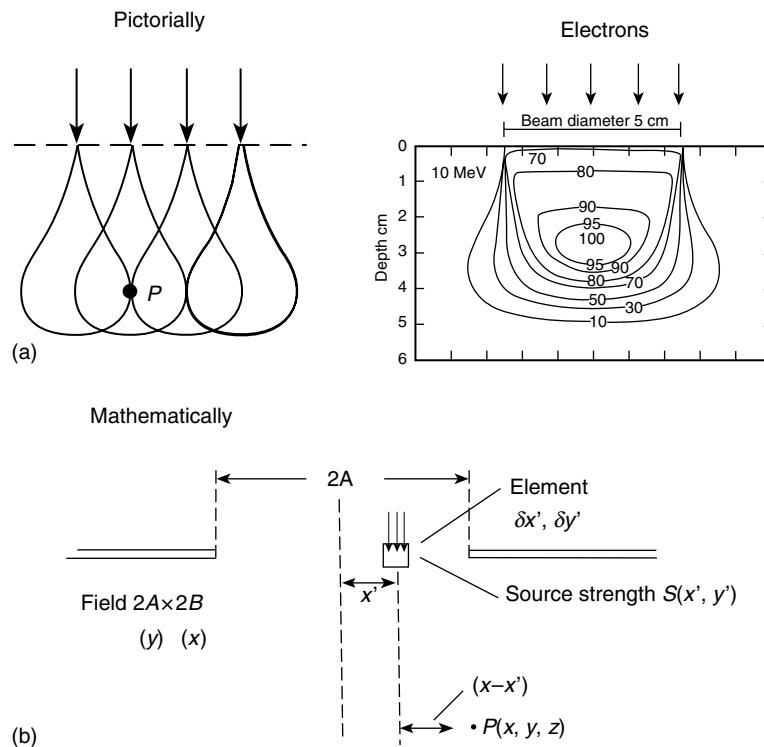

The overall concept is the same regardless of the incident particle type, i.e. integration or *convolution* with the incident fluence at the collimator, but the physical forms of the elementary photon and electron pencil-beam dose distributions are very different. This is due to the difference between the physics of photon and electron transport in matter, at least as far as the primaries are concerned (see [Chapter 3](#) and [Chapter 4](#)). Naturally, the photons produce electrons which then must, in principle, be transported in the same way as if they were the primary particles.

For photons, the *excitement* since the mid 80s has not been about pencil-beam methods, but about the *convolution* of *point spread dose functions (kernels)* with the spatial distribution of primary-photon fluence (see [Section 26.3.4](#)). For photons, pencil beams represent one level below this in complexity but with the advantage of shorter computation times (see [Section 26.3.3](#)). On the other hand, for electrons there is *no* level beyond that of the pencil beam. It makes no sense to discuss electron point spread dose functions because there is no *primary* component; all the electrons interact immediately upon entering the medium or the patient; in other words, *the scatter component is 100% at all depths* (see [Chapter 3](#)).

**FIGURE 27.1**

Perturbation of electron-beam dose distribution due to a low-density heterogeneity. The distribution in a homogeneous water phantom is shown on the right side. The introduction of an air cavity (2 cm × 2 cm), shown on the left side, causes an alteration of the shapes of the isodoses including a *hot* region of 103% relative to the maximum dose on the left side. (Reproduced from ICRU, Report 71, International Commission on Radiation Units and Measurement, Bethesda, MD, 2004. With permission.)

**FIGURE 27.2**

Decomposing a broad beam into narrow pencils and summing them up to give the dose at a point. (Reproduced from Nahum, A. E., in *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Nahum, A. E., Ed., Medical Physics Publishing, Madison, WI, 1985, pp. 151–184.)

Up until the early 1980s, electron-beam patient dose-calculation methods had mirrored the simplest of those for photon beams (see [Section 26.2](#)), following a 1-D approach where the effect of inhomogeneities was accounted for by simply shifting the isodoses by an amount depending only on the extent and density of the inhomogeneity along the ray line passing through the dose point.

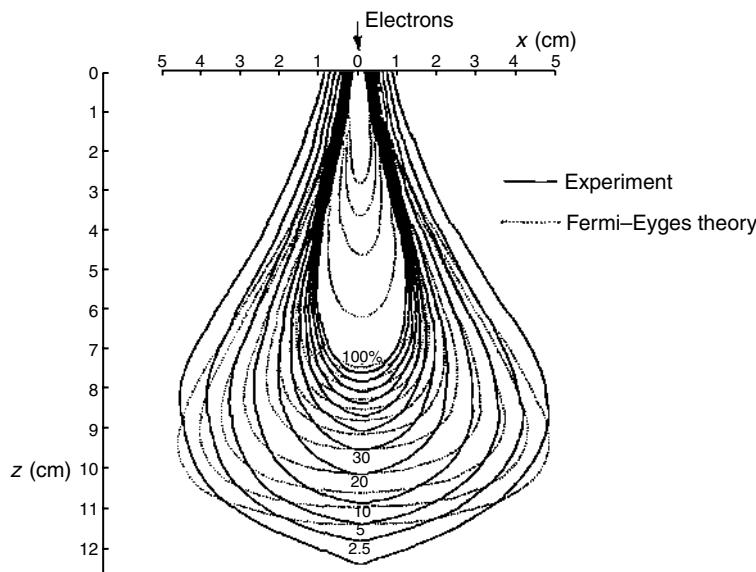

[Figure 27.1](#) shows how the presence of an air cavity produces a so-called *hot spot* downstream from the cavity; there is no way that the 1-D isodose-shift method can predict such a distribution (e.g. especially regions with dose greater than 100%).

A natural alternative to the 1-D rayline approach is to decompose the beam into narrow pencils. The dose at a point then becomes a sum over the pencils comprising the beam. Figure 27.2 illustrates the idea. The dose distribution due to a narrow electron beam is shown in [Figure 27.3](#).

## 27.2 THE FERMI–EYGES PENCIL-BEAM ALGORITHM IMPLEMENTATION (HOGSTROM MODEL)

### 27.2.1 GENERAL

Hogstrom et al. (1981) showed that the Fermi–Eyges analytical form of the pencil beam for a geometry consisting of inhomogeneous layers is capable of predicting the existence and approximate position of *perturbations* in dose distributions caused by inhomogeneities

**FIGURE 27.3**

Narrow-beam dose distribution for 3 mm diameter 22.5 MeV electron beam in water. (Adapted from Brahme A., Lax, I., and Andreo, P., *Acta Radiol. Oncol.*, 20, 147–158, 1981.)

(though not necessarily their magnitude; see later sections). Furthermore, the effects of a lack of lateral scattering equilibrium on oblique incidence are correctly accounted for. For irregular fields the pencil-beam approach is the natural choice, as it clearly lends itself to integration over any shape of aperture or collimator.

The first implementations of the pencil-beam approach were limited to two-dimensional descriptions of inhomogeneities. This was solely due to the practical requirement for reasonable calculation times. Calculations were generally carried out for points defined by the plane of a particular CT slice (Figure 27.5). The two-dimensional approach implies that the inhomogeneities present in the slice are assumed to extend infinitely in the direction perpendicular to the CT-slice plane. This enables the dose summation to be carried out over a series of *strip beams* rather than pencils. It has been shown that the 2D model can introduce serious errors for cases where the inhomogeneity actually extends only a short distance perpendicular to the CT plane (Cygler et al. 1987; Mah et al. 1989). Ideally, the pencil-beam model should be fully 3D; this is generally the case with the pencil-beam models in treatment planning systems today. However, despite its apparent sophistication, there are still major limitations to a purely analytical pencil-beam approach (see in particular Section 27.3).

The basic ideas behind the electron pencil-beam approach will be covered in the remainder of this section, with an emphasis on the Hogstrom model developed at the M.D. Anderson Hospital (Hogstrom et al. 1981; Nahum 1985; Jette 1995; Hogstrom and Steadham 1996).

## 27.2.2 THEORY OF THE FERMI–EYGES PENCIL-BEAM MODEL

An analytical solution to the transport equation for charged particles in the small-angle approximation, first developed by Fermi, was extended by Eyges (1948) to inhomogeneous media and to take account of energy loss. The Fermi–Eyges solution involves both angular and spatial variables. In what follows, the angular dependence has been removed by integration over all possible directions of particle motion.

Referring now to a Cartesian coordinate system ( $x,y,z$ ) and an electron, incident perpendicularly on a medium at  $(0,0,0)$  in the  $z$  direction, the Fermi–Eyges expression for the probability of finding the electron at depth  $z$  with displacement between  $x$  and  $x+dx$ ,  $y$  and  $y+dy$  is

$$p(x,y,z)dx dy = \frac{1}{2\pi\sigma_{MCS}^2} \exp\left[-\frac{x^2+y^2}{2\sigma_{MCS}^2}\right] dx dy \quad (27.1)$$

where

$$\sigma_{MCS}^2 = \frac{1}{2} \int_0^z (z-u)^2 T(u) du \quad (27.2)$$

The quantity  $T(u)$  is the linear scattering power of the medium at depth  $u$  (see [Section 3.5](#)); this is evaluated at the mean energy of the electrons at the depth in question (MCS stands for multiple coulomb scattering).

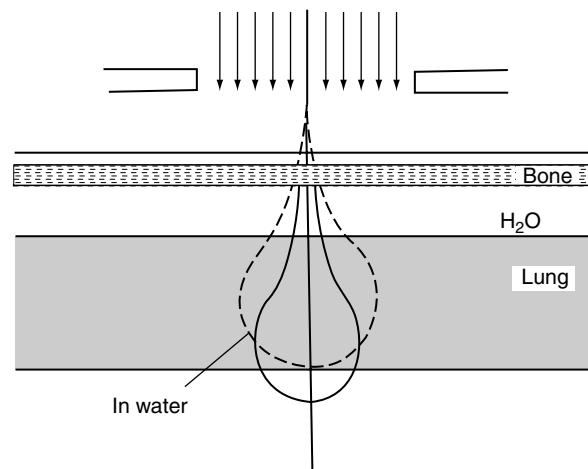

The expression  $p(x,y,z)$  can be separated into the product  $p(x,z) \times p(y,z)$ , where it can be seen that

$$p(x,z)dx = \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{x^2}{2\sigma^2}\right] dx \quad (27.3)$$

is a Gaussian, or normal distribution, and  $\sigma$  can be identified as the *standard deviation*, which is a measure of the width of the distribution. As the depth increases,  $\sigma_{MCS}$  increases and the pencil spreads out. The evaluation of  $\sigma_{MCS}$  through Equation 27.2 allows the medium to change in a layered manner, as indicated in Figure 27.4, with  $T(u)$  appropriate to the layer in question. The pencil that would have resulted from water only is shown by the dashed outline.

The integration of a Gaussian can be expressed as

$$\text{erf}(x) \equiv \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt$$

**FIGURE 27.4**

The layered geometry to which the Fermi–Eyges expression applies. (Adapted from Hogstrom, K. R., Mills, M. D., and Almond, P. R., *Phys. Med. Biol.*, 26, 445–459, 1981.)

which defines the error function  $\text{erf}(x)$ . It should be noted that  $\text{erf}(-x) = \text{erf}(x)$ ,  $\text{erf}(\infty) = 1$  and  $\text{erf}(x) > 0.995$  for  $x > 2$ ; extensive use is made of tabulations of the error function in practical implementations. The above integral can be recast in a more directly useful form as

$$\int_0^A \exp\left(\frac{-x^2}{2\sigma^2}\right) dx = \sqrt{\frac{\pi}{2}}\sigma \text{erf}\left(\frac{A}{\sqrt{2}\sigma}\right) \quad (27.4)$$

For a field of size  $2A \times 2B$  and a uniform source strength, ignoring beam divergence, the total probability of finding an electron, or the *electron number*, at position  $(x,y,z)$  per unit area will be given by

$$N(x,y,z) = \frac{1}{2\pi\sigma_{\text{MCS}}^2} \int_{-B}^B \exp\left[\frac{-(y-y')^2}{2\sigma_{\text{MCS}}^2}\right] dy' \times \int_{-A}^A \exp\left[\frac{-(x-x')^2}{2\sigma_{\text{MCS}}^2}\right] dx' \quad (27.5)$$

which, with the help of Equation 27.4, reduces to

$$N(x,y,z) = \frac{1}{4} \left[ \text{erf}\left(\frac{A-x}{\sqrt{2}\sigma_{\text{MCS}}}\right) + \text{erf}\left(\frac{A+x}{\sqrt{2}\sigma_{\text{MCS}}}\right) \right] \left[ \text{erf}\left(\frac{B-y}{\sqrt{2}\sigma_{\text{MCS}}}\right) + \text{erf}\left(\frac{B+y}{\sqrt{2}\sigma_{\text{MCS}}}\right) \right] \quad (27.6)$$

Recalling that  $\text{erf}(x)$  is very close to unity for  $x > 2$ , it can be seen that  $N(x,y,z) = 1$  if both  $x$  and  $y$  are more than about  $3\sigma_{\text{MCS}}$  from the field edges, i.e. the dose profile is *flat* away from the edges of a broad beam, exactly as one would expect.

The above result also implies that  $N(x,y,z)$  is constant with depth, i.e. the build-up due to scattering (see Section 24.2.2) is not predicted. This is because  $N(x,y,z)$  is proportional to the *planar* fluence (Section 6.3.5; Nahum and Brahme 1985). Furthermore, Fermi–Eyges theory cannot account for electron loss. An empirical correction factor is necessary in order to reproduce measured depth–dose curves.

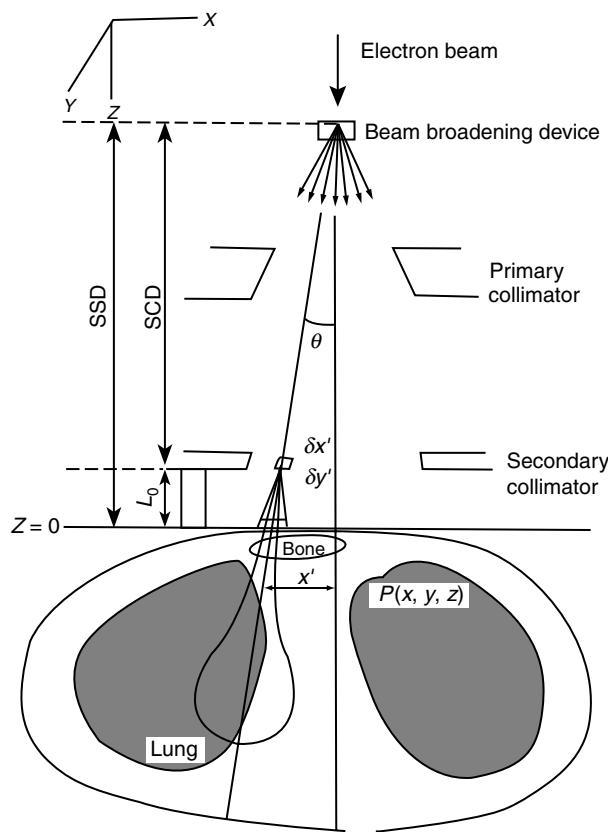

### 27.2.3 ADAPTATION OF FERMI–EYGES THEORY TO THE TREATMENT SITUATION

The application of the Fermi–Eyges theory to the treatment situation described here follows the approach developed by Hogstrom et al. (1981). The electron pencils are started at the level of the beam-defining device, or secondary collimator. Figure 27.5 explains the situation.

The electrons begin to spread out as they leave the vacuum window due to air scattering. The scattering-foil system broadens the beam in order to produce a uniform profile (see Section 11.4.5.2). The appreciable angular spread present in the beam at the secondary collimator level must be incorporated into the model. This is done by giving the pencils an initial angular distribution  $\sigma_{\theta_x}$  (this is the *sigma* of the angular distribution projected onto the  $x-z$  plane). As a result of this initial divergence, the elementary pencils started at the secondary collimator would continue to spread out even in the absence of any material further downstream. The resulting lateral spread  $\sigma_{\text{air}}$  at depth  $z$  follows from Equation 27.2 by putting  $T(u)\Delta z = 2\sigma_{\theta_x}$ :

$$\sigma_{\text{air}} = (z + L_0)\sigma_{\theta_x} \quad (27.7)$$

where  $L_0$  is the distance between the secondary collimator and the  $z=0$  plane (Figure 27.5); the small amount of extra scattering caused by the air over the distance  $L_0$  has been neglected.

**FIGURE 27.5**

Schematic representation of an elementary pencil in the  $x$ - $z$  plane in the treatment situation. (Reproduced from Hogstrom, K. R., Mills, M. D., and Almond, P. R., *Phys. Med. Biol.*, 26, 445–459, 1981. With permission.)

The lateral spread of the beam at a depth in the patient is obtained by convolving one Gaussian with spread  $\sigma_{\text{air}}$  with another Gaussian with spread  $\sigma_{\text{MCS}}$ , which results in a Gaussian with spread  $\sigma_{\text{med}}$ :

$$\sigma_{\text{med}}^2 = \sigma_{\text{air}}^2 + \sigma_{\text{MCS}}^2 \quad (27.8)$$

### 27.2.3.1 Incorporation of Measured Depth-Dose Curves

The Fermi-Eyges function  $p(x, y, z)$  gives the spatial distribution of the *planar fluence* of electrons due to an electron pencil. To transform this to a (pencil) *dose* distribution  $d(x, y, z)$ , a weighting factor  $\mathcal{J}(z)$  is defined such that

$$d(x, y, z) = p(x, y, z) \mathcal{J}(z) \quad (27.9)$$

Note that the weighting factor is a function of depth,  $z$ , only.

The full expression for the dose  $\delta D(x, y, z)$  from a pencil originating from the small element  $\delta x' \delta y'$  with an intensity weighting  $W(x', y')$ , for a given source-skin distance (SSD) (see Figure 27.5), now becomes:

$$\delta D(x, y, z) = W(x', y') \frac{1}{2\pi\sigma_{\text{med}}^2} \exp \left[ -\frac{(x-x')^2 + (y-y')^2}{2\sigma_{\text{med}}^2} \right] \mathcal{J}(z) \left[ \frac{\text{SSD}}{\text{SSD} + z} \right]^2 \delta x' \delta y' \quad (27.10)$$

which should be compared with Equation 27.1.

An absolute requirement of the model is that it be able to reproduce measured central-axis depth-dose distributions,  $CAXD(z)$ , at different regular field sizes. This is effected by choosing the weighting factor  $\mathcal{J}(z)$  such that the dose as a function of depth on the central axis derived from integrating  $\delta D(x,y,z)$  over a given field size  $2A \times 2B$  exactly equals the measured  $CAXD(z)$  for that field size. This measured  $CAXD(z)$  is first corrected to infinite SSD and then the bremsstrahlung dose, assumed constant at all depths less than  $R_p$ , is subtracted (see [Section 27.2.3.4](#)) to yield  $D_{\text{meas,e}}(0,0,z)$ .

Integrating the expression in [Equation 27.10](#) out to the projected field edges at depth  $z$ , but with no SSD term as  $\mathcal{J}(z)$  is defined for an infinite SSD beam, one arrives at:

$$\mathcal{J}(z) = \frac{D_{\text{meas,e}}(0,0,z)}{\operatorname{erf}\left[\frac{A(1+z/\text{SSD})}{\sqrt{2}\sigma_{\text{med}}(z)}\right] \operatorname{erf}\left[\frac{B(1+z/\text{SSD})}{\sqrt{2}\sigma_{\text{med}}(z)}\right]} \quad (27.11)$$

where the two pairs of error functions involving  $x$  and  $y$ , respectively, in [Equation 27.6](#) are identical because  $x=y=0$  and thus have been reduced to two single erfs; and consequently the factor 1/4 in [Equation 27.6](#) is multiplied by 4; and SSD refers to the value at which the reference  $CAXD(z)$  was measured. The  $\sigma_{\text{med}}(z)$  is evaluated from [Equation 27.7](#) and [Equation 27.8](#), where  $\sigma_{\text{MCS}}(z)$  is for a uniform water medium in this case. Physically,  $\mathcal{J}(z)$  is the effective *broad beam, infinite SSD*, central-axis depth-dose distribution in water corresponding to a particular field size. In practice,  $\mathcal{J}(z)$  must be determined for a range of field sizes for a beam of a particular energy as the model can only predict the change in  $CAXD(z)$  over a small range of field sizes (see [Section 27.3](#)).

### 27.2.3.2 The $F_{\text{air}}$ Weighting Factor

The Fermi-Eyges theory is strictly valid only for a layered geometry ([Figure 27.4](#)); the  $\sigma_{\text{MCS}}(z)$  for each pencil is evaluated along a ray line through the patient, with only the inhomogeneities along this ray line being accounted for. This approximation works best at small depths where the pencil has not spread out significantly. However, in order to model the increase in the penumbra with depth, the pencils are started at the level of the secondary collimator. As [Figure 27.5](#) makes clear, the pencils already have a certain spread, or *width*, when they meet the patient surface. This means that the effect of inhomogeneities close to the surface will be underestimated as the contribution to  $\sigma_{\text{med}}$  due to changes in  $\sigma_{\text{MCS}}$  will be swamped by the value of  $\sigma_{\text{air}}$ . In order to remedy this, Hogstrom et al. (1981) split  $\sigma_{\text{med}}$  back into its *MCS* and *air* components (technically this is a deconvolution).

The (planar) fluence at position  $(x,y,z)$  in the absence of all matter below the secondary collimator is calculated by integrating the unmodified Fermi-Eyges pencils, with  $\sigma_{\text{air}}(z)$  evaluated from [Equation 27.7](#), over the projected collimator area at depth  $z$ , i.e. as for [Equation 27.5](#), but replacing  $\sigma_{\text{MCS}}$  by  $\sigma_{\text{air}}$  and the field limits A, B by the collimator, or endframe shape for the field in question. This special fluence, which is denoted here by  $F_{\text{air}}$ , is then used to weight pencils that start at the level of the final collimator and which have a *width* given now by  $\sigma_{\text{MCS}}$  alone; these MCS-pencils do not begin to broaden out until the patient surface or any bolus is reached. In other words, the pencils have been *redefined* at the final collimator level (see [Section 27.5](#) and Boyd et al. 2001c).

### 27.2.3.3 The Final Expression for the Elementary Pencil

The final expression for the dose  $\delta D(x,y,z)$  due to an elementary pencil located at  $(x',y')$  then becomes

$$\delta D(x,y,z) = \frac{1}{2\pi\sigma_{\text{MCS}}^2(z)} \exp\left[-\frac{(x-x')^2 + (y-y')^2}{2\sigma_{\text{MCS}}^2(z)}\right] W(x',y') F_{\text{air}}(x',y',z') \mathcal{J}(z) \left[ \frac{\text{SSD}}{\text{SSD} + z} \right]^2 \delta x' \delta y' \quad (27.12)$$

where  $F_{\text{air}}$  is the air fluence weighting factor and  $W$  is the intensity weighting factor that accounts for beam non-uniformities. This is the expression used to calculate the dose distribution for an inhomogeneous patient and an arbitrary field aperture.

### 27.2.3.4 The Photon Dose

The dose due to bremsstrahlung was originally subtracted from the measured depth-dose curve. This must now be added back to the electron dose, after putting back the inverse square law dependence. It is assumed that the dose beyond the depth of the practical range (see Section 24.4.2) is entirely due to photons. The photon dose at a given depth is further assumed to be constant within the collimator and zero outside it. Thus the field size dependence and the shape of the penumbra are entirely due to the electron dose as given by Equation 27.12.

### 27.2.3.5 Practical Implementation for an Inhomogeneous Patient

The two most basic parameters in the model that depend on the depth are the weighting factor  $\mathcal{g}(z)$  and the mean electron energy at depth  $z$ ,  $\bar{E}_z$ . The latter must be known in order to evaluate  $\sigma_{\text{MCS}}$ . The quantity  $\mathcal{g}(z)$  is determined for water (see above). It is scaled for the inhomogeneous patient by means of an effective water depth  $d_{\text{eff}}$ , i.e. the value  $\mathcal{g}(d_{\text{eff}})$  is used. This quantity  $d_{\text{eff}}$  is calculated according to

$$d_{\text{eff}}(z) = \int_0^z \frac{(S_{\text{tot}})_{\text{med}}}{(S_{\text{tot}})_{\text{water}}} dz \quad (27.13)$$

where  $S_{\text{tot}}$  is the total (linear) stopping power (see Section 3.4.1).  $d_{\text{eff}}$  is that depth in water having approximately the same  $\bar{E}_z$  as the geometrical depth  $z$  in the patient (see also Section 25.2). Values of  $(S_{\text{tot}})_{\text{water}}$  as a function of energy are given in Table M.2. It is assumed that  $(S_{\text{tot}})_{\text{med}}/(S_{\text{tot}})_{\text{water}}$  is independent of  $\bar{E}_z$ . The value of  $d_{\text{eff}}$  can be calculated from the CT numbers (Hogstrom et al. 1981).

The mean energy at depth in water,  $\bar{E}_z$ , is required. Hogstrom et al. (1981) used the approximate formula (see also Section 18.5.5):

$$\bar{E}_z = \bar{E}_0(1 - z/R_p) \quad (27.14)$$

where  $\bar{E}_0$  is the mean energy at the surface and  $R_p$  is the practical range. More accurate values, based on Monte Carlo simulation, have been given by Andreo and Brahme (1981).

The patient will exhibit density variations from point to point. Consequently the inhomogeneities along any ray line will in principle differ from those along any other ray line, i.e.  $\sigma_{\text{MCS}}(z)$  will be a function of the  $x$  and  $y$  position. In 2D implementations the rectangular beam aperture is divided into strips of a constant length in the  $y$  direction for the evaluation of  $\sigma_{\text{MCS}}(z)$  (Hogstrom et al. 1981; Nahum 1985). In a 3D model account is also taken of the variations in patient density (and surface contour) in the direction perpendicular to the dose calculation plane. Small rectangular sub-beams, with centre  $(x_k, y_k)$  at depth  $z$ , described by  $\sigma_{\text{MCS}}(x_k, y_k, z)$  are therefore required instead of the 2D strip-beams.

The calculation of  $\sigma_{\text{MCS}}(z)$  involves the medium- and energy-dependent scattering power  $T_{\text{med}}(\bar{E}_z)$  at all depths up to  $z$  (Equation 27.2). It is generally assumed that  $T_{\text{med}}/T_{\text{water}}$  is energy independent. Values of  $T_{\text{water}}(E)$  and  $T_{\text{med}}/T_{\text{water}}$  can be found in ICRU (1984); a conversion relation between CT number and  $T_{\text{med}}/T_{\text{water}}$  is given in Hogstrom et al. (1981).

## 27.2.4 INPUT DATA

This section is not intended to be a detailed description of exactly how these quantities are to be determined for the user's beams, which will depend on the particular implementation and the manual of the user's particular treatment planning system should be consulted.

### 27.2.4.1 Measured Depth-Dose Distributions

Depth-dose distributions for electron beams of a given  $\bar{E}_0$  are extremely dependent on the particular beam transport system (scattering foils or scanning system, applicator design, etc.) of the user's accelerator (see [Section 24.2](#)). The Fermi-Eyges model requires central-axis depth-dose distributions,  $CAXD(z)$ , for a number of different rectangular field sizes, as input data in order to determine the infinite-SSD, broad-beam weighting factor  $g(z)$  which converts planar fluence into dose in water (see [Section 27.2.3.1](#)).

### 27.2.4.2 Dose Profiles

A dose profile is required in order to derive the weighting factor  $W(x,y)$ . This should be measured at or near  $d_{\max}$  in a principal plane across the larger field dimension for each field for which the  $CAXD(z)$  is required.

### 27.2.4.3 Mean Energy at the Surface, $\bar{E}_0$

The quantity  $\bar{E}_0$  required in Equation 27.14 can be determined from the approximate formula:

$$\bar{E}_0(\text{MeV}) = 2.33R_{50}(\text{cm}) \quad (27.15)$$

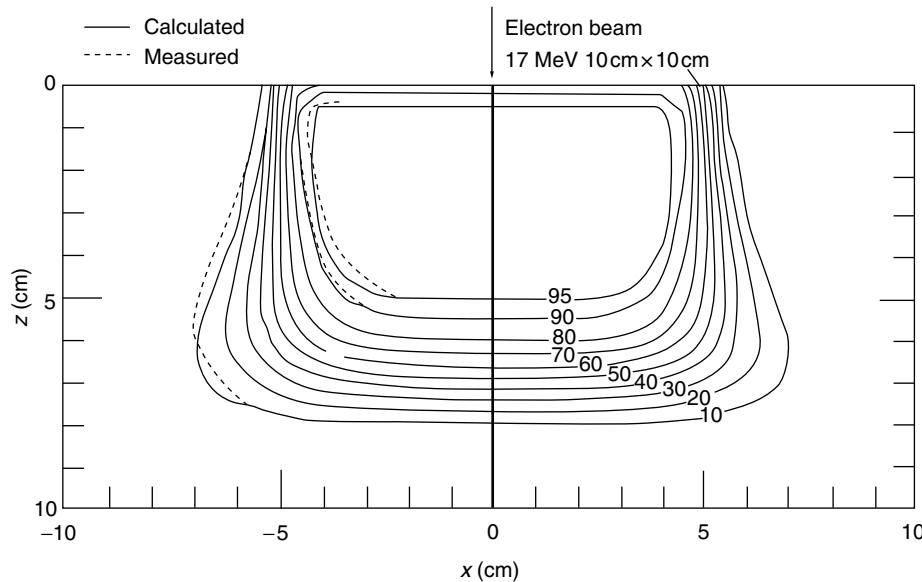

where  $R_{50}$  is the depth at which the dose has fallen to 50% of its maximum value. The dose distribution should be for a *broad beam*, corrected to infinite SSD. Alternative methods may be given in National and International dosimetry protocols (e.g. IPEMB 1996, IAEA 1987, see also [Section D.3.2](#)).

### 27.2.4.4 The Initial Angular Spread, $\sigma_{\theta_x}$

This parameter can be determined from in-air measurements of the penumbra at different distances from the collimator using film (Hogstrom et al. 1981). Plots of the width of the penumbra measured as the distance between the 90% and the 10% isodoses against distance below the collimator for both the  $y$ -axis and the  $x$ -axis penumbrae should be straight lines cutting the ordinate-axis at the effective collimator position. The angular sigma is then given by 0.391 multiplied by the slope of the line fitting the points, with all distances in the same units. An average of the two values obtained should be used for  $\sigma_{\theta_x}$ .

### 27.2.4.5 The Penumbra Adjustment Factor, $FMCS$

The exact form of the penumbra at depth will vary from accelerator to accelerator. Furthermore, Fermi-Eyges theory can only predict the penumbra approximately (see below) even for perfectly *clean* beams, i.e. not contaminated with electrons scattered from the side walls of the applicator. The predictions of the model should be compared to the measurements in the penumbra region ([Figure 27.6](#)) and improved somewhat by the use of a penumbra adjustment factor,  $FMCS$ , which multiplies the theoretical value of  $(\sigma_{MCS})^2$ . Suitable values are between 1.0 and 1.4. However, perfect agreement cannot be expected. A value of  $FMCS$  as close to unity as possible is preferable in order not to distort the predictions of the model in regions of inhomogeneities.

**FIGURE 27.6**

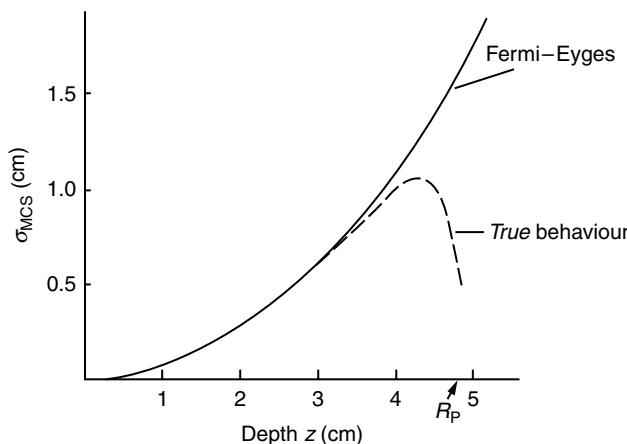

Comparison of calculated (full line) with measured (broken line) isodose curves for 10 cm  $\times$  10 cm field size at 100 cm SSD for a 17 MeV beam from a Therac 20 linear accelerator. (Reproduced from Hogstrom, K. R., Mills, M. D., and Almond, P. R., *Phys. Med. Biol.*, 26, 445–459, 1981. With permission.)

## 27.3 LIMITATIONS OF THE FERMI-EYGES PENCIL-BEAM MODEL

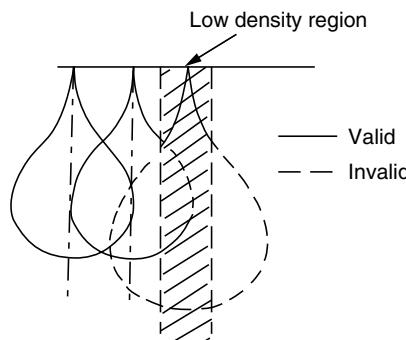

Electron-beam penetration in matter is extremely complex (see Chapter 3). The Fermi-Eyges pencil-beam model described above may appear to be sophisticated but in fact contains some severe approximations. Firstly the Fermi-Eyges model predicts that the pencil-beam *planar* fluence, and hence the dose (as the weighting factor  $g(z)$ ) is only a function of depth not lateral position) has a Gaussian off-axis distribution at all depths. Figure 27.3 makes this point clearly by comparing a measured narrow-beam dose distribution with one calculated with Fermi-Eyges theory; there are considerable differences. It has been clearly demonstrated that the Gaussian prediction is only approximately true at small and large depths, with very considerable deviations in-between (Brahme et al. 1981; Lax et al. 1983); the Gaussian fall-off with off-axis distance is generally much too rapid. One consequence is that the Hogstrom/Fermi-Eyges model only predicts the change in shape of the central-axis depth-dose distribution over a narrow range of field sizes; this is why measured depth-dose distributions are required at several different field sizes. Lax et al. (1983) proposed therefore an alternative pencil-beam model where the elementary pencil was composed of three Gaussians fitted to a Monte-Carlo generated distribution (see Section 27.5).

A further factor that is not generally taken into account in pencil-beam models is scatter from the edges of customised low-melting-point alloy cut-outs (Bruinvis 1987; Ebert and Hoban 1995). This will affect the irregular field calculations, which should be checked against measurement.

The pencil-beam width as a function of depth,  $\sigma_{MCS}(z)$ , calculated using Equation 27.2, agrees well with experiment at small and moderate depths but then continues to increase, whereas in reality it goes through a maximum and finally decreases (Figure 27.7). This is due to the reduction of the number of electrons in the beam at large depths due to *range straggling* (see Section 3.4.2). Attempts have been made to modify the Fermi-Eyges model so

**FIGURE 27.7**

The true behaviour of  $\sigma_{MCS}(z)$  compared to the predictions of unmodified Fermi-Eyges theory, for a 10 MeV beam in water. (Reproduced from Nahum, A. E., in *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Nahum, A. E., Ed., Medical Physics Publishing, Madison, WI, 1985, pp. 151–184. With permission.)

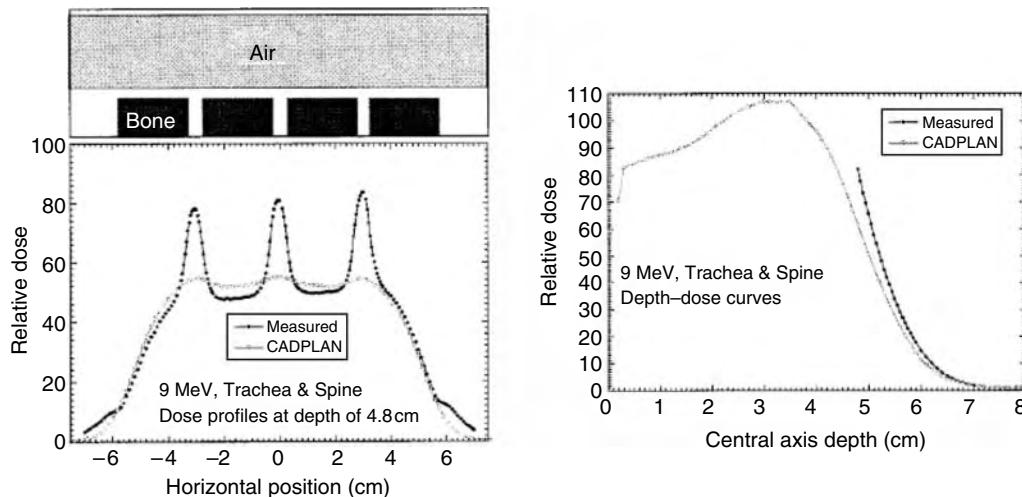

**FIGURE 27.8**

Experimental tests of accuracy of electron-beam treatment planning systems. Schematic representation of the errors introduced by the *central-ray approximation* in presence of inhomogeneities. (Reproduced from Nahum, A. E., in *The Computation of Dose Distributions in Electron Beam Radiotherapy*, Nahum, A. E., Ed., Medical Physics Publishing, Madison, WI, 1985, pp. 151–184. With permission.)

that it can predict electron loss (Bruinvvis et al. 1989; Jette and Walker 1992; Jette 1995). In the Hogstrom model the electron loss is effectively incorporated through the factor  $g(z)$ .

The most significant approximation in the pencil-beam models concerns the effect of the so-called *central-ray approximation* on the treatment of inhomogeneities. Each pencil is corrected for inhomogeneities by computing  $\sigma_{MCS}(z)$  according to the material along the central ray of the pencil. This is equivalent to assuming that the pencil is incident on a layered phantom (Figure 27.4). Some of the consequences of this approximation are illustrated schematically in Figure 27.8. The pencil farthest to the left is *correct at all depths*, but the other two are only *correct at small depths*. As a result, one cannot expect that the effect of inhomogeneities which are narrow in the beam direction will be accurately predicted at depths where the pencil has spread out appreciably\*. In fact, this seemingly insoluble limitation (but see Section 27.5) is one of the main factors propelling the development of Monte Carlo approaches to electron dose distributions in inhomogeneous media (see Section 27.4 and Chapter 28).

\* Lax (1986) should be consulted for a more complete discussion.

**FIGURE 27.9**

Calculated (CADPLAN pencil beam) and measured dose distributions for a 9 MeV beam from a Siemens KD2 linear accelerator incident on a trachea and spine phantom. The base of the phantom was a slab of solid water 15 cm × 15 cm × 4.7 cm. There was a long cylindrical hole, diameter 26 mm, with its long axis perpendicular to the central axis of the beam 2 mm below the top surface. Four 14 mm thick, 25 mm diameter hard-bone disks, separated by 5 mm, were situated 5 mm below the trachea with their axes parallel to the beam axis. The measured depth-dose curve starts at the bottom of the solid water phantom which was placed in water. (Reproduced from Ding, G. X. et al., *Med. Phys.*, 26, 2571–2580, 1999. With permission.)

## 27.4 EXPERIMENTAL TESTS OF ACCURACY OF ELECTRON-BEAM TREATMENT PLANNING SYSTEMS

Significant inaccuracies of the 2D version of the Hogstrom pencil-beam algorithm (see Section 27.2.1) have been demonstrated by Lax (1987) and by Cygler et al. (1987) amongst others. However, of greater interest are experimental tests of the more recent three-dimensional implementations of pencil-beam algorithms. Blomquist et al. (1996) evaluated the Lax et al. (1983) generalized Gaussian pencil beam algorithm as implemented in the Helax-TMS treatment planning system (version 2.10-J) at electron energies between 10 MeV and 50 MeV in a number of specially built phantoms including ones simulating a *neck* and a *nose*. The Helax pencil-beam results were mostly within  $\pm 2\%$  of the measured doses, when averaged over volumes larger than a sphere of 15 mm diameter, or  $\pm 2$  mm in isodose position. More significant deviations were found for oblique incidences and below small air cavities.

A rigorous and comprehensive evaluation of the CADPLAN (version 2.7.9, Varian/Dosetek) electron-beam algorithm was made by Ding et al. (1999). They focussed on inhomogeneous phantoms and used both measurements and Monte Carlo calculations. A pencil beam size of 2.5 mm × 2.5 mm was used. Their trachea and spine phantom is a relatively complex 3D inhomogeneous geometry and represents a severe test for any analytical dose-calculation method. Figure 27.9 shows the significant underestimation of the dose peaks just behind the gaps between the bone disks.

Measured and calculated electron cut-out factors (ratio of doses at respective  $d_{\max}$  for cut-out field to that for an open applicator) were also compared at 6 MeV, 12 MeV, and 18 MeV for an ELEKTA SL20 linear accelerator. The agreement was within between 1% and 2% except for very small fields. The authors point out that the CADPLAN algorithm does not take into account the dose contribution from electrons scattered from low-melting-point-alloy shaped cut-outs and thus all CADPLAN predicted cut-out factors are less than or equal to unity. Ding

et al. (1999) concluded that their results were similar to those found by Samuelsson et al. (1998) for homogeneous phantoms, except that large discrepancies were found very close to the surface. Quite severe limitations of the CADPLAN pencil-beam algorithm were exposed when phantoms with high-density material such as aluminium and relatively complex 3D inhomogeneities such as the trachea and spine phantom were investigated.

---

## 27.5 OTHER ELECTRON-BEAM ALGORITHMS

An alternative to the Hogstrom pencil-beam model was developed by Lax et al. (1983). In their model, the dose profile at each depth is represented by the sum of three Gaussian distributions, with their parameters derived from Monte-Carlo calculated pencils. This model produces much better agreement with measurement than the Hogstrom-Fermi-Eyges one in the penumbra region (addressing, for example, the problems illustrated in [Figure 27.3](#) and [Figure 27.6](#)). The Gaussians are scaled for layered media as described by Lax and Brahme (1985); however, the assumption that the central-ray of each pencil passes through material of infinite lateral extent is retained. This generalized Gaussian pencil-beam model was implemented in the CADPLAN treatment planning system, for example (Hyödynmaa 1991). Shiu and Hogstrom (1987) have described a *pencil-beam redefinition algorithm* (PBRA) which attempts to remove the *central-ray* limitation but at the expense of a substantial increase in calculation time. However, the *small-angle approximation*, which is invalid at large depths, is still retained and the input of a measured depth-dose distribution of a broad beam is still required. Further development of the PBRA is reported in Boyd et al. (2001b).

Another approach has been suggested by Dutreix and Briot (1985). It consists in extending to electron beams the concept of primary-scatter separation, which was originally developed for photon beams (see [Section 26.3.2](#)). For electron beams this separation has no strict physical meaning but, as a first approximation, the electrons undergoing very small deviations in the patient could be considered to behave as *primary* particles. Their fluence decreases very rapidly from the surface to the practical range according to a function which can be determined experimentally by extrapolation to a zero field area for a full range of energies, or modelled analytically. The difference between depth-dose curves for various circular (or square) fields and this primary depth-dose curve, all of them being normalised at the phantom surface where the electron fluence is not much influenced by the collimator opening, provides *scatter* functions. These functions could then be used to perform a 2D-pencil like (or even 3D) Clarkson integration (see [Figure 26.8](#)). A similar approach has been suggested by Van de Geijn et al. (1987) and a method to predict and accurately represent the penumbra for this model has been devised by Rosenwald et al. (1994). Since the calculation is based on a separation of components from experimental data, followed by a recombination of these components after corrections for patient shape and inhomogeneities, the result is quite accurate and this algorithm has been implemented in the ISIS and DOSIGRAY (now combined in the ISOGRAY) treatment-planning systems.

The 6D *phase-space-time-evolution* (PSTE) model (Huizenga and Storchi 1989; Morawska-Kaczynska and Huizenga 1992; Janssen et al. 1994) has been developed as a more accurate alternative to the pencil-beam model. The PSTE model is a numerical solution to the transport equation in phase space (see [Section 5.1](#)). The model is based on the various physical processes of electron interactions with matter, i.e. energy loss, scattering, secondary electron and bremsstrahlung production (see [Chapter 3](#)). Huizenga and Storchi (1989) showed that it could predict the depth-dose distribution of a broad, clinical, high-energy electron beam in a homogeneous medium, in contrast to the Fermi-Eyges model. Morawska-Kaczynska and Huizenga (1992) extended the PSTE model to a multi-layered geometry and found excellent agreement with Monte-Carlo simulation, but in shorter calculation times. Korevaar et al. (2000) state that it takes 30 min (on a Hewlett-Packard 9000/B1000 workstation) for the PSTE model to

calculate a 3D dose distribution with a  $5\text{ mm} \times 5\text{ mm} \times 5\text{ mm}$  calculation grid. This can be compared with 15 min for the CADPLAN (Varian-Dosetek) pencil-beam model for the complete 3D dose distribution consisting of 30 (CT) slices, i.e. only a factor of 2 faster. However, the pencil-beam model can calculate the distribution in a *single slice* in around 30 sec, which is not an option with the PSTE model. Monte-Carlo calculations (EGS4/PRESTA) took 6 times longer to reach 2% statistical uncertainty and 25 times longer for 1% uncertainty (see [Chapter 28](#)).

---

## 27.6 CONCLUDING REMARKS

Pencil-beam models, including the Hogstrom model (described in some detail here) represent a significant advance over earlier *broad-beam* methods. The Hogstrom et al. (1981) and Lax et al. (1983) pencil-beam algorithms correctly predict the existence of *hot* and *cold* spots due to inhomogeneities which are narrow compared to the field width but are less successful in getting the *magnitude* of these dose perturbations correct. Some serious limitations remain, including that of the *central-ray approximation* and the inability to predict central-axis depth-dose distributions. The considerably more sophisticated PSTE method has not yet been implemented in a commercial treatment-planning system. Monte-Carlo simulation ([Chapter 5](#) and [Chapter 28](#)) has demonstrated its high accuracy against measurements in heterogeneous geometries (e.g. Shortt et al. 1986) and is currently routinely used as a *gold standard* against which to compare analytical methods. Increases in calculation speed means that it is now feasible for Monte Carlo methods to be used to calculate electron-beam patient dose distributions for clinical applications (see [Chapter 28](#)).

## 28.1 INTRODUCTION

The various *analytical* methods used to compute the dose distribution in patients irradiated by photon and electron beams have been described in Chapter 26 and Chapter 27. These methods attempt to account for the effect of irregular patient surface and inhomogeneities in the body with varying degrees of success. For photon beams, three-dimensional convolution of the point-spread function or *kernel* with the primary photon fluence is the most sophisticated analytical method to date (see Section 26.3.4). The kernels are derived from Monte-Carlo

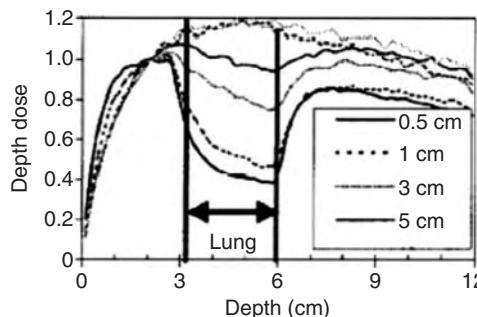

**FIGURE 28.1**

The limitation of *point kernel scaling* illustrated with an example of the electron tracks resulting from 100.5 MeV photons generated by Monte-Carlo simulation. The approximation involved is explained in the text. (Reproduced from Keall, P. J. and Hoban, P. W., *Med. Phys.*, 22, 1413–1418, 1995. With permission.)

(MC) simulation in water (Mackie et al. 1988). However, there is no exact analytical way to modify these water kernels to account for the non-water patient and thus approximate *scaling* methods have been devised. Figure 28.1 is an elegant illustration of the approximations involved in such kernel scaling. The pattern of electron tracks at an equivalent path length (indicated by the horizontal dashed line) *downstream* from the interaction point is clearly different depending on the order of the varying densities. In the situation on the right, at the level of the dashed line, the tracks are clearly more *spread out* than on the left. Therefore, using a *scaled kernel* (i.e. stretched according to the tissue density) to calculate the dose at the level of the dashed line is clearly unphysical.

Other approximations are also often employed in practical implementations of the 3D convolution method in treatment planning systems in order to reduce the otherwise considerable computation times, such as a spatially-invariant *polyenergetic* kernel and the so-called *collapsed cone* method (e.g. Ahnesjö and Aspradakis 1999; Figure 26.15). Despite the considerable improvements obtained from 3D point-kernel convolution as compared to primary-scatter separation or the pencil-beam approach, there are still some approximations, especially related to electron transport close to interfaces of different density or composition (Figure 28.1 being one example) which can yield inaccurate results (Mohan 1997; Arnfield et al. 2000; Krieger and Sauer 2005).

Radiotherapy in heterogeneous regions of the body such as the thorax can cause particular difficulties for analytical photon-beam algorithms due, for example, to the small fields used in stereotactic techniques (Solberg et al. 1995; Ayyangar and Jiang 1998; Solberg et al. 1998; Verhaegen et al. 1998) and the narrow beam *elements* of differing fluence in intensity-modulated fields. There may be a lack of charged-particle equilibrium on the central axes of these very small fields, especially at the higher end of the clinically used megavoltage range. Figure 28.2 is a graphic illustration of the effect of a low-density inhomogeneity, in this case lung, on the dose distribution in a 24 MV x-ray beam. The figure clearly demonstrates the large drop in dose at small field sizes close to and inside the heterogeneity due to lack of *lateral* electron equilibrium. Any analytical dose-calculation method that does not faithfully account for (secondary) electron transport will not correctly predict the dose in such situations (Carrasco et al. 2004).

**FIGURE 28.2**

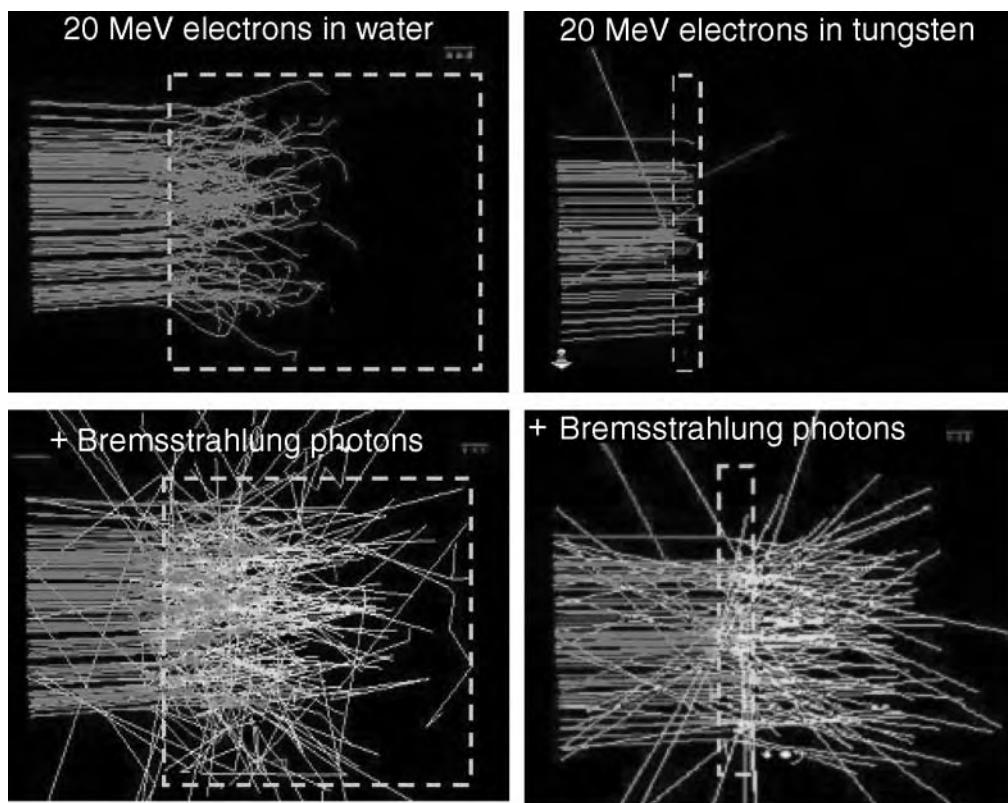

Depth-dose curves for a 24 MV photon beam showing the change in dose caused by a lung slab (density  $0.26 \text{ g cm}^{-3}$ ) sandwiched in water, for different field sizes, calculated using the EGSnrc Monte Carlo code system. (Reproduced from Jones, A. O., Das, I. J., and Jones, F. L., *Med. Phys.*, 30, 296–300, 2003. With permission.)

For electron beams, the pencil-beam method (see [Section 27.2](#)), is well established in commercial planning systems. However, due principally to the unavoidable assumption that, for each individual *pencil*, only the inhomogeneities on its central axis can be accounted for (the *central-ray approximation*; see [Figure 27.4](#) and [Figure 27.8](#)) the agreement with experiment is not satisfactory when large density differences (such as those encountered in lung and bone) are involved. This has been documented in several studies (Samuelsson et al. 1998; Ding et al. 1999). It is fair to say that the 3D planning of electron treatments has been severely impeded by a general lack of confidence in current dose-calculation methods.

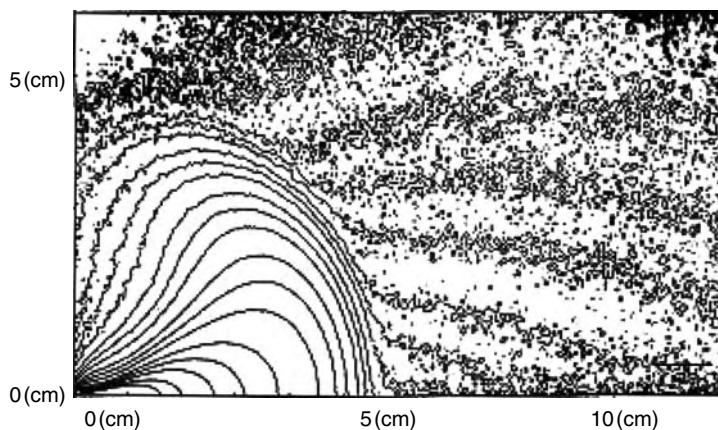

There is a calculation technique that can, in principle, avoid all the approximations referred to above: Monte-Carlo simulation of radiation transport. The basic principles of MC methods are explained in [Chapter 5](#). Due to its accuracy in both homogeneous and heterogeneous media, MC simulation has found extensive application in medical radiation physics (Andreop 1991). This is especially the case in radiotherapy dosimetry where it has been used to compute quantities essential to accurate absolute-dose determination such as (water/air) stopping-power ratios and backscatter factors (see [Chapter 18](#)) and also the point-spread functions employed in the 3D convolution method for photon-beam dose calculation referred to above and discussed in detail in [Section 26.3.4](#) (Nahum 1988; Mackie 1990; Rogers and Bielajew 1990; Andreo 1991; Rogers 1991; Nahum 1999; Bielajew 2001; Carrier et al. 2004).

The following figures illustrate some of the power and the pedagogical value of MC simulation in situations relevant to radiotherapy. [Figure 28.3](#) is a beautiful example of how individual *histories* in an MC simulation can be plotted as *tracks* by recording the coordinates of the many interaction positions making up each history. In the upper part of the figure only the electron tracks are shown. The tortuous nature of their tracks in the medium and their finite ranges are apparent. In the lower part the bremsstrahlung photon tracks have been added and it can be seen that these are straight. The rare case of an electron backscattered from tungsten can be seen in the top right figure. One sees at a glance how much more efficient tungsten is, compared to water, at generating such photons.

The next example ([Figure 28.4](#)) involves a further processing of the raw output from a simulation, this time into isodose lines so familiar in planar views of radiotherapy treatment plans. Close to the beam axis and at depths less than around 5 cm, the isodoses are extremely well defined and show the pear-shaped electron distribution characteristic of electron penumbra, which is due to the strong scattering of megavoltage electrons in condensed media. At greater depths and off-axis distances, the increase in statistical noise becomes evident, as is inevitable at some low level of dose in any MC simulation.

**FIGURE 28.3**

(See colour insert following page 590.) 20 MeV electron tracks generated by the EGS4 code system incident from a vacuum on phantoms of water (left, top and bottom) and tungsten (right, top and bottom). In the top figures, only the charged particle tracks are shown. In the bottom figures, the bremsstrahlung photon tracks have been added. (Courtesy of the EGS development group at the National Research Council of Canada.)

**FIGURE 28.4**

A simulation of a so-called electron pencil beam incident on a semi-infinite water medium. The electron energy is 10 MeV. The cylindrically symmetrical dose distribution has been transformed into isodose lines. (Courtesy of P. Andreo.)

A further example of the pedagogical value of Monte-Carlo simulation can be seen in Figure 3.17 at the end of Chapter 3 on charged-particle interactions. In that example, various electron-interaction phenomena have been successively switched off with dramatic effects on the shape of the depth-dose curve (Seltzer et al. 1978). In Figure 3.17, it can be seen that electrons would show a *Bragg peak*, familiar from heavy charged-particle physics (see Section 46.2.2), if the decrease of the electron fluence resulting from the large scattering effect did not take place. Further, the almost imperceptible build-up at small depths can be seen to be due to the forward transport of *delta rays*.

The main reason that MC methods are not already in widespread use for computing dose distributions in patients undergoing radiotherapy is the vast amount of computer-processing power necessary (Bielajew 1994; Mohan 1997). A little over a decade ago this was estimated to be of the order of hundreds of hours for a photon-beam radiotherapy treatment plan using the computer hardware then available to medical physicists (Nahum 1988), but nevertheless some groups made pioneering efforts (e.g. Manfredotti et al. 1987; Ito 1988). Today, however, due to the continuing reduction in the cost of ultra-fast processing power, MC-based treatment planning is perfectly feasible (e.g. Ma et al. 1999; Sempau et al. 2000; Fraass et al. 2003; Leal et al. 2003; Cygler et al. 2004; van der Zee et al. 2005).

---

## 28.2 CHOICE OF AVAILABLE MONTE-CARLO CODES

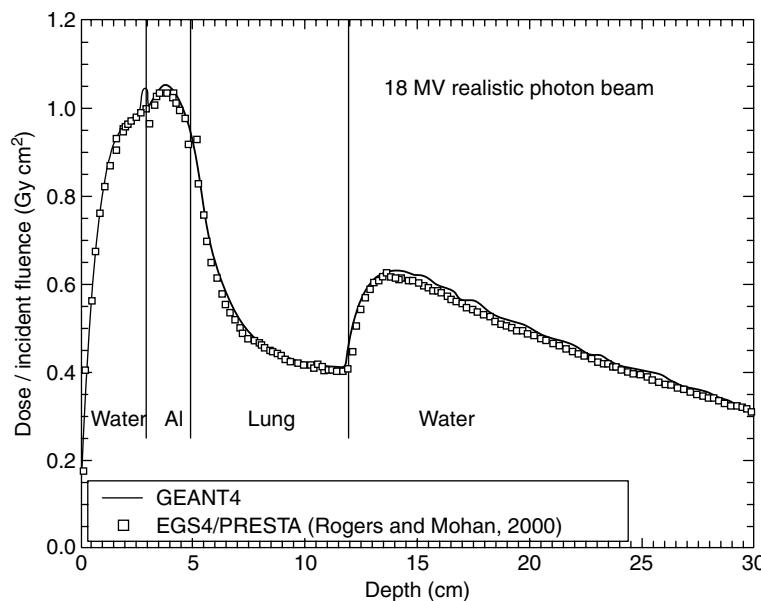

It is generally no longer necessary for radiation physicists to write their own MC radiation transport codes. Many decades of research and development have resulted in a number of very powerful software packages or code systems being made available, the majority of which are freely distributed, for example, at relevant websites. The following does not claim to be an exhaustive list but includes, in no particular order, the principal codes that are currently applied to problems in medical radiation physics, and in radiotherapy in particular. Where known, the names of the most recent versions and also the website from which the code may be downloaded are listed. In other cases, the potential user may have to enrol on a course in order to obtain the code in question, e.g. BEAMnrc at the National Research Council of Canada or MCDOSE/MCSIM at the Fox-Chase Cancer Center.

1. EGSnrc (the new version of the Electron Gamma Shower (EGS) code system, following on from EGS4 (Nelson et al. 1985) the most widely used code in medical physics, cited thousands of times in the medical physics literature; EGSnrc is the only code demonstrated to be able to simulate (gas-filled) ion chamber response in an entirely valid manner)
  - a. Kawrakow 2000a; Kawrakow and Rogers 2003
  - b. <http://www.irs.inms.nrc.ca/inms/irs/EGSnrc/EGSnrc.html>
2. BEAMnrc (technically not an independent code but a version of the EGS system designed for modelling radiotherapy treatment machines, primarily a *research* tool, as it is not optimised for speed)
  - a. Rogers et al. 1995
  - b. <http://www.irs.inms.nrc.ca/inms/irs/BEAM/beamhome.html>
3. MCNPX (includes neutron transport; very extensive use in nuclear power industry and increasingly in medical physics)
  - a. Briesmeister 2000; MCNPX 2003
  - b. <http://mcnpx.lanl.gov/>
4. GEANT4 (huge, many-particle MC toolkit; beginning to be used in medical physics)
  - a. Agostinelli et al. 2003;
  - b. <http://geant4.web.cern.ch/geant4/>

5. MMC (Macro MC: semi-numerical i.e. hybrid electron transport code for fast electron-beam radiotherapy treatment planning)
  - a. Neuenschwander and Born 1992; Neuenschwander et al. 1995, 1997
6. PENELOPE (sophisticated electron transport; a *research* code)
  - a. Salvat et al. 1996
  - b. <http://www.nea.fr/html/dbprog/penelope-2003.pdf>
7. PEREGRINE (developed specifically for radiotherapy planning; available commercially through the NOMOS corporation)
  - a. Hartmann Siantar et al. 2001; Heath et al. 2004; Boudreau et al. 2005
  - b. <http://www.llnl.gov/peregrine/>
8. MCDOSE/MCSIM (developed specifically for fast treatment planning, based on EGS4/BEAM but optimized for speed due to, e.g. *electron-track repeating*; has user-friendly, measurement-based clinical beam commissioning system)
  - a. Ma et al. 2002; Ma et al. 2004b
  - b. [http://www.fccc.edu/clinical/radiation\\_oncology/monte\\_carlo\\_course.html](http://www.fccc.edu/clinical/radiation_oncology/monte_carlo_course.html)
9. Voxel-MC (VMC)++ (developed specifically for fast treatment planning; exploits *electron-track repeating*; is the MC dose engine in the MC option for electron-beam treatments in the Nucletron treatment planning system (TPS) *Oncontra/Masterplan*)
  - a. Fippel 1999; Kawrakow and Fippel 2000; Cygler et al. 2004, 2005
10. Particle DMLC (further development of the EGS/BEAM-based MCV system involving fast particle transport through dynamic multileaf-collimator geometry specifically for intensity-modulated radiotherapy (IMRT))
  - a. Siebers et al. 2000a; Keall et al. 2001; Siebers et al. 2002
11. DPM (developed specifically for fast radiotherapy treatment planning; electron transport scheme involves large condensed-history *steps* crossing medium boundaries)
  - a. Sempau et al. 2000; Chetty et al. 2003
  - b. <http://www.upc.es/inte/downloads/dpm.htm>
12. ORANGE (a fast MCNP-based dose engine for radiotherapy treatment planning)
  - a. van der Zee et al. 2005

Although the MC simulation of radiation transport can take account of all the *physics* involved, nevertheless, some differences between different MC codes cannot be ruled out, especially where charged-particle transport is concerned (e.g. Nahum 1988, 1999; Rogers and Bielajew 1988; Jeraj et al. 1999; van der Zee et al. 2005). As is explained in [Section 5.3](#), photon transport is simulated in an *analogue* manner (i.e. interaction by interaction), which means that this component of any code will be virtually identical (except for possible differences in the interaction cross sections). By contrast, it would be hopelessly inefficient to construct the tracks of charged particles in this analogue manner; consequently, all the above codes use the condensed-history approach (see [Section 5.4](#)) but in ways that can differ considerably from one code to another. It is thus imperative that careful tests (sometimes known as *benchmarking*) are carried out when a particular code is applied to a new situation where charged-particle transport is critical. One such example is illustrated in [Figure 28.5](#). Here, the general-purpose-many-particle GEANT4 code has been compared to the specialist medical physics version of the EGS4 code using the PRESTA electron-transport scheme (Bielajew and Rogers 1987), in a standard test geometry designed by Rogers and Mohan (2000) specifically for treatment-planning purposes. Subsequently, van der Zee et al. (2005) used this same standard geometry and 18 MV beam quality to demonstrate equally good agreement between their MCNP-based code ORANGE and EGS4/PRESTA.

However, none of the above code systems are free from limitations; it will always be possible to find a class of problems that any given code fails to tackle in a valid manner. A good example of this is the failure of GEANT4 (and most other well-known MC codes) to yield

**FIGURE 28.5**

Depth-dose curve for a multislab phantom irradiated by a 18 MV *realistic* clinical beam, showing the excellent agreement between EGS4/PRESTA and GEANT4 Monte Carlo codes. (Reproduced from Carrier, J.-F., Archambault, L., and Beaulieu, L., *Med. Phys.*, 31, 484–492, 2004. With permission.)

correct results when simulating the response of an ionisation chamber (the radiation quality in this particular case (Poon et al. 2005) was a 1.25 MeV photon beam). This is in contrast to EGSnrc (Kawrakow and Rogers 2003), which has a highly sophisticated electron-transport scheme, with a user-controlled *switch* from *condensed-history* to *analogue* electron transport and back again, developed specifically to tackle the ion-chamber problem (Kawrakow 2000a, 2000b).

## 28.3 TREATMENT-MACHINE SIMULATION

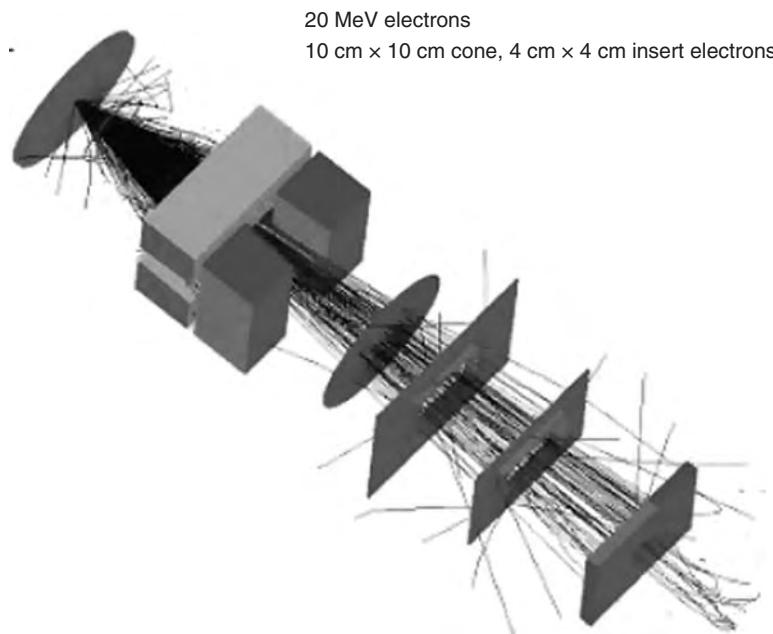

As input data for each beam quality, most treatment planning systems require extensive measurements of dose distributions in water at different field sizes for open and wedged fields (see Table 19.1). MC simulation can only make use of such data in an indirect way. Instead, what is required is that the initial state of the particles in the beam, incident on the patient surface, be accurately known, i.e. the energies, directions and positions of the photons, electrons (and positrons). This data set is referred to as *phase-space*\*. There is no practical way to obtain such information by measurement; a portable spectrometer would be required with a degree of sophistication not yet available to radiotherapy clinics. Instead, the MC method itself has to be used, where one starts the simulation at the position where the electron beam leaves the vacuum window of the linear accelerator.

It was first demonstrated by Mohan (1988) for photon beams and by Udale (1988) for electron beams (which is a much more critical case) that only when such detail is incorporated into the simulation can good agreement with measurement in water phantoms be obtained. Consequently, there have been extensive efforts to simulate in full geometrical detail the passage of radiation through the complex treatment heads (target, flattening filter, monitor chamber,

\* Phase-space is a standard mathematical term for a multi-dimensional array that describes a system.

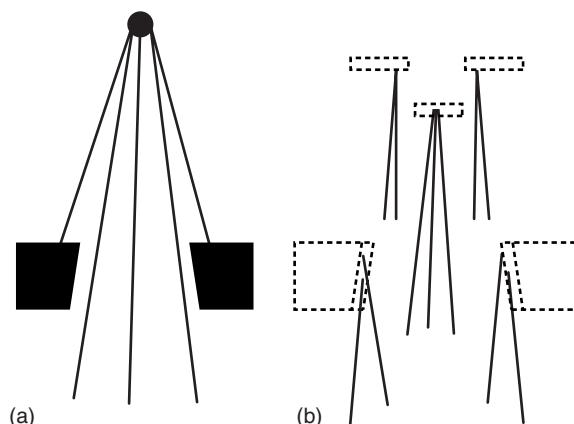

collimating jaws, multileaf collimators, etc.) of modern clinical linear accelerators (Rogers et al. 1995; De Vlamynck et al. 1999; Lewis et al. 1999; Ma and Jiang 1999; Verhaegen and Das 1999; Jiang et al. 2000; Verhaegen and Seuntjens 2003). Rogers et al. (1995) developed an exquisitely detailed EGS4 usercode called BEAM for the purpose of detailed treatment-head modelling. BEAM produces a (very large) phase-space file of co-ordinates (particle type, energy, direction, position) above the level of the devices that define the beam shape for an individual treatment. This detailed modelling is only possible, however, if the accelerator manufacturers provide full information on the dimensions and composition of the key components in the treatment head of their machines. Figure 28.6 is an example of the kind of spectacular graphics that can be generated from detailed treatment-head simulations, in this case, using the EGS/BEAM code system (Rogers et al. 1995).

An alternative to the generation of a phase-space file from a simulation of the accelerator treatment-head geometry is the so-called *source model* approach (Ma and Rogers 1995; Ma et al. 1997). The first step is to devise an appropriate representation of the beam for a given design of treatment head. The beam representation is a concise mathematical description of the phase space, generally in terms of multiple (virtual) *sources*, such as the target, the primary collimator and the flattening filter (Ma et al. 1997). In the second step, the phase space is reconstructed from these separate *sources* and then fed into the dose-calculation code one particle at a time, thus eliminating the need to store large amounts of phase-space data. Figure 28.7 illustrates the general idea of source models. Deng et al. (2000) have further developed this multiple-source modelling approach and obtained excellent agreement (within two percent) in heterogeneous lung and bone phantoms when using the source model as input to the MC calculations instead of the complete phase-space. Fippel et al. (2003) have developed what they term a *virtual photon energy fluence* model based largely on measured dose distributions in water and air, with additional technical information on the linear accelerator in question. Fix et al. (2004) present a similarly detailed three-component source model for 6 MV and 18 MV photon beams that match the full phase-space data. Fippel et al. (2003) go so far as to state that “by comparison

**FIGURE 28.6**

**FIGURE 28.7**

Schematic examples of source models: (a) the linac is replaced by a simple point source representing photons emerging from the target, with the jaws acting as perfect absorbers; (b) the treatment head is modeled as a number of sub-sources. (Reproduced from Verhaegen, F. and Seuntjens, J., *Phys. Med. Biol.*, 48, R107–R164, 2003. With permission.)

with results derived by the BEAM-NRC software system, it is demonstrated that time-consuming MC simulations of the whole accelerator head are unnecessary for radiation therapy planning purposes". Undoubtedly, such a method based on measured dose distributions is the most practical for a clinical MC system.

A further parameter must be known in order to simulate a treatment beam: the *energy* and possibly the *spectrum* of the electrons emerging from the vacuum window of the linear accelerator waveguide system. It cannot be assumed that, for example, the emerging electrons have an energy of exactly 6.0 MeV when the linac is set to produce a *nominal* 6 MV photon beam (see Section 22.2.2). The strategy generally adopted is to *deduce* the value of the electron energy that gives the best agreement between measured and simulated depth-doses in water by a process of trial and error. In the case of photon beams, it has been found (e.g. Verhaegen and Seuntjens 2003) that the central-axis depth-dose curve is relatively insensitive to small changes in electron energy, whereas the shape of the cross-beam *profiles* are much more sensitive, with the *horns*\* becoming more pronounced as the energy is lowered. It is generally also necessary to set up radial and angular intensity distributions of the incident electrons and then adjust these to produce the best agreement between measured and simulated depth-dose characteristics. For example, to achieve good agreement for an Elekta SL linac at (nominal) 6 MV, Seco et al. (2005) found that the best fit was obtained for electron energy of 6.0 MeV, an energy spread of 7% and a pencil-beam radius of 0.5 mm. Huang et al. (2005) found by measurement that, for a Varian Clinac 21EX linac, the electron focal spot was elliptical with a full width at half maximum (FWHM) between 1.69 mm and 2.24 mm and, additionally, a divergent (elementary) beam model was necessary to obtain good agreement with measurement for large field electron beams. There have also been instances when it has not been possible to obtain good agreement between measurement and MC simulation no matter how the initial electron distributions in energy, angle and space have been *adjusted*. The reason has generally been traced to incorrect or incomplete information provided by the linac manufacturers. An interesting example of this is how Bieda et al. (2002) deduced by MC-guided trial and error process how the scattering foil system had to be configured in a linac in electron mode, a form of MC *detective work*, and subsequently discovered that they had been correct.

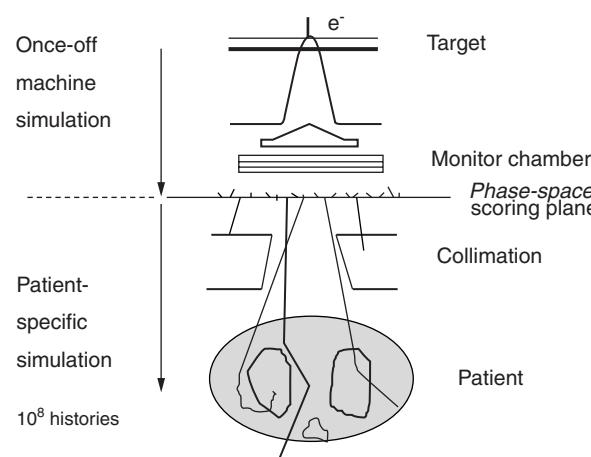

\* Horns are high-dose regions, relative to the beam's central axis, at the edge of the beam, when measured in air or close to the surface of a phantom (see Figure 22.8).

The MC modelling of electron beams from medical accelerators was reviewed in detail by Ma and Jiang (1999). A similarly comprehensive review of MC photon-beam modelling has been written by Verhaegen and Seuntjens (2003). It can be noted that in addition to megavoltage photons from linear accelerators, cobalt-60 units (Han et al. 1987) and kilovoltage x-ray therapy machines have also been simulated using the MC method with a high degree of success (Verhaegen et al. 1999).

## 28.4 MONTE-CARLO SIMULATION OF THE DOSE DISTRIBUTION IN THE PATIENT

The simulation of radiation transport in the patient is generally started from the plane of the *phase-space* file, the particles being tracked through the particular beam-defining devices as illustrated schematically in Figure 28.8 (e.g. Hartmann Siantar et al. 1997; DeMarco et al. 1998). Note that the phase-space scoring plane must be above the level of the moving jaws. The patient geometry is represented by a 3D cartesian array of voxels, as for other 3D dose-calculation methods (see [Section 25.2](#)). Mora et al. (2001) recommend (cubic) voxel sizes of no larger than 3 mm for the head and 5 mm elsewhere in the body. Schemes have been developed for deriving appropriate parameters such as density and material type (tissue, lung, bone, air, etc.) from the CT numbers and associating these with the appropriate cross-section data required for the MC simulation (e.g. Schneider et al. 2000). This conversion from CT number to atomic composition is far from trivial, as the detailed analysis by Verhaegen and Devic (2005) makes clear.

Naturally, the key factor in all this is the central processor (CPU) time required to achieve an acceptably low uncertainty. For *electron* beams, runtimes of the order of a few minutes for 1% to 2% uncertainty ( $1\sigma$ ) with a small voxel size (1 mm to 2 mm) have been demonstrated by Neuenschwander et al. (1997) using the macro Monte Carlo (MMC) approach on hardware with a performance comparable to a Pentium 200 MHz personal computer (PC). For primary *photon* beams (used far more often than electrons in radiotherapy) of the order of  $2 \times 10^8$  histories are required (compared to about  $10^7$  for electron beams) to achieve 1 mm to 2 mm resolution; the PEREGRINE group first demonstrated this using a 16-CPU Pentium Pro-based system (Hartmann Siantar et al. 1997). Their runtimes

**FIGURE 28.8**

Schematic illustration of the two-step approach to Monte Carlo simulation in radiotherapy treatment planning. (Reproduced from Nahum, A. E., *Radiat. Environ. Biophys.*, 38, 163–73, 1999. With permission.)

were under 30 minutes. It can be noted that in a multi-beam plan the total number of histories required for a given level of uncertainty in dose in voxels of a given volume is essentially *independent of the number of beams* (Ma et al. 2005). This is because this uncertainty is determined solely by the number of energy-deposition events in the scoring volume, whether these arise from one or several beams. This is in marked contrast to the situation for analytical algorithms, where the total computation time generally increases approximately in proportion to the number of beams.

An approximate formula for the number of photon histories incident on the phantom/patient surface,  $N_\gamma$ , required to obtain a statistical uncertainty,  $\delta$ , on the dose (in the central part of the beam) has been given by Spezi et al. (2002):

$$N_\gamma = \frac{1}{\delta^2 \mu_{\text{en}}^{\text{eff}}} \frac{A_{\text{beam}}}{V_{\text{voxel}}} \quad (28.1)$$

where  $(\mu_{\text{en}}^{\text{eff}})$  is the *effective* linear energy-absorption coefficient for photons in water (*effective* because x-ray beams are not monoenergetic) for a beam of area  $A_{\text{beam}}$  and volume of dose-scoring voxel  $V_{\text{voxel}}$ . Though this expression is for a single beam, it can also be used to estimate the total number of histories required in the case of a multibeam treatment plan provided that each beam has a similar area (and quality). This total number is then divided up among the beams in proportion to the number of monitor units for each beam.

When employing a phase-space file, for reasons of finite storage size ( $\approx 2$  Gb is around the current practical limit) the number of particles in the phase-space file may be smaller than the number of histories required to achieve the desired uncertainty in the phantom or patient; this will frequently be the case for photon beams. As an example, in simulations of a Varian Clinac 23EX performed in 2004 in the radiotherapy department of Copenhagen University Hospital, the 2-Gbyte phase-space files contained around 67 million histories. For a 6 MV photon beam with a  $40 \text{ cm} \times 40 \text{ cm}$  field size, approximately  $3 \times 10^9$  histories were run (Jutemark 2005), i.e. the phase-space file *generated* this number of particles, which represents oversampling (i.e. reuse of a given history) by a factor 45.

This *recycling* of the particles in the phase-space in order to improve the statistics of the final dose calculations can have undesirable effects. Sheikh-Bagheri and Rogers (2002) state that the phase-space can be recycled up to 80 or 90 times, provided that the statistics in the phase-space file are good enough to represent all categories of particles (e.g. photons, electrons, primary, scattered, etc.). However, should this condition not be met, any *noise* in the phase space will be propagated through the system and still be present in phantom or patient simulations, irrespective of how many histories are run in the latter simulation. Fix et al. (2004) consider that the limited size of the phase-space file gives rise to what they term a *systematic error*, also known as *latent* or *remnant variance* (Sempau et al. 2001; Fippel et al. 2003). They point out that this limitation can be overcome through the use of source models and, as an alternative to analytical source models (see Section 28.3), they recommend a *histogram-based* source model based on the phase-space data (Schach von Wittenau et al. 1999). Through sampling the initial parameters of a particle from such histogram distributions no particle is reused, which reduces the latent variance.

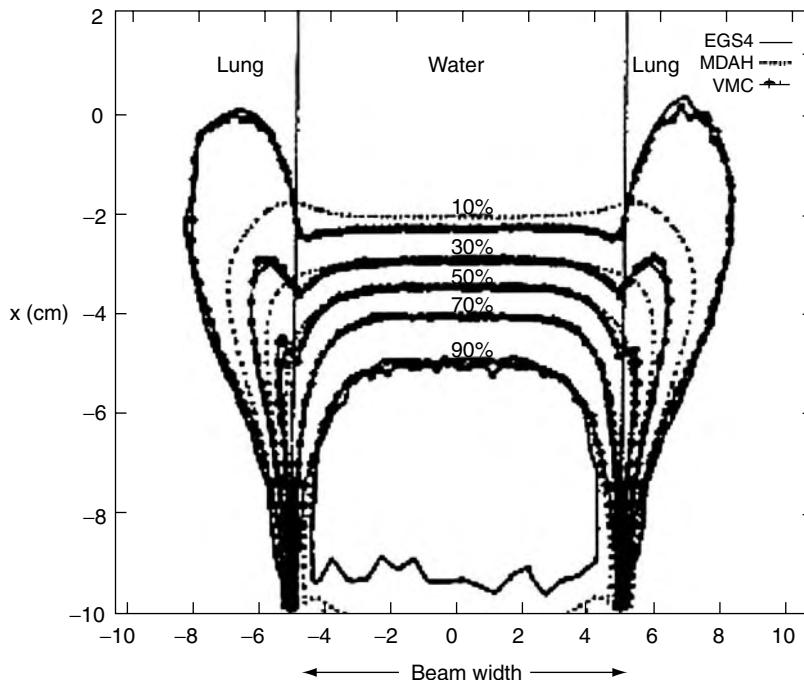

## 28.5 MONTE-CARLO TREATMENT PLANNING IMPLEMENTATIONS

Several implementations of MC simulation in treatment planning systems have appeared in the literature: Kawrakow et al. (1996), Hartmann Siantar et al. (1997), Neuenschwander et al. (1997), DeMarco et al. (1998), Wang et al. (1998, 1999), Ma et al. (1999, 2002), Li et al.

(2000), Siebers et al. (2000a), and He (2002). A variety of different codes have been used, as indicated in [Section 28.2](#).

The important subject of *variance reduction* in MC simulation has been introduced in [Chapter 5](#). Techniques such as photon interaction forcing, particle splitting, Russian roulette, electron range rejection, correlated sampling and indeed the condensed-history method itself are commonly employed in applications of MC in medical radiation physics (e.g. Bielajew and Rogers 1988; Rogers and Bielajew 1990; Andreo 1991; Ma and Nahum 1993). However, researchers have gone even further in looking for ways of improving efficiency specifically for the MC simulation of radiotherapy treatment planning. The first of these was MMC (Neuenschwander and Born 1992; Neuenschwander et al. 1995, 1997), which used pre-calculated MC electron dose distributions in small spheres and led to electron-beam treatment plan computation times of the order of minutes. The VMC method (Kawrakow et al. 1996; Fippel 1999; Kawrakow and Fippel 2000) re-uses the same electron history in different patient regions. This is also known as *electron-track repeating* and has been exploited by several other research groups (Keall and Hoban 1996a; Li et al. 2000; Ma et al. 2002). There is also Super MC (Keall and Hoban 1996b; Keall et al. 1998), which combines the convolution/superposition method for photon beams (see [Section 26.3.4](#)) with MC electron transport. Figure 28.9 shows that the VMC method can achieve virtually identical results to the extensively benchmarked EGS4 MC code (Nelson et al. 1985) in a lung-water phantom, with a reduction in runtime by a factor of around 35. The limitations of the MD Anderson Hospital Hogstrom pencil-beam algorithm, discussed in [Section 27.3](#), in this particular geometry are clearly shown.

Sempau et al. (2000) have developed DPM, an MC code specifically optimised for treatment planning calculations, principally through a highly efficient electron-transport scheme that permits long transport steps (of the order of 5 mm) which can straddle boundaries

**FIGURE 28.9**

A comparison of the Voxel Monte-Carlo (VMC) method with EGS4 and with the MDAH/Hogstrom pencil-beam algorithm for 16 MeV electrons. The phantom consists of water and lung ( $0.26 \text{ g cm}^{-3}$ ), and the boundaries of the lung region coincide with the edge of the radiation field. (From Kawrakow, I., Fippel, M., and Friedrich, K., *Med. Phys.*, 23, 445–457, 1996. With permission.)

between different media. Sempau et al. (2000) stated that the simulation of 1 million 10 MeV electrons on a water phantom of  $128^3$  cubic voxels of 1 mm side length took approximately three minutes on a modern desktop workstation. Chetty et al. (2003) tested the accuracy of the DPM code for small field sizes and heterogeneous media (water/lung/water) for 6 MV and 15 MV photon beams; the phase-space files for a Varian 21EX linac were generated using the BEAMnrc code (Rogers et al. 1995). For the inhomogeneous phantom, DPM depth-dose calculations were within  $\pm 1\%$  (based on the root-mean-square deviation) of measurements. Relative profile differences at depths within and beyond the lung were, on average, within  $\pm 2\%$  in the inner and outer beam regions. It was concluded that the DPM MC code was capable of accurate photon-beam dose calculations in situations of pronounced lateral electron disequilibrium.

It is imperative that developers of such special MC codes demonstrate that their modifications of the transport physics do not introduce errors that could be significant in the radiotherapy context; MC simulation would otherwise become ‘just another dose-calculation method involving approximations’. An interesting discussion of these issues has been given by Ma et al. (2005).

Cygler et al. (2004, 2005) have reported on the first implementation of MC for electron-beams in a commercial treatment planning system (Nucletron Oncentra/Masterplan). The dose engine is VMC++ (Kawrakow and Fippel 2000). Runtimes (for  $10^4$  histories/cm $^2$ ) were typically around one minute on a 2.2 GHz Pentium 4 Xeon computer for voxel sizes of 3 mm  $\times$  3 mm  $\times$  3 mm ( $\approx 500\,000$  voxels). Good agreement with measurement (relative doses) was obtained for most of the situations tested and for monitor unit calculations the agreement was described as excellent. The authors state that, as they are now more confident of the actual dose delivered to the patient, they calculate 3D dose distributions for a wider variety of electron-beam techniques and anatomical sites than has previously been their practice. Further, this has led to changes in treatment decisions.

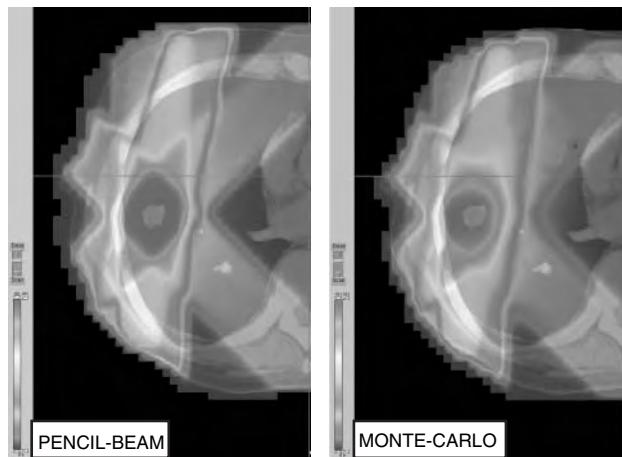

Heath et al. (2004) have described the performance of the PEREGRINE code (Hartmann Siantar et al. 2001), which is the first MC code *commercially available* for photon-beam treatment plan dose calculations. Bar et al. (2003) found that MC dose calculation did not have a significant impact in head-and-neck planning. Boudreau et al. (2005) compared dose distributions calculated with the *finite-size-pencil-beam* algorithm (using an equivalent pathlength correction for heterogeneities) in the CORVUS TPS (Nomos corporation) with those computed with the PEREGRINE MC algorithm for 11 head-and-neck cases treated with a 6-MV IMRT technique. It was concluded that for head-and-neck cases the differences between the finite-size-pencil-beam plans and the MC plans “may not be significant enough to warrant the use of a MC based algorithm for treatment planning” but that sites located in the thoracic region “may be prime candidates for the use of MC based dose calculation”. An example of the difference in dose distribution that can be obtained in the lung between (BEAMnrc) MC and a pencil-beam algorithm (here using the Varian ECLIPSE TPS) is shown in [Figure 28.10](#). However, the differences between MC and the point-kernel collapsed-cone convolution algorithm are not as large (Carrasco 2004).

---

## 28.6 SPECIAL FEATURES OF MONTE-CARLO BASED TREATMENT PLANNING

### 28.6.1 ABSOLUTE DOSE PER MONITOR UNIT

A further feature of the MC approach is the accurate calculation of Monitor Units (MU) for each beam, taking into account the (heterogeneous) patient. Manual methods to calculate MU rely on a series of formulae which are largely based on the water-phantom

**FIGURE 28.10**

(See colour insert following page 590.) A comparison of patient CT-based 6 MV photon-beam dose distributions computed at Copenhagen University Hospital. The *pencil-beam* calculation from the Eclipse TPS (Varian-Dosetek) is on the left, and that from the Monte-Carlo code system BEAMnrc is on the right; the linear accelerator is a Varian 2300EX. MC parameters: ECUT = 0.70 MeV, PCUT = 0.10 MeV, voxel size = 2.5 mm,  $9 \times 10^7$  histories per beam ( $\approx 3 \times 10^6$  particles in the phase-space file for each beam); runtime = 0.6 h on 12 parallel CPUs. (Lasse Rye Aarup, personal communication).

situation (see [Section 23.3](#)). Adjustment for anatomical geometry and composition is subject to approximations which may introduce errors.

Monte-Carlo methods, used for the calculation of the absolute dose in terms of monitor units, rely on the correct calibration of monitor units for the reference field size by measurement (see also [Section 25.3](#)). Hence, the first step is the conventional *calibration of the beam* (see [Chapter 18](#)) by placing an ionisation chamber at the reference depth in a reference field size,  $A_{\text{ref}}$ , generally 10 cm  $\times$  10 cm, and determining the dose (to water) in Gy per monitor unit,  $D(A_{\text{ref}})/MU$ . A MC simulation of this exact geometry and beam quality is then carried out, starting from the phase-space plane, i.e. using particles from the phase-space file. This simulation yields  $D_{\text{MC}}(A_{\text{ref}})$  *per simulated particle* (i.e. per number of histories run from the phase-space file) or  $D_{\text{ref}}(A_{\text{ref}})/\text{history}$ , which can be written as  $D_{\text{ref,MC/hist}}(A_{\text{ref}})$ . A *calibration factor* for this beam quality,  $F_Q$ , can then be derived:

$$F_Q = \frac{D_{\text{ref}}(A_{\text{ref}})/MU}{D_{\text{ref,MC/hist}}(A_{\text{ref}})} \quad (28.2)$$

This MC calibration factor  $F_Q$  should only depend on the beam quality (e.g. 6 MV photons or 10 MeV electrons) and has dimensions of *particles per monitor unit*. The phantom is now replaced by the patient, and the field size is adjusted to what is specified in the treatment plan, say  $A_{\text{plan}}$ . A MC simulation of this new situation is done and yields, per history from the phase-space file, a dose  $D_P(A_{\text{plan}})_{\text{MC/hist}}$  at some position of interest,  $P$ , in the patient. The dose in *Gy per monitor unit* at  $P$  will be given by

$$D_P(A_{\text{plan}})/MU = F_Q \times D_P(A_{\text{plan}})_{\text{MC/hist}}$$

or, the *absolute* dose at  $P$ , in Gy, is

$$D_P(A_{\text{plan}}) = MU \times F_Q \times D_P(A_{\text{plan}})_{\text{MC/hist}} \quad (28.3)$$

for *MU* monitor units set on the treatment machine. Ma et al. (2004a) derived an equivalent expression, using a slightly different formalism, and extended this to cover intensity-modulated treatments.

The above expression assumes that changing the field size has no influence on the signal from the monitor ion chamber. However, there is a possibility that photons will be (*back*)-scattered from the collimator jaws into the monitor chamber. This can lead to a dependence of the monitor chamber signal on the settings of the collimator jaws, necessitating a correction to Equation 28.2. Verhaegen et al. (2000) studied this problem for the 6 MV and 10 MV photon beams from a Varian 2100C linac, finding a 2% to 3% increase in the monitor chamber signal due to backscatter for a field size of  $0.5\text{ cm} \times 0.5\text{ cm}$  compared to  $40\text{ cm} \times 40\text{ cm}$ . An empirical correction factor  $B_{\text{mon}}$  can be defined as

$$B_{\text{mon}}(A) = \frac{MU_{\text{backscatter}}(A_{\text{ref}})}{MU_{\text{backscatter}}(A)} \quad (28.4)$$

where  $MU_{\text{backscatter}}(A)$  is the ratio of the monitor ion chamber signal, including backscatter, to that excluding it, for a fixed beam current, for field size  $A$ . Thus,  $B$  varies between unity for large field sizes and  $\approx 1.03$  for very small field sizes. This modifies Equation 28.3, which becomes

$$D_P(A_{\text{plan}}) = MU \times F_Q \times B_{\text{mon}}(A_{\text{plan}}) \times D_P(A_{\text{plan}})_{\text{MC/hist}} \quad (28.5)$$

It can be noted that if one started the simulations from a position *upstream* of the monitor chamber and thus automatically included the monitor chamber response in the simulation then this backscatter issue would disappear, but at the expense of significantly increased calculation time.

It has been demonstrated that *Output Factors* for irregular electron-applicator shapes (see [Section 24.7](#)) can be predicted within 2% or better (Kapur et al. 1998; Verhaegen et al. 2001). Thus MC holds out the prospect of high accuracy in *absolute* as well as *relative* dose determination. Ultimately, it may well be the MU computation that proves to be the most significant component in the improvement of dosimetric accuracy in radiotherapy due to Monte-Carlo simulation (Ma et al. 2005).

### 28.6.2 DOSE TO MEDIUM OR DOSE TO WATER?

One implicit feature of MC-based patient dose calculation is that the doses are computed in the actual media (i.e. one obtains dose to tissue, dose to lung, dose to bone, etc.). Treatment planning systems, however, give the dose distributions in (effective) dose to water whether corrections are made for heterogeneities or not. Siebers et al. (2000b) have explored this important issue. They strongly recommend that the MC doses be converted to dose to water by multiplying by the water-to-tissue, water-to-bone (etc.) mass absorption coefficient ratio or mass stopping-power ratio. Fortunately, however, this ratio is very close to unity except for the case of bone and air (but the dose to air cavities in the body has no clinical significance). For such cases, if this stopping-power ratio conversion is *not* made then there is a danger that comparisons between dose distributions based on MC and those based on analytical dose-calculation methods will be invalid, as one will be comparing *apples* with *pears*.

It should be borne in mind that all the experience of clinical radiation oncologists since the advent of radiotherapy at the turn of the previous century is based on dose to water, however imperfectly calculated. Thus, it can be argued that the dose distributions to be fed into *biological* models for Tumour Control Probability (TCP) and Normal Tissue Complication Probability (NTCP) ([Chapter 36](#)), which are currently in the form of dose-volume histograms ([Section 35.3](#)) ought to be in terms of dose to water. Any change in this philosophy would require a consensus in the worldwide radiation-therapy community. Similar issues arise when considering whether to change dose prescriptions as a result of changes in dose distributions brought about by the introduction into the clinic of a new (or updated) treatment planning system with a different (hopefully improved) non-MC-based dose calculation algorithm.

The re-analysis of the connection between lung doses and complications by De Jaeger et al. (2003) is a good example of this dilemma.

### 28.6.3 COMPUTER HARDWARE CONSIDERATIONS

Shorter and shorter execution times to carry out simulations of the vast numbers of histories (of the order of  $10^8$ ) required for photon-beam treatment plans are being reported in the literature. One reason for this reduction in total simulation time is the use of variance-reduction techniques tailor-made for the treatment-planning situation, such as the two-stage phase-space file approach, *electron-track repeating* or MMC (see Figure 28.5). However, another important factor is the inherently *parallel* nature of MC simulation; each history is totally independent of any other history. This means that the total number of histories required can be divided up between a number of independent machines and the simulations run in parallel. Each machine, generally a *state-of-the-art* PC, runs the complete simulation, and therefore the complete software system must be loaded onto it. These days, the capacity of PCs is such that this is no problem at all, even for large, complex and comprehensive code systems such as MCNPX, GEANT and EGSnrc. It is now commonplace for a research group or radiotherapy clinic to purchase between 10 and 50 PC-CPUs and configure them in a cluster. One of these PCs acts as the server and copies the necessary input or job-initiation files to each PC in the cluster, together with *different* random-number seeds to ensure that there is no duplication of histories. Thereafter, no communication between the machines in the cluster is necessary. The results from each CPU in the cluster are then combined with weights proportional to the number of histories run on that machine. As an example, Seco et al. (2005) employed a *Linux Beowulf* cluster consisting of 30 CPUs with an average speed of 1.4 GHz. Increases in speed roughly in proportion to the number of machines in a cluster have been obtained (Jutemark 2005).

---

## 28.7 CONCLUDING REMARKS

The use of Monte-Carlo simulations to compute patient dose distributions for treatment planning appears to have many advantages, in terms of accuracy, in heterogeneous parts of the human anatomy. To date, however, while there are a growing number of commercial TPS with an electron MC option, there is currently no standard commercial TPS offering a photon MC dose calculation algorithm (apart from specialist Monte-Carlo planning systems such as Peregrine). This is despite some fifteen years of continuous development of MC applied to external-beam treatment planning. This slowness of clinical progress is possibly because there are still some important issues to be resolved before MC comes into widespread clinical use. One of these is whether the all-important characterisation of clinical beams is done by each user for the particular accelerators in the clinic or whether generic phase-space files or source models can be used for a particular type of accelerator. The paper by Fraass et al. (2003) contains a summary and recommendations from a workshop specifically convened to identify issues limiting the clinical use of MC in radiotherapy treatment planning. Among the key points in this paper are:

- The desirability of a procedure that would promote distribution of accurate MC machine modelling data from manufacturers
- The desirability of methods to validate phase-space models and/or simulations of accelerator-head geometry
- The need to study the sensitivity of MC dose calculations to uncertainties in machine design, machine tuning and changes in accelerator components known to occur over time
- How should radiation oncologists use this more accurate dose information? Retrospective MC-based dose assessments of already existing clinical complications and local control data should be carried out

- Additional study of variance-reduction techniques, improved computational techniques, including parallel processing and de-noising (Deasy et al. 2002; El Naqa et al. 2005) are all warranted
- Improved implementation of IMRT delivery techniques into the MC algorithms and integration of MC calculation algorithms into the inverse planning/optimisation process for IMRT in a time-effective way
- Education of physicists and physicians about MC principles and the clinical implications of MC algorithms and their implementation is crucial. Without such efforts, there is a risk that the potential superior accuracy of MC methods will be accepted as fact. In reality, they may be worse than existing clinical dose-calculation methods in clinics which do not properly implement and understand the method.

The use of MC simulations in radiotherapy treatment planning offers a number of new possibilities in addition to the potential increase in the accuracy of the calculated dose distributions. Among these are

- Computation of the photon or electron fluence spectra at any position thus allowing the computation of stopping-power or mass-energy-absorption-coefficient ratios for the actual beam quality for dosimetric purposes (see [Section 18.5](#))
- *Benchmarking* of other algorithms (e.g. pencil beam or 3D convolution) to quantify the effect of their particular approximations with a minimum of measurements
- Investigation of the physics of dose delivery by allowing the effect of modifying the real physics to be observed (e.g. by changing the electron cutoff energies)
- Visualisation of the particle or photon tracks both as a teaching aid and to verify the code

Where MC dose calculation produces different results from traditional methods, this will potentially affect the expected results of treatment. This should be estimated via TCP and NTCP models ([Chapter 36](#)) so that the impact of MC dose calculation can be assessed.

Because of the time required for MC beam calculation it is likely for some time to come that a simpler algorithm will be needed to support *forward planning* of conventional beams. Recalculation of the dose distribution after small changes, e.g. beam angle or weight, are made needs to be in almost *real time* for this purpose. However, MC *recalculation* of the dose distribution once the optimum *forward* plan has been designed will be perfectly feasible. For intensity-modulated radiation therapy (IMRT), the *inverse-planning* approach attenuates the need for a *real time* response and MC algorithms could be used within the optimisation loop. Because inverse planning will modify the beam intensities based on the calculated dose distribution, including any imperfections in the calculation, it becomes more important that the calculation should be accurate at all points in the patient and not just at the ICRU reference point (see [Section 37.6](#)). However, *intensity modulation* means a large number of sub-beams of different intensity and small cross-section in addition to the problem of heterogeneities in the patient's body. This places even greater demands on beam calculation methods. MC is now being applied to IMRT and both static and dynamic delivery using multileaf collimators is being simulated (Laub et al. 2000; Ma et al. 2000; Keall et al. 2001; Pawlicki and Ma 2001; Leal et al. 2003; Seco et al. 2005). Furthermore, MC simulation has been applied to the radical new Tomotherapy machine (see [Section 43.3.4](#)) with its narrow-intensity-modulated beams delivered in a helical pattern (Jeraj et al. 2004) and has been shown to produce virtually perfect agreement with measurement. It can be expected that MC dose computation will have an important role to play in increasing our confidence in using these new treatment techniques.

Because of the difficulties in modelling the passage of the electrons from the accelerator gun to the target, MC dose calculation will probably always require some matching of the model to experimental measurement. However, provided that the physics of radiation transport has been correctly modelled and the interaction coefficient data used by the MC code are

accurate, then uncertainties in MC-generated dose distributions are primarily statistical in nature and can be quantified by a standard deviation that will depend only on the size of the scoring volume and the number of particle histories (see Equation 28.1). This is in contrast to the uncertainties in analytical methods, which depend on the quality of experimental beam data and on approximations in the physics that may be impossible to quantify and cannot simply be reduced by changing, say, the grid size of the calculation. The day is finally in sight when the radiotherapy physicist can rely on an MC dose calculation to overcome the limitations of *model-based* algorithms.

## INTRODUCTION

Treatment planning is the process of determining the most appropriate way to irradiate the patient. It is a combination of the following five essential steps:

1. Choosing an appropriate patient positioning and immobilisation method so that treatments will be reproducible;
2. Identifying the shape and the location of the tumour (i.e. the *target*) and of the neighbouring organs at risk;
3. Selecting a suitable beam arrangement;
4. Evaluating the resulting dose distribution;
5. Calculating the treatment machine settings to deliver the required absolute dose.

This results in the flow of data illustrated in [Figure 39.1](#).

Prior to treatment planning, it will be necessary to determine the nature and extent of the tumour using various diagnostic techniques. Occasionally, it will be possible to conduct the diagnostic investigation in such a way as to provide appropriate data for treatment planning, but normally, it will be necessary to carry out a separate imaging study. This occurs because the requirements of diagnostic imaging and treatment planning are largely incompatible. For diagnosis, the priority is to obtain artefact-free images with appropriate enhancement of the tumour. Treatment planning requires a geometrically accurate three-dimensional model of the patient in the precise treatment position together with a means of transferring the three-dimensional coordinate system to the treatment machine. For accurate tissue inhomogeneity corrections, the electron density distribution of the patient is also required.

For common treatment situations, a standard beam arrangement will be established as a class solution and planning will consist of establishing the correct beam geometry followed by a dose computation to determine the monitor unit settings required. However, it is important to realise that the arrangement of the beams relative to each other can have a significant effect on the dose gradient at the edge of the target volume. Therefore, where the edge of the target volume is determined by the penumbra of only one beam, the dose gradient will be shallower than when more than one beam edge is involved—as in the superior or inferior direction for coplanar transverse beams. For this reason, purely geometric planning is not sufficient. In determining the field margins to be geometrically applied in such class solutions and for non-standard treatments, the relationship between the edge of the target volume and the edge of the dose distribution will need to be considered in detail.

The size of the target volume and the margins around what is visible on an image should be determined as suggested in ICRU 50 (ICRU 1993) and ICRU 62 (ICRU 1999). This is covered in [Chapter 29](#). [Chapter 30](#) and [Chapter 31](#) describe how the various imaging methods can be used and combined to obtain a representation of the patient where the target volume and the organs at risks are properly identified. [Chapter 32](#) considers the solutions for beam setup in relationship to patient anatomy. [Chapter 33](#) and [Chapter 34](#) look at ways of combining beams to achieve an appropriate dose distribution for photon and electron beams, respectively. It is possible to calculate the effect of simple beam combinations using manual graphical methods to estimate the summed contributions. Although such methods can be instructive and can help the student to understand the effect of combining beams, modern treatment planning is almost exclusively carried out using computer algorithms (see [Part F](#)); therefore, manual methods will not be discussed. Finally, in [Chapter 35](#) and [Chapter 36](#), methods of evaluating the dose distributions to establish the physical relationship with the target volume and to obtain an estimate of the biological effect of the treatment are considered.

Treatment planning requires a combination of a large amount of data and computer systems to produce the final result. It is essential that there is a detailed quality assurance programme to minimise the risk of error. This is covered in [Part H, Chapter 39](#).

## 29.1 INTRODUCTION

The therapeutic use of radiation (radiotherapy) is an established method of treating malignant tumours. Radiotherapy is a local treatment and is complementary to systemic treatments such as chemotherapy and hormone therapies. It is important to appreciate that the desired anti-cancer activity of radiotherapy is only seen in the tissues directly irradiated by the primary beam(s).

Definition of the tumour, adjacent organs at risk (OAR), and other anatomical structures are therefore an essential part of the planning process to ensure that the beam size, number,

trajectory and weighting are optimised in relation to these structures. This will in turn ensure that the prescribed radiation dose is delivered to the appropriate volume of tumour-bearing tissue to achieve the endpoint of tumour cure or palliation (symptom control) while incurring an acceptable rate and severity of both early and late radiation morbidity.

In recent years, radiotherapy has become increasingly complex. The current trend is toward the implementation of conformal radiotherapy and intensity modulated radiotherapy (see [Chapter 43](#)). These aim to reduce normal tissue toxicity by limiting irradiation of normal tissues while still irradiating the tumour in its entirety. This should in turn produce reduced morbidity for a given absorbed dose compared with standard treatment techniques, or allow dose escalation for an equivalent level of morbidity. These technologically demanding treatments can only fulfil their promise if the therapeutic absorbed dose is delivered to the tumour reliably and reproducibly from day to day during a protracted course of treatment.

The aim of this chapter is to outline the basic principles of target definition, exploring the associated problems and uncertainties, and how they can be addressed in everyday clinical practice. The detailed procedures for acquiring the anatomical data needed for the definition of target volumes and other anatomical structures of interest will be described in [Chapter 30](#) with special reference to computerised tomography (CT) imaging. The specific role of magnetic resonance (MR) imaging for treatment planning will be described in [Chapter 31](#).

---

## 29.2 THE INTERNATIONAL COMMISSION ON RADIATION UNITS AND MEASUREMENTS VOLUMES

The International Commission on Radiation Units and Measurements (ICRU) 50 report (ICRU 1993) stipulates standard protocols for recording and reporting radiotherapy treatments of all degrees of complexity. These include the adoption of standard terminology to describe the volumes relevant to radiotherapy treatment planning. The adoption of these terms serves several purposes:

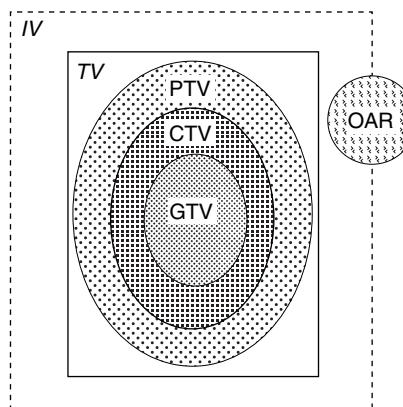

- Improves clarity of thought and encourages a logical approach to planning
- Promotes consistency in physics planning and clinical practice
- Allows standardisation of clinical trial protocols, particularly for complex, multi-phase treatments
- Facilitates communication between different centres and within clinical trials

Since the publication of the ICRU report 50, there has been considerable discussion in the literature about volume definition and related uncertainties. A comprehensive review and analysis of these issues can be found in a booklet published by the British Institute of Radiology (2003). The recommendations of ICRU Report 50 have been further developed in ICRU Report 62 (ICRU 1999) (see [Section 29.4](#)).

The volumes originally defined in the ICRU 50 report are described below ([Figure 29.1](#)).

### 29.2.1 GROSS TUMOUR VOLUME

The gross tumour volume (GTV) is the gross palpable, visible and demonstrable extent and location of the malignant growth. This is determined by physical examination by the oncologist and the results of radiological investigations relevant to the site of the tumour. As the term suggests, tumours have a length, breadth and depth, and the GTV must therefore be identified using orthogonal 2D or 3D imaging. It may be clearly delineated for some tumours (e.g. cerebral metastases or lung cancers) and very ill-defined for others (e.g. high grade gliomas of the brain or tumours diffusely involving an organ). Even the imaging

**FIGURE 29.1**

Schematic representation of the volumes defined in ICRU Report 50 demonstrating the relationship of different volumes to each other: GTV, gross tumour volume; CTV, clinical target volume; PTV, planning target volume; TV, treated volume; IV, irradiated volume; OAR, organ at risk. (Adapted from ICRU, Report No. 50, International Commission on Radiation Units and Measurements, Bethesda, MD, 1993.)

modalities with the best tissue contrast (CT and MR) may not resolve the tumour edge with precision, and indeed may not distinguish between tumour and inflammatory tissue reaction. The role of the various imaging techniques with respect to GTV delineation will be further discussed in [Section 29.3.1](#), [Chapter 30](#) and [Chapter 31](#).

## 29.2.2 CLINICAL TARGET VOLUME

The clinical target volume (CTV) is a tissue volume encompassing the GTV but with an additional margin accounting for any microscopic extension of the primary tumour or regional lymph node spread. It is impossible to ascertain the degree of microscopic tumour invasion around a tumour unless it is removed completely. Therefore, this volume may not be defined separately but considered when defining the planning target volume (PTV) (see [Section 29.2.3](#)). When specified, the CTV is usually obtained from a somewhat empirical margin added concentrically to the GTV. In a limited number of cases, the results of clinico-pathological studies of primary tumours where microscopic extent could be measured, and correlated with tumour type and other pathological markers of invasiveness, are available (Holland et al. 1985; Giraud et al. 2000). The involved lymph nodes, which are often also to be irradiated, can be considered as a different type of CTV. In spite of efforts to standardise the delineation of such volumes (Martinez-Monge et al. 1999; Grégoire et al. 2000), individual clinical judgment often remains the basis for their delineation. The increasing use of positron emission tomography (PET) images (see [Section 30.3.4](#)) could provide additional data in the future. However, in all cases it is imperative that the CTV receives the prescribed radiation dose; otherwise, tumour cure is unlikely.

## 29.2.3 PLANNING TARGET VOLUME

The PTV is usually the final volume defined by the clinician during the planning process. It fully encompasses the GTV and CTV. It is in effect obtained from a safety margin added to the GTV/CTV to take account of the organ motion and of the uncertainties inherent in radiotherapy setup and treatment delivery (BIR 2003). Once again, a concentric margin around the GTV/CTV is often used. This margin should ideally be determined from uncertainty analysis. In practice, it is often the result of a compromise between two contradictory issues: making sure that the CTV will receive the prescribed dose while at the same time ensuring that OARs

will not receive an excessive dose. Asymmetric margins are therefore used for certain tumours (e.g. prostate, in the posterior direction to protect the rectum). Since the problem of organ motion is quite different from setup uncertainties, these issues have been considered separately in a more recent ICRU report (see [Section 29.4](#)).

In contrast with the GTV and the CTV which are purely oncological concepts, independent of any therapeutic approach, the PTV is a purely geometric volume, which does not necessarily correspond to tissue or organ borders. It is used to select the appropriate beam sizes, shapes and arrangements to ensure that the prescribed dose is actually delivered to all parts of the CTV.

#### 29.2.4 TREATED VOLUME

The treated volume (TV) is the volume of tissue enclosed by an isodose surface selected and specified by the clinician as being appropriate to achieve the aim of treatment, i.e. cure or palliation. For example, this may be the volume encompassed within the 95% isodose surface (with 100% in the centre of the PTV) for a curative treatment plan. The TV should not be significantly larger than the PTV. The use of 3D treatment planning and shaping the radiation fields to the shape of the PTV using conformal radiation delivery techniques ensures that the TV encloses the PTV with as narrow a margin as possible. This ensures minimal irradiation of surrounding OARs while coverage of the PTV is assured.

#### 29.2.5 IRRADIATED VOLUME

The irradiated volume (IV) is the tissue volume receiving a radiation absorbed dose that is considered significant in relation to normal tissue tolerance. This concept is not often considered in practice but may be useful when comparing one or more competing treatment plans. Clearly, it would be preferable to accept the plan with the smallest IV, all else being equal.

#### 29.2.6 ORGANS AT RISK

Organs at risk are organs adjacent to the PTV which are non-target, as they do not contain malignant cells. The aim should therefore be to minimise irradiation of OARs as they are often relatively sensitive to the effects of ionising radiation and, if damaged, may lead to substantial morbidity. The OARs to be considered will vary greatly according to the anatomical region being treated, the size of the PTV and the location of the PTV in these regions. The following are examples of the most common OARs that must be considered:

- Brain: lens of eye, optic chiasm, brain stem
- Head & neck: lens of eye, parotid glands
- Thorax: spinal cord, lungs
- Abdomen: spinal cord, large bowel, small bowel, kidneys
- Pelvis: bladder, rectum, femoral heads, large bowel, small bowel

Many OARs have a defined tolerance dose at which a given level of late radiation morbidity can be expected. These are summarised well by Emami et al. (1991a). Some OARs such as lung, brain and kidney demonstrate a volume effect with increasing loss of function as an increasing proportion of the organ is irradiated.

Controversy exists concerning the outlining of hollow OARs, e.g. the colon or rectum. Delineation of the outer surface of the wall of the structure is adequate for determining the

anatomical position. However, when considering the expected side effects, it is the dose to the wall of the organ that is likely to be relevant. A dose volume histogram (DVH, see [Section 35.3](#)) of the whole organ may not be representative of the volume of the wall and the risk of side effects may be overestimated. Several approaches to this problem have been applied, with some centres outlining the outer and inner walls and others calculating *dose surface histograms* (see [Section 35.3](#)).

---

## 29.3 CLINICAL ISSUES IN TARGET DEFINITION

The acquisition of high quality images and the definition of the ICRU 50 volumes are integral parts of treatment planning. Outlining of these volumes (segmentation) is a time-consuming and tedious process, and therefore prone to random errors due to lapses in concentration and uncertainties in the definition of the tumour boundary. Other steps in the planning process may introduce other random and systematic errors. Failure to consider these issues will lead to errors being implemented during the patient's treatment. It is therefore vital to appreciate and if possible eliminate sources of error and uncertainty. Some recognised problems with volume definition are discussed below. Although many of the examples given are related to brain tumours, most issues are similar for other clinical sites. Specific issues relate to the type of OAR close to the tumour, to the imaging technique used and to the mobility of the organs.

### 29.3.1 POOR ORGAN/TUMOUR DEFINITION

For some malignancies, it is the usual practice to treat the whole of the organ from which the tumour originates (e.g. the prostate or the bladder). In these instances, the primary tumour may not be clearly seen, but this is irrelevant due to the large margin for error.

Some tumours are well circumscribed with an easily defined margin of demarcation from the surrounding normal tissue. For example, benign tumours (e.g. meningiomas of the brain and acoustic neuromas) have little propensity to invade the surrounding tissues and are often encapsulated, making the tumour stand out clearly from the tissue of origin. The same can be said for some malignant tumours such as brain metastases, low grade gliomas of the brain and some soft tissue sarcomas. In these examples, there will be little dispute regarding delineation of the GTV, and in turn the PTV.

Inevitably, there are some tumours that are far less well defined. This may be because of diffuse infiltration at the tumour periphery or because the tumour has a similar radiographic density compared to the surrounding normal tissue. Thus, it is possible that the tumour size and shape will not be fully appreciated by the clinician. This is a particular problem with high grade gliomas arising within the brain ([Figure 29.2](#)), where clinico-pathological studies have shown tumours extending for some centimetres beyond the edge of the main tumour mass. This is usually accounted for by allowing a large (e.g. 3 cm) margin between the GTV and PTV. Imaging with MR is deemed superior to CT due to the superior soft tissue contrast for neural tissue which is rich in lipids (and therefore protons), but it does not always allow clear tumour delineation.

Comparison of CT and MR volumes suggests that in some cases there is a substantial difference in the tumour volumes (Ten Haken et al. 1992). Similar issues are found in prostate cancer (Khoo et al. 1999; Rasch et al. 1999; Sannazzari et al. 2002).

The appreciation of the position and extent of the GTV and of OARs clearly benefits from the combination of several complementary imaging modalities. This requires that the various image data sets are mapped onto a common coordinate system. This process, called *image registration*, is mostly used to combine CT and MR images and has been developed initially for the brain (see [Section 31.6.2](#)). The CT images are used as the reference and the MR images are

**FIGURE 29.2**

CT image of a high grade glioma of the brain (see arrow). Note the poor demarcation between tumour and the surrounding brain and in turn the difficulty in delineating the GTV. (Courtesy Institut Curie, Paris.)

recalculated and registered with respect to the CT coordinate system, using one of the methods described in [Section 31.6.2](#).

The practical use of registered multimodality data sets requires specific tools which must be made available as part of a specific radiotherapy imaging console or be included in the treatment planning system used for calculation of dose distributions. One solution can be to display the reference and the registered images side by side and have a cursor linked pixel for pixel, so that the clinician can move from one imaging modality to the other, modifying the volume according to the image which demonstrates it best. The images can also be overlaid on the top of each other, with the possibility to switch instantaneously from one modality to the other. Finally, the two images can be blended into a single image with the possibility in some systems of interactively changing the relative weight of each of them. This process is commonly called image fusion.

### 29.3.2 INTER-OBSERVER VARIATION

Some tumours are well circumscribed, and in these instances, there can be little debate regarding the extent of the GTV. However, for more ill-defined tumours, there can be some considerable inter-observer variation. It is clear that if the same set of images were presented to a panel of specialists, one would expect some degree of concordance. In the study by

Leunens et al. (1993), CT images from several glioma patients were presented to a multi-disciplinary group of clinicians including radiation oncologists, diagnostic radiologists and neurosurgeons, each varying in seniority. Comparison of the GTVs and PTVs suggested considerable variation from person to person in the GTV contour, in some cases with a substantial difference in tumour volumes\*. The only way to eliminate such subjectivity and improve consistency may be to use computer image analysis, although there are no data to suggest that this would be superior to the average oncologist.

### 29.3.3 INTERNAL ORGAN MOVEMENTS

For many years, it was assumed that internal organs did not move much from day to day, or hour to hour throughout the day. Accordingly, little attempt was made to account for these variations. This assumption is satisfactory for some sites where the tissue containing the tumour has very little scope for movement, e.g. the brain. However, with the emergence of precision radiation delivery techniques such as conformal radiotherapy, these issues have had to be considered. For example, conformal radiotherapy to the prostate ensures conformation of the shape of the TV to the PTV with as small a margin as possible. Therefore, there is little room for error, and slight movement of the prostate may result in under-treatment, resulting in failure to control the tumour, or over-treatment of an OAR, leading to excessive radiation morbidity. As conformal radiotherapy has been most widely used for treatment of the prostate, it is for this indication for which most data are available. The prostate is moderately fixed within the bony pelvis by a series of ligaments. The bladder lies anteriorly, a hollow, muscular sac that undergoes regular distension and contraction according to the volume of urine contained within it. The rectum lies posteriorly, a similarly hollow, muscular sac that also undergoes regular distension and contraction according to the amount of gas and faeces contained within it. Laterally lie the relatively immobile and inflexible bony wall of the pelvis and femoral heads. It is clear that unless care is taken to ensure consistency of bladder and rectal filling at the time of imaging, and subsequently at the time of treatment delivery, diurnal variations could lead not only to changes in the position of the prostate CTV, but also to intrusion of the bladder and rectal walls (each OARs) into the TV. This hypothesis has been elegantly demonstrated by Ten Haken et al. (1991) using beam's-eye-view images of the prostate, bladder and rectum and 3D dose distributions. Other investigators have since demonstrated the vectors and magnitudes of these movements using, for instance, radio-opaque marker seeds (Balter et al. 1995a, 1995b). Such information can be used to optimise the margin allowed between the CTV and the PTV.

Although it has been conventional practice to add a uniform margin around the GTV to yield a PTV for planning, some authors have advocated the use of non-uniform margins to take account of the particular treatment technique and anatomical relations between the PTV and OARs. For example, Pickett et al. (1995) have proposed the use of margins varying from less than 1 cm up to more than 2 cm for the prostate gland treated with a co-planar 6 field conformal radiotherapy technique. This approach may provide the best compromise between CTV coverage and avoidance of OARs. Similar data are available for other internal organs susceptible to motion. For example, in the abdomen the kidneys are often in close proximity to the radiation beam trajectory and occasionally are themselves susceptible to malignant disease. They are also very susceptible to the late effects of ionising radiation and essential for the day-to-day metabolic function of vertebrates. Being close to the thoracic cavity, the kidneys are susceptible to respiratory motion, moving inferiorly with inspiration and superiorly with expiration. The study by Schwartz et al. (1994) suggests that the inferior poles of the

\* The variability of the results may have been greater than would have been obtained by a group of experienced oncologists alone because of the different criteria being used by the different groups.

kidneys may move by more than 4 cm in the superior-inferior direction between maximum inspiration and expiration (mean 1.7 cm), while other studies have indicated that the displacement may be even greater (Moerland et al. 1994).

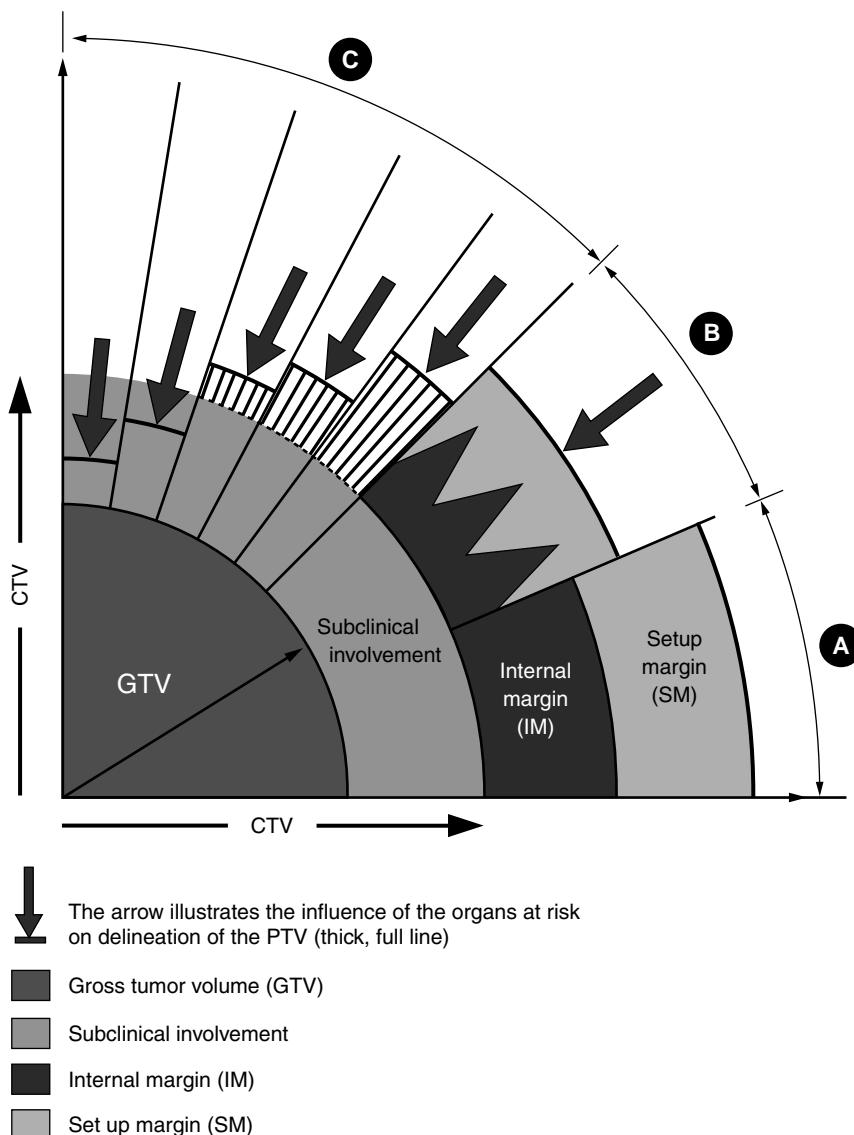

It has been noted that respiration leads to measurable variations in the CT volume relationships of both the lungs and the liver, which can be appreciated by changes in the dose volume histograms for these organs (Balter et al. 1996). For those organs which move with respiration, it is of course impractical to plan and deliver treatment during a breath hold without some form of gating or respiration-monitoring system. In the past, the relatively slow image acquisition of CT images in transverse mode gave a time averaged picture which could be considered as representative of the situation during treatment. However, this is not any longer true with modern CTs for which each transverse slice is randomly acquired throughout the respiratory cycle. Empirical corrections in the superior-inferior direction can be used when planning intrapulmonary tumours to take account of respiratory excursion, but it is recognised that this may lead to increased normal tissue complication probabilities for the OARs (Ten Haken et al. 1997). Other options include the use of a stereotactic body frame to restrict lung movement or to employ a *respiratory-gated* treatment in which the CT scanner, and subsequently the therapeutic radiation beam, is switched on only at a predetermined phase of the respiratory cycle. Several techniques are used clinically, either based on active or passive breath-holding, or based on movement detection and synchronised irradiation. More details on these techniques are given in the introduction to Part I.

---

## 29.4 ICRU 62 ADDITIONS TO ICRU 50

To address some of these issues, ICRU Report 62 (1999) has been introduced as a supplement to ICRU Report 50. The definitions of GTV and CTV remain unchanged, as these are oncological concepts independent of any technical developments. The main relevant changes include:

- The margin between the CTV and PTV is segregated into an *internal margin* (IM) to take account of variations in the size, shape and position of the CTV relative to anatomical reference points, and a *setup margin* (SM) to take account of uncertainties related to setup errors, reproducibility of patient position and mechanical stability of the treatment unit. The addition of an IM to the CTV results in an *internal target volume* (ITV) that is intermediate between the CTV and the PTV. The ICRU report reflects the obvious uncertainty as to how these two margins should be added together to produce the composite margin and therefore allow definition of the PTV (see Figure 29.3). At least it may serve to clarify thought and lead to a custom-defined PTV that takes into account the relative vectors of these uncertainties, accepting that the whole process is a compromise that relies on the experience and judgement of the radiotherapy team.
- OARs are defined according to their pattern of response to radiation damage (see Section 8.9). *Serial* OARs have an architecture whereby damage to any one functional subunit in a linear chain leads to sudden organ failure and in turn manifestation of morbidity (e.g. spinal cord injury leading to radiation myelitis). *Parallel* OARs require damage to a critical number of functional subunits to manifest radiation damage, and increasing radiation damage leads to progressive loss of organ function (e.g. lung, kidney). *Serial-parallel* OARs demonstrate attributes of both types (e.g. heart).
- Introduction of the concept of *planning organ at risk volumes* (PRVs) which take account of changes in the size, shape, volume and position of OARs. The PRV's derivation from the OAR is therefore analogous to the PTV relative to the CTV. The PTV and PRV(s) may of course overlap, in which case judgement and experience must prevail, but it is usual to give more weight to giving a sufficient dose to the PTV than to sparing a margin around the OAR.
- Introduction of the concept of a *conformity index*, defined as the quotient of the TV and PTV, where the TV encompasses the PTV (see Section 35.4.2).

**FIGURE 29.3**

(See colour insert following page 590.) Schematic representation of different possibilities to combine uncertainties to define the PTV from the GTV: (A) linear addition of margins; (B) probabilistic addition of IM and SM; (C) definition of a *global* safety margin based on an empirical compromise between adequate coverage of GTV and unacceptable irradiation of OARs. (From ICRU, Report No. 62, International Commission on Radiation Units and Measurements, Bethesda, MD, 1999. With permission.)

## 29.5 CONCLUSIONS AND FUTURE TRENDS

The increasing sophistication of treatment planning and radiation delivery has outstripped our capability to delineate the ICRU volumes with precision and consistency. A comprehensive methodology to include systematic and random uncertainties into the volume definition and into the treatment planning process has been developed by a working party of the British Institute of Radiology (BIR 2003). They made a distinction between the various origins of the overall uncertainty: the systematic errors which can be either Gaussian

(doctor's delineation; target position, shape and size; phantom transfer\*; patient setup) or linear (patient breathing; treatment planning beam algorithm) and the treatment execution errors assumed to be Gaussian (daily setup; target position, shape and size). The methodology was illustrated for several clinical cases. This approach may be considered as too cumbersome. However, failure to consider uncertainties in daily practice will undermine the treatment and ultimately will lead to an undesirable shift in the balance between tumour control and normal tissue morbidity.

Future improvements in medical imaging such as functional imaging (PET or single photon emission computed tomography (SPECT)) and their incorporation into the planning process will contribute to delineation of the GTV for ill-defined tumours. More clinico-pathological data are necessary to relate tumour type, size and grade to the degree of microscopic tumour extension around the GTV. These data may be used to determine the optimum margins to be allowed around tumours to form the CTV; particularly for those tumours that have reduced in size due to treatment with chemotherapy or hormone therapy prior to radiotherapy. The acquisition of more data regarding internal organ motion may also permit a better estimation of the margin that is necessary between the CTV and ITV.

It must be recognised that using a common language in the definition of the volumes which are used throughout the treatment planning process constitutes the basis for consistency within one centre and between different centres for prescribing, recording and reporting the dose to the patient. The ICRU has played a significant role in promoting this approach and complementary reports addressing the problem of other treatment techniques have been produced, such as electron therapy (ICRU 2004), or are in preparation, such as proton or intensity modulated beams. The ICRU has also sought to reduce uncertainties relating to different approaches to the definition of dose and these are discussed in [Section 37.6](#).

---

\* In this context, phantom transfer encompasses all uncertainties associated with imaging, planning and treatment equipment or procedures which can be quantified using a phantom instead of a real patient.

## 30.1 INTRODUCTION

Patient data acquisition is the first step in the treatment planning process. It is required for three different purposes:

1. To assess the position and extent of the target volume in relation to the other anatomical structures, particularly the organs at risk (see [Chapter 29](#))
2. To acquire the data required for accurate computation of the dose distribution (e.g. shape and composition of the body)
3. To acquire the information necessary for the accurate set up of the patient (e.g. landmarks or reference structures)

In all cases, it is essential that the patient position be defined at the beginning and maintained throughout the whole treatment planning and delivery process. This will be addressed in

Section 30.2. Patient data for treatment planning is often based on data acquired using a single imaging modality with the aim of achieving the goals listed above. The most common methods are described in [Section 30.3](#). A full chapter is dedicated to the use of Magnetic Resonance (MR) imaging for treatment planning, which is becoming increasingly important (see [Chapter 31](#)). With some imaging modalities, such as positron emission tomography (PET), and to some extent MR, the geometric accuracy and the lack of electron density information makes it necessary to co-register the data with CT. The methods used to register image sets obtained from different modalities are described briefly in [Section 31.6.2](#) in the context of the use of Magnetic Resonance Imaging in radiotherapy.

---

## 30.2 PATIENT POSITIONING AND IMMOBILISATION

An important issue in the radiotherapy process is the ability to reproduce accurately the same patient position throughout the treatment and to keep the patient still during each fraction. This fixed position must be decided before the acquisition of the patient data. It must enable the optimal beam directions to irradiate the planning target volume (PTV) without colliding with the treatment machine or its accessories.

Some of the patient movement can be prevented by positioning patients comfortably and sympathetically and explaining the importance of keeping still. The use of additional positioning accessories or immobilisation devices throughout planning and treatment is often recommended. Examples of such devices include the following:

- Simple sand/bolus bags for general support
- External arm supports and body *boards*, e.g. for breast and thoracic treatments
- Thermoplastic casts, e.g. for head and neck, and pelvic treatments
- Vacuum bags, e.g. for breast and pelvic treatments
- Thermochemical polystyrene devices (headrests and knee supports), e.g. head and neck, and pelvic treatments
- Stereotactic frames, e.g. for brain treatments

The standard devices that can be used for a series of patients can be either homemade or purchased. They are more and more frequently made of carbon fibre, which allows the beams to pass through the material without too much perturbation of the dose distribution\*. Individual casts can also be used. These are kept only during the treatment course and must be disposed of afterwards. The casts can be made either of polyurethane foam (often referred to under the commercial name of *Alpha Cradle*) or consist of sheets of thermoplastic material that are moulded directly on the patient's body (e.g. head, thorax, limbs, etc.). An intermediate solution is to mould some parts of the body with vacuum bags containing small polystyrene beads. Such bags maintain their shape as long as there is no air input. They can be kept evacuated throughout the treatment and reused afterwards for other patients.

Unfortunately, these devices are often insufficient to ensure an accurate reproducibility of the treatment position. Even individual head casts or masks allow some movement of the patient's head inside. Therefore, it is fundamental that the patient set-up be performed by experienced therapy radiographers. Accurate set-up must still rely to some extent on skin

---

\* When a photon treatment beam passes through part of an accessory used for patient set-up, in addition to the attenuation there is a risk that the build-up effect will be restored and result in significant skin reactions. Perturbations could also be important in electron beams. In all cases, the possible modifications of dose distribution must be carefully investigated before accepting that the beam is intercepted by a positioning device.

marks or bony landmarks, which must coincide with crosses projected by wall-mounted lasers and other optical aids. The radiographers should also be involved in the imaging procedures used for patient data acquisition.

The more accurate solution for head immobilisation is the use of a stereotactic frame screwed to the skull and used as a reference both for imaging and treatment (see [Section 45.1](#)). Intermediate, less-invasive solutions are also available and have been developed for the head and other parts of the body. They consist of devices that are firmly attached to some fixed landmarks (e.g. a moulded *bite block* fixed to the upper jaw, ear plugs, etc.) (see [Section 44.3.6](#) and [Section 45.5.2](#)). For greater accuracy, it is also possible to define a number of fixed landmarks (anatomical or fiducial) that can be seen on images performed systematically before each fraction. These images are then compared with a reference image to enable the treatment position or beam parameters to be adjusted. Appropriate imaging procedures must be devised for such techniques.

---

## 30.3 IMAGING FOR TREATMENT PLANNING

The clinician must be able to define the size, shape, and location of the gross tumour volume and organs at risk in three-dimensional (3D) space. Small, superficial tumours (e.g. skin cancers and tumours of the oral cavity) are easily visualised and palpated and therefore may be fully appreciated by the clinician without requiring complex medical imaging methods. However, for less well-defined tumours, particularly those arising within the deeper parts of the body, accurate information can only be obtained by one or more methods of medical imaging. Quality assurance at each stage is essential to ensure integrity between the planning and implementation of the treatment.

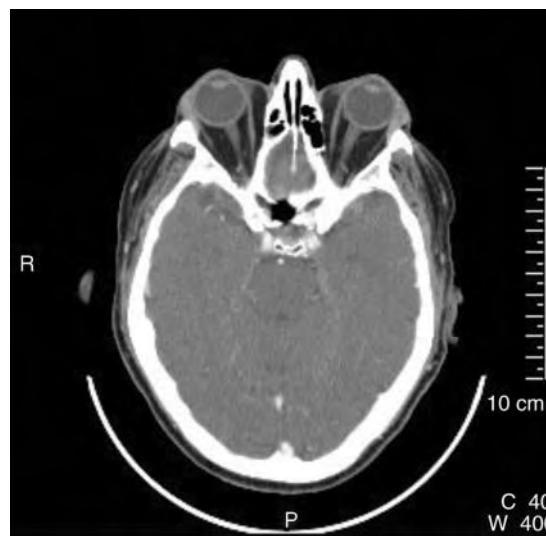

The ideal imaging modality for radiotherapy treatment planning would have the following attributes:

- Well-tolerated and atraumatic
- Quick to acquire images (less movement artefact)
- Excellent soft tissue and bone contrast with high resolution
- No geographical image distortion
- Able to record a 3D imaging data-set
- Provides data that can be used for radiotherapy dose calculations
- Widely available and cost effective

Although for many years treatment plans have been prepared using patient external contours acquired with mechanical or optical devices (see [Section 32.2.1](#)), the direct use of images is the standard practice today. The most widely used imaging modalities will now be compared and contrasted with the context of radiation treatment planning.

### 30.3.1 COMPUTED TOMOGRAPHY

Computed tomography (CT) should be considered the *gold standard*, especially with regard to geometric accuracy. A description of the principles of CT imaging can be found in most basic textbooks on medical imaging. The clinical use of CT imaging in radiotherapy started in the late 1970s (Goitein 1979; Hobday et al. 1979; Battista et al. 1980). CT is now widely available at all cancer centres and many small *district* hospitals. An example of a CT image of the head is shown in [Figure 30.1](#). The images can be acquired reasonably quickly and comfortably, so movement artefact should not be a problem, except in the thorax. The images of the tumour can be augmented by the injection of radio-opaque iodinated contrast

**FIGURE 30.1**

An example of a CT image of the head. The grey scale ranges from white (bones) to black (air). This scale is mapped onto a range of Hounsfield units (HU) within a window, W, corresponding to 400 HU centred around a value C equal to 40 HU (range = -160 to 240 HU). Other important parameters for 3D reconstruction are the slice position and thickness.

media; this is particularly useful for tumours of the central nervous system. Overall, soft tissue contrast is very good, with high resolution due to the small pixel size attainable. Bone contrast is excellent, a useful attribute when bone invasion must be visualised, e.g. for tumours arising within the base of the skull and those invading adjacent bone. The modest radiation exposure is not a problem for the cancer patient, but it does mean that children and anxious adults must remain unaccompanied during imaging.

CT produces a full 3D set of imaging data which are easily imported to and handled by all commercial treatment planning systems. The high resolution is important when small surface landmarks (e.g. a small radio-opaque point marker as a reference point) must be resolved. There is no inherent image distortion, and therefore the 3D positional data are reliable, provided that adequate quality assurance is performed (see [Section 39.2.1](#)). One particular advantage of CT is that the images are an indirect representation of the various tissue–electron densities within the images. Because megavoltage radiation interacts with tissue predominantly according to electron density (Compton scattering), the CT data can be used directly for radiation-absorbed dose calculations, provided a correction factor is applied to take into account the kilovoltage photon energy used for CT data acquisition. This is particularly relevant when the radiation beams traverse tissue inhomogeneities, such as lung and bone, in which the attenuation is very different from that of a homogeneous volume of soft tissue. The direct use of CT density data is far preferable to making manual corrections from densities approximately allotted to the different organs. The pixel information of a CT image is expressed in Hounsfield units, where an arbitrary value of -1000 is set to air and a value of zero is set to water. The CT scanner must be calibrated to measure the relationship between tissue density and Hounsfield units. A typical example of this relationship is shown in [Figure 39.2](#).

CT is particularly useful for acquiring the 3D external contour of the patient, which would be very tedious to acquire manually (although there are a number of laser devices commercially available for this purpose). The external contour is essential for planning because it represents the interface between air and tissue and therefore allows the planning computer to take into account the variations in beam attenuation and obliquity of incidence to calculate dose

distributions. Fortunately, automatic segmentation algorithms can be used on the 3D data to draw the external contour on each transverse image.

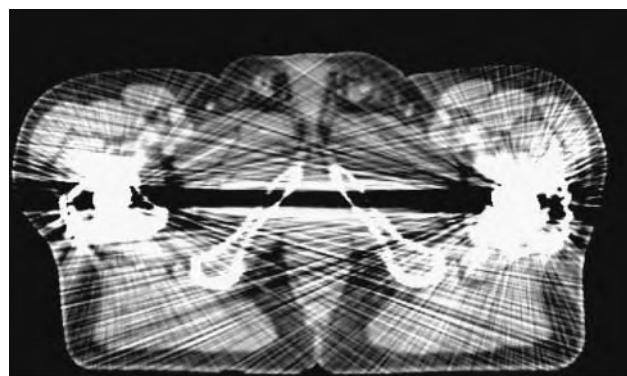

When acquiring treatment-planning images, CT is sufficiently versatile to permit imaging in the radiotherapy treatment position. This will entail substitution of the convex couch top that is normally used for diagnostic imaging with a flat one so that the set-up emulates a radiotherapy or treatment couch\*. As with conventional simulator-based planning<sup>†</sup>, it is important that the patient be placed in treatment position by a therapy radiographer. This position should be both comfortable and reproducible, preferably following a standard departmental protocol employing the placement of radio-opaque fiducial reference points and the use of immobilisation devices as appropriate.

It has been customary to acquire data as a sequence of transverse images for which the crano-caudal resolution is limited by the slice spacing. However, most modern scanners have the capability to use a faster helical data acquisition mode. The volume to be imaged will be determined by the anatomical region occupied by the tumour, the extent of the likely PTV, and the likely trajectories of the beams that will be used to cover it. Any organs at risk must be imaged in their entirety if dose volume histograms (DVHs) or biological endpoints such as normal tissue complication probability (NTCP) will be calculated (see [Section 35.3](#) and [Section 36.3](#)). The imaging protocol will require that contiguous transverse images are captured to ensure that a full 3D appreciation of the anatomy is obtained. The image slice separation will not normally be greater than 10 mm; often it will be 5 mm or less, particularly when the tumour region itself is imaged and even more so when the gross tumour volume (GTV) is very small, e.g. in the brain. The use of narrower slice widths for image acquisition through the region of the tumour allows accurate delineation of the superior and inferior extent of the GTV, which in turn increases the accuracy of the final CTV and PTV. Acquisition of thin contiguous slices (e.g. with a thickness smaller than 5 mm) over a long supero-inferior distance has the drawbacks of needing a large amount of computer storage space and the tedium of outlining the therapy-relevant outlines on a large number of individual images. On the other hand, because large series of thin images are useful for the generation of good quality digitally reconstructed radiographs (see [Section 32.4.5](#)), a reasonable compromise must be reached.

The restricted aperture and field of view of a conventional diagnostic CT scanner can be a problem for treatment planning, particularly for breast cancer patients who would normally be treated with the arm elevated. This problem can be overcome if the CT option on a simulator is used ([Section 13.3.3](#)). Older simulators were restricted by the time required for each slice, which required one rotation of the gantry, and the limitations of tube heating. The introduction of cone-beam CT algorithms has made it possible, with a single gantry rotation, to acquire a full 3D data set over a length of about 20 cm, albeit with poorer Hounsfield unit accuracy. Specialist CT scanners with a wider (85 cm) bore are now available (see [Section 13.3.4](#)), but there is a slight loss in image quality associated with the greater source detector distance. One other disadvantage of CT is seen when there is a metallic implant such as a joint prosthesis (see [Figure 30.2](#)) surgical clips, or large masses of dental amalgam. Such objects can lead to considerable streaking of the CT images, which may make it impossible to identify the tumour accurately. They also make it impossible to use the CT images directly to perform inhomogeneity corrections, since the image artefacts would be interpreted as density changes (Reft et al. 2003) (see also [Section 39.2.2](#)).

\* This is sometimes done using an insert with a flat top. In this case it is important to ensure that it fits correctly so that the flat top of the insert is horizontal.

<sup>†</sup> Simulator-based planning consists of choosing the beam position with the assistance of a simulator (see [Chapter 13](#)) and without preliminary patient data acquisition. The corresponding procedure is described in [Section 32.2.1](#).

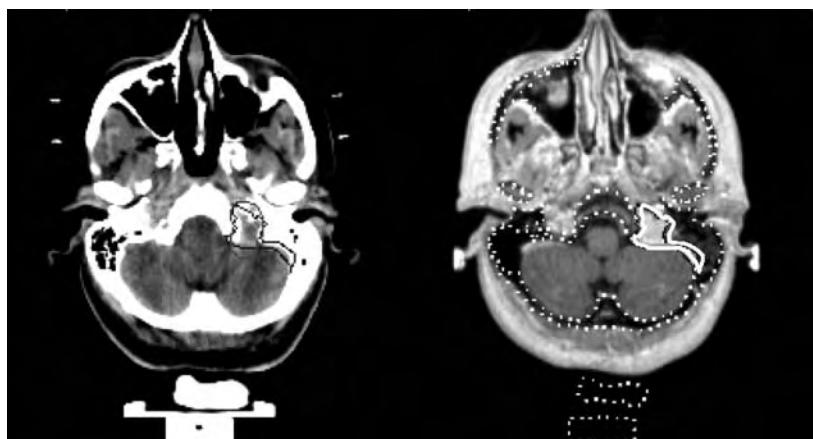

**FIGURE 30.2**

A CT image of the pelvis, with artefacts from a metallic hip prosthesis. (Courtesy of the Institut Curie, Paris.)

### 30.3.2 MAGNETIC RESONANCE IMAGING

Magnetic resonance (MR) imaging provides an important added value to CT imaging, especially for target delineation. Although often presented in axial sections like CT images, MR images can also be obtained in coronal and sagittal sections. The appearance of an MR image varies widely depending on the acquisition sequence and the display settings. Because of the MR principle and acquisition method, the bony structures do not exhibit any signal (i.e. appear as black areas) while small differences in soft tissue composition can be easily seen. A comparison between registered CT and MR images of the skull is shown in Figure 30.3.

The increasing importance of MR imaging for treatment planning is such that a full chapter ([Chapter 31](#)) is devoted to this topic.

**FIGURE 30.3**

(See colour insert following page 590.) A side-by-side display of a CT image (left) and an MR image (right) of the skull. The bony structures cannot be seen on the MR image, where the dotted line corresponds to the registered bony outline of the CT image. The tumour delineation (shown as a continuous white line on the MR image) is much easier to tell on the MR image. On the left image the tumour is shown using the MR delineation (black) and the volume that would have been delineated using CT alone (grey). (From Khoo, V. S. et al., *International Journal of Radiation Oncology Biology Physics*, 46, 1309–1317, 2000. With permission.)

### 30.3.3 ULTRASOUND

Ultrasound is cheap, simple to perform, non-invasive, and well tolerated. It provides reasonable images of tumours, but only when they are in close proximity to the probe. Thus, ultrasound is unsuitable for tumours situated deep within the thorax or abdomen. Bone significantly limits the depth of ultrasound penetration and is itself not resolved with much detail. Generally, ultrasound images are both difficult for the non-expert to interpret and open to subjectivity. Image quality has been improved in recent years by the introduction of transducers that can be introduced into body cavities to visualise adjacent structures, e.g. rectal ultrasound probes to image the prostate (see [Section 54.4](#)). Because ultrasound relies on assumptions about the speed of sound in tissue, it may be subject to geometrical distortion.

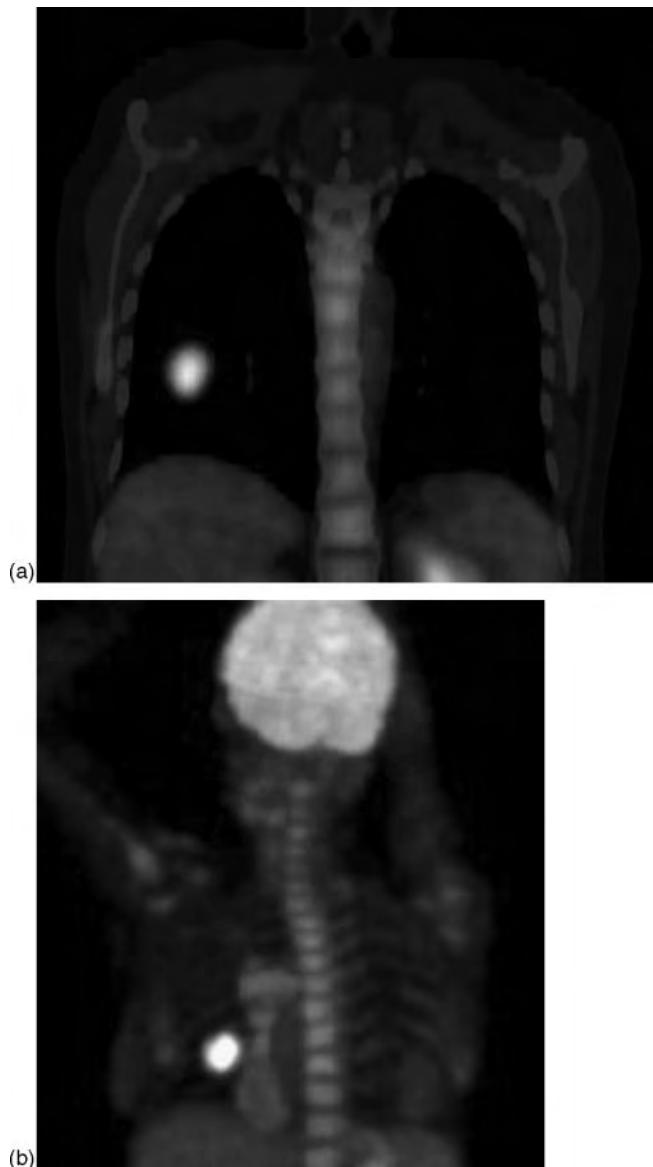

Another limitation of ultrasound for radiotherapy is that it does not produce a full 3D data set for processing by a treatment planning computer. Instead, it is more likely to yield a succession of 2D images obtained at the discretion of the radiologist.

Apart from its use in prostate seed implants, the role of ultrasound is currently confined to providing staging information that complements the other imaging modalities and that can indirectly guide the clinician faced with the task of volume definition. Simple depth measurements of the chest wall are useful for planning electron boosts in breast cancer patients, as they help select the optimum electron energy. In the pelvic region, it is also sometimes used at the time of treatment delivery as a means for checking in real time the position of the target with respect to the CT image used for initial planning (Lattanzi et al. 2000; Artignan et al. 2004).

### 30.3.4 POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) uses positron-emitting and biologically active molecules. Thus, PET images reflect the biochemical function of tissues and organs rather than their structure, producing information complementary to that obtained from CT and MR. PET yields 3D data sets which can be imported into the treatment planning computer. It may have a useful role in helping to define the edge of ill-defined, metabolically highly active tumours such as gliomas of the brain (Gross et al. 1998). Both CT and MR imaging may not yield much information regarding the involvement of regional lymph nodes, and often involvement can only be inferred when the node is significantly enlarged. In contrast, PET may help to determine whether a node of borderline size is likely to be involved, and it can even detect a tumour in nodes that appeared normal using CT or MR. Therefore, PET imaging can provide a means for direct evaluation of the CTV, since it is likely to provide useful information on the spread of the microscopic disease. In addition to the investigation of brain tumours, PET is being used in radiotherapy (e.g. to assess the extent of the node involvement) in non-small-cell lung cancers and head and neck tumours (Bradley et al. 2004; Scarfone et al. 2004).

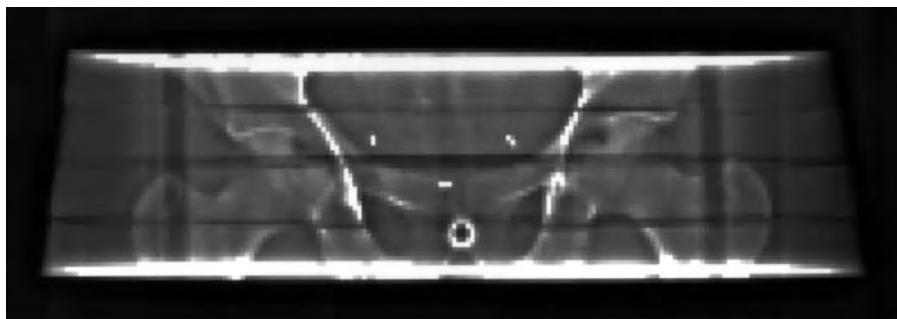

As with MR, the images must be registered to the CT data (Daisne et al. 2003). Because PET images are rather low in resolution compared to CT and MR, PET machines are frequently coupled with CT to provide a straightforward hardware registration of the two image sets (Ciernik et al. 2003; Costa et al. 2003). An additional benefit is that the CT densities obtained from the CT images can be used to apply a transmission correction that significantly improves the quality of the PET images. One of the main disadvantages, however, is the fact that PET imaging facilities are few and far between, and the technology is expensive both in terms of capital and revenue cost. Even fewer centres have a dedicated cyclotron for generating the precious short half-life positron-emitting isotopes. An example of a PET image is shown in [Figure 30.4](#). An alternative to the PET scans available from dedicated PET scanners is the use of a double-headed gamma camera to obtain PET images. Unfortunately, these images have even poorer resolution. They can be adequate to identify active lung tumours, but they are being systematically replaced by dedicated PET imaging devices.

**FIGURE 30.4**

(See colour insert following page 590.) An isolated right lung metastasis demonstrated by fluorodesoxyglucose (FDG) PET imaging. The PET image is blended with a registered grey scale CT image, both acquired on a PET-CT machine. The PET image is usually displayed in colour. The upper image (a) is a coronal slice through the metastasis and the lower image (b) is a 3D reconstruction in maximum-intensity projection (MIP) mode. (Courtesy of the Institut Curie, Paris.)

### 30.3.5 PLANAR RADIOGRAPHS

Planar radiographs have the advantage of being easy to obtain and interpret. However, since it is important that their geometry be the same as that of the treatment machine, the images should be obtained using a treatment simulator (see Chapter 13). Planar radiographs may be used alone to define primary tumours of the lung or secondary tumours of bone where there is sufficient contrast between the tumour and surrounding tissues. Reliance on such 2D images may be sufficient for the planning of non-conformal curative treatments (e.g. head and neck) or of non-curative, palliative treatments where a geographically inaccurate tumour

**FIGURE 30.5**

A CT topogram showing three gold seeds within the pelvis of a humanoid phantom.

delineation may not affect symptom relief and where normal tissue toxicity is not as much of an issue because lower treatment doses are used. A single film may be sufficient when an anterior-posterior parallel opposed pair of beams is to be used. Orthogonal films are used when the tumour has to be more precisely defined. An anterior film allows delineation of the tumour in the superior-inferior and left-right directions, while a lateral film allows delineation in the superior-inferior and anterior-posterior directions.

Contrast-enhanced radiographs are useful in non-3D planning when it is important to identify the position of a hollow organ. The following techniques may be used:

- Barium may be swallowed to outline the oesophagus, stomach, and small bowel
- Barium may be given as an enema to outline the rectum and lower colon
- Radio-opaque tampons may be inserted into the vagina to outline the structure
- Intravenous iodinated contrast may delineate the kidneys and allow them to be avoided when the abdomen is treated
- Iodinated contrast may be introduced into the bladder to outline it and suggest the position of the top of the prostate
- Iodinated contrast may be introduced into the urethra to suggest the position of the inferior extent (apex) of the prostate
- Metallic seeds may be introduced into the pelvis under guidance of trans-rectal ultrasound to define the prostatic apex and base of seminal vesicles (see Figure 30.5).

---

## 30.4 CONCLUSIONS

Acquisition of high-quality 3D imaging data is becoming increasingly necessary to exploit recent advances in the precision delivery of radiation. CT and MR are the cornerstones of any imaging protocol. The use of PET imaging, preferably combined with CT within the same piece of equipment, is likely to become standard practice in the future. Care must be taken to ensure consistency of patient set-up for each imaging modality and for each subsequent step of the planning process. This requires the implementation of a quality assurance program, as discussed in [Chapter 39](#).

## 31.1 INTRODUCTION

Computed tomography (CT) has made a dramatic impact on the accuracy of radiotherapy treatment planning in the past two decades by improving the localisation of target volumes. Improved target localisation will allow higher local control rates with less geographical misses and permit better awareness of the surrounding critical organs, thereby potentially minimising normal tissue complications (Goitein 1979; Goitein et al. 1979). The development of magnetic resonance (MR) has introduced several added imaging benefits that may confer an advantage over the use of CT in treatment planning.

---

## 31.2 PRINCIPLES OF MAGNETIC RESONANCE IMAGING

The basis of magnetic resonance techniques is the measurement of radiofrequency radiation, resulting from transitions induced between nuclear spin states of tissue hydrogen atoms (protons) in the presence of a strong external magnetic field. Whereas CT depends on x-ray attenuation by tissues that are a function of atomic number and electron density, relative pixel intensities in MR images are a function of proton densities and the different proton spin relaxation times in different tissues. Magnetic resonance imaging (MRI) does not use ionising radiation.

The major source of contrast in clinical MRI is the difference in relaxation times between different tissue types. The two parameters that are often used to characterise the behaviour of an MR signal and that can be used as a basis for generating MR contrast are the Spin-Lattice (T1) and Spin-Spin (T2) relaxation times. MR images are calculated from signals acquired by applying a particular imaging or pulse sequence comprised of one or more radiofrequency pulses and associated magnetic field gradients. The image itself represents the rate at which the transitions or relaxation times occur. The nature of the acquired MR signal and the image contrast depends on the relative timings of the applied pulse(s), gradients, and signal acquisition in relation to the proton density structure of the tissue(s) being imaged.

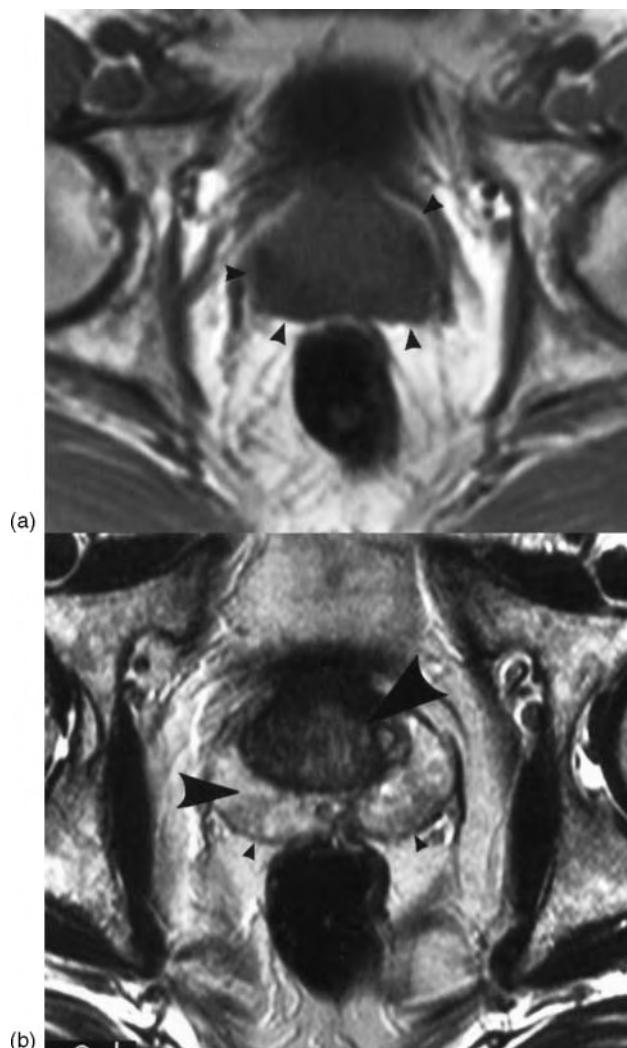

A feature of MRI is that there is no standard, universally applied imaging sequence; there are an infinite set of combinations of possible timings and arrangements of the various imaging sequence components. In practice, sequences are often designed to give images that are weighted according to a particular relaxation time (i.e. T1- or T2-weighted). Even when utilising a particular type of weighting, there is flexibility and variability in the imaging parameters used. Therefore, T1 weighted images acquired on different MR scanners are often obtained using slightly different values of the echo (TE) and repetition (TR) times, resulting in images with subtle differences in contrast. Pixel intensities also vary from measurement to measurement, depending on the instrument design and calibration. MRI has a greater flexibility in varying contrast compared to CT where essentially fixed imaging parameters are used.

The flexibility inherent in MRI can be used, to some extent, to tailor the image contrast to meet clinical requirements. Choice of contrast is then influenced by both clinical considerations and scanner constraints. Some of the clinical factors include the need for varying relaxation times, the administration of appropriate contrast agent, the choice of the optimal imaging plane (i.e. axial, sagittal, coronal, etc.), the scanning volume, and patient tolerance. Other factors that influence image quality include image signal-to-noise and contrast-to-noise ratios, the image resolution, and the scanning time. The acquired MR image is often a compromise between interdependent and mutually exclusive imaging requirements.

### 31.3 RATIONALE FOR THE USE OF MAGNETIC RESONANCE IMAGING IN TREATMENT PLANNING

The main advantage of MR compared to CT is its ability to better demonstrate and characterise tumours and soft tissues.

Contrast between healthy and malignant tissue can be obtained from differences in the T1 and T2 relaxation times exploited by using the appropriate imaging sequences. Imaging sequences can be conveniently characterised in terms of Spin-Echo (SE) or Gradient-Echo (GE) sequences. A common patient scanning protocol involves both T1-weighted spin-echo imaging (short TE and TR) for good anatomical delineation and T2-weighted spin-echo imaging (long TE and TR) to differentiate pathological from normal tissues. An example of this can be seen for the prostate gland (Figure 31.1).

**FIGURE 31.1**

(a) T1 weighted MR image of the prostate. T1 weighted images are useful for highlighting the periprostatic tissues that lie between the prostatic capsule and the puborectalis muscle (indicated by small arrows). (b) T2 weighted MR image of the prostate. T2 weighted images show the internal prostatic structure better with the central zone appearing dark (indicated by large arrows on right side) and the peripheral zone appearing brighter (medium arrow on left side). The prostatic capsule is also easily visualised (small black arrow heads inferiorly).

Anatomical regions surrounded by thick bone will absorb x-rays from CT, reducing soft tissue image quality, producing artefacts, and decreasing the visualisation of nearby tumours. This effect is absent with MR because cortical bone does not provide an MR signal and appears as a dark area. Tumours within the posterior fossa or brainstem and tumours centred at bony prominences or enclosures such as the spinal cord are better defined.

The use of MR contrast agents such as Gadopentetate dimeglumine (Gd-DTPA) may further enhance visualisation of the tumour or disease process under investigation. MR has been shown to be superior to CT in the staging of soft tissue (Herrlin et al. 1990) and pelvic tumours (Hricak 1991), and it is sensitive in detecting and defining the extent of bone marrow disease (Kattapuram et al. 1990). It is the imaging modality of choice for brain, spinal cord, and some head and neck tumours (De Vries and Bydder 1988; Sze 1988).

Detailed MR images can be acquired in any orthogonal or non-orthogonal plane without loss of spatial resolution. This multiplanar capability provides greater functionality for 3D treatment planning compared to CT. Furthermore, 3D volumetric data sets can be obtained, avoiding the need for separate axial, sagittal, and coronal plane acquisitions. Recent developments have produced faster imaging and real time applications. MRI in cine mode display can provide beam's-eye-view capability (Ogino et al. 1993) and may be used to assess organ motion (Padhani et al. 1999). These developments may allow the development of *virtual* or *real-time* MR treatment simulation (Mizokawi et al. 1996).

By combining the high resolution anatomical information from MR with functional information available from positron emission tomography (PET) and single photon emission computed tomography (SPECT), a clinically useful structure-function map can be produced. This procedure has been used in glioma radiotherapy (Pardo et al. 1994) and applied with radiolabeled monoclonal antibodies or radioimmunotherapy to evaluate the 3D dosimetry of the target to surrounding normal tissue absorbed-dose ratios (Sgouros et al. 1993).

MR can also provide physiological and biochemical tumour information. MR angiography can assess cerebral vasculature, providing a non-invasive method to plan stereotactic radiotherapy for cerebral vascular malformations and angiomas. MR spectroscopy can non-invasively measure the behaviour of a range of clinically significant biochemical compounds and may offer new methods to study morphological alterations and physiological and metabolic changes non-invasively within tumours during and post-treatment (Leach 1994). This may allow individual modification of radiation dose or prompt alternative treatments for non-responders. MRI provides a much wider range of applications not only for treatment planning but also for cancer management. CT is limited in these aspects, showing only anatomical images with contrast based solely on differences in intrinsic or contrast agent generated x-ray attenuation. Differences between CT and MRI are listed in [Table 31.1](#).

---

## 31.4 PROBLEMS WITH THE USE OF MAGNETIC RESONANCE IMAGING IN TREATMENT PLANNING

Although the imaging quality and versatility of MR is ideal for acquiring the necessary information for treatment planning, MR has not yet seriously challenged CT for treatment planning in most sites for the reasons described in the following sections.

### 31.4.1 ELECTRON DENSITY INFORMATION

Whereas CT depends on x-ray attenuation by tissues, which is a function of atomic number and electron density, relative pixel intensities in MR images are a function of proton densities and tissue relaxation times. For CT data, electron density can be automatically derived from Hounsfield units, but MR signal intensity has no such correlation. For dose calculations, MR images will either need to have absorption coefficients assigned to the relevant anatomical

**TABLE 31.1**

General Comparisons between Magnetic Resonance Imaging (MRI) and Conventional CT Imaging

Subject	Parameters	MRI	CT
Patient	Magnetic safety concerns	Present	Nil
	Radiofrequency heat deposition	Present	Nil
	Ionizing radiation dose	Nil	Present
	Claustrophobia in scan tube	More marked	Minimal
	Scanning noise	Moderate	Minimal
	Contrast materials allergy:		
	Iodinated contrast	Not applicable	Present
	Gd DTPA (gadolinium)	Minimal	Not applicable
	Soft tissue contrast	Excellent	Moderate
	Cortical bone contrast	Poor	Excellent
Characteristics	Detection of calcifications	Poor	Excellent
	Metallic artefacts:		
	Non-ferromagnetic material	Some	Marked
	Ferromagnetic material	Marked	Marked
Machine	Size of tunnel aperture	Smaller	Larger
	Image resolution	Good	Better
	Scanning time	Moderate <sup>a</sup>	Short <sup>a</sup>
	Electron density information	Nil	Present
	Functionality and technical sequences	Large	Limited
	Geometrical image accuracy	Distortion present <sup>b</sup>	Excellent
	Multiplanar imaging	Any plane	Limited
	Multiplanar reconstructions	Available	Available
	Cost	Higher	Lower
	Availability	Restricted	Widely available

<sup>a</sup> Scanning times are dependent on the imaging volume, number of slices, and for MRI on the pulse sequences used.<sup>b</sup> Object, sequence and machine dependent.

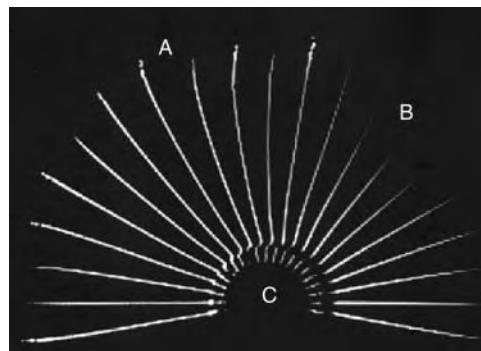

structures and regions or to register the MR and CT images so that the superior tumour definition of MR can be transferred to the CT data for planning.

### 31.4.2 IMAGING OF BONE

Cortical bone in MRI is shown as regions of very low signal intensity. The presence, type (compact bone vs. spongy bone), shape, and extent of bone are important in assessing bone and tissue or bone and air inhomogeneities for dose calculations. Bony boundaries and landmarks are not clearly visible on Magnetic Resonance images, which can limit image registration (see [Section 31.6.2](#)).

### 31.4.3 MAGNETIC RESONANCE IMAGE DISTORTION

A highly uniform magnetic field with perfectly linear orthogonal gradients is desired for MRI. However, inhomogeneities of the main magnetic field and non-linearities in the gradients together with the presence of objects within the magnet field will cause both geometric and signal intensity distortion in clinical practice. The presence of any imaging distortion presents a major hindrance to the utilisation of MR images for treatment planning as it will provide inaccurate spatial information and preclude accurate image correlation. In contrast, CT data are spatially accurate and can be used directly in treatment planning systems without the need for correction. Sources of MR image distortion can be conveniently

**FIGURE 31.2**

Various forms of MR-related distortion can be seen in this image of a coplanar array of water-filled tubes supported within a circular solid plastic block. System-related distortion effects are seen in the apparent curvature of the tubes at A and their disappearance at B that was due to warping distortion of the imaging plane.

considered as system-related distortions and object-induced (i.e. patient-dependent) effects, Figure 31.2. Magnetic susceptibility differences because of the presence of the plastic support block at C give rise to object-induced distortions in the form of discontinuities at the point where each tube enters the support block. The resultant displacements have occurred along the readout (horizontal) direction.

#### 31.4.3.1 System-Related Distortions

System-related image distortions arise because of inhomogeneities in the main magnetic field, non-linearity of magnetic field gradients, and the presence of eddy-current effects. All magnetic fields possess inhomogeneities that result from imperfections in the magnet windings or stray external magnetic fields and that cause image-slice distortion and in-plane distortions in the read-out gradient direction. For a given magnet inhomogeneity, the magnitude of the resulting image distortion is inversely proportional to the gradient strength. The homogeneity of the static magnetic field ( $B_0$ ) decreases with increasing distance from the centre of the magnet bore; therefore, the degree of distortion increases for larger fields-of-view.

MR images can also be distorted by non-linearities in the applied gradients and by the presence of eddy currents that cause both slice and in-plane distortion in both the read-out and phase-encoding directions. Eddy currents arise when the applied gradients are turned on or off, resulting in the presence of transient magnetic fields that contribute to image distortion. Newer MR scanners utilise shielded and compensated gradients to reduce eddy currents. In practice, these distortions remain constant if the imaging sequence and its parameters (TE, TR, etc.) are unchanged. Therefore, eddy current-induced distortions may be quantified and corrected provided the same imaging sequence is used for mapping distortions and imaging patients.

For brain imaging with head coils or similar fields-of-view (i.e. between 10 cm and 15 cm in each direction), investigators have reported distortion errors of 3 mm to 4 mm at the periphery and less than 1 mm at the centre of the image; these images were considered satisfactory for planning purposes (Schad et al. 1987a; Pötter et al. 1992; Hill et al. 1994). With larger fields-of-view between 20 cm and 40 cm, phantom studies have revealed point displacements of up to 10 mm or 16 mm, respectively at the edge of the image (Kokoves 1991; Finnigan et al. 1997). Uncorrected images with distortions of this magnitude cannot be used for the generation of accurate patient outlines in treatment

planning. The system-related distortions are strongly dependent on the design of the MR system. They are also influenced by the imaging sequence, the size of the gradients employed, and the position within the field-of-view.

### 31.4.3.2 Object-Induced Distortions

Object-induced distortions principally arise from magnetic susceptibility and chemical shift effects. The magnetic susceptibility effect occurs because any object placed within a magnetic field changes the value of that field. This distortion is particularly marked at boundaries of structures having different intrinsic magnetic susceptibilities, and it tends to be most pronounced at air and tissue boundaries, for example, near the outline of the head and at internal cavities such as the sinuses. These effects can be complex as they depend on the orientation of the boundary to the main magnetic field and can influence the value of the field at substantial distances from the susceptibility interface.

Another major source of object-induced distortion is the chemical shift effect caused by the different resonance frequencies of protons in fat and water that results in an apparent positional shift of fatty tissues relative to water-based tissue along the read-out gradient direction. Chemical shift effects are more noticeable in the abdomen and pelvis because of the extensive presence of fatty tissues. They have also been documented in head and neck regions (Tien et al. 1991; Sakurai et al. 1992) but may not be as obvious for MR images of the central nervous system because of the relatively limited presence of fat.

The functional dependence of susceptibility and chemical shift effects is similar to that for main field inhomogeneities in that the resultant distortions are inversely proportional to gradient strength. Phantom studies of susceptibility effects at Royal Marsden Hospital have demonstrated shifts of the fiducial markers in the read-out gradient by between 2 mm and 3 mm with respect to the phantom (Finnigan et al. 1997). When the same markers were imaged on the pelvic skin surface of patients, the apparent shift had increased to 5 mm. This additional shift was attributed to the contribution of chemical shift from subcutaneous fatty tissues and correlated well with the expected chemical shift of 3.2 ppm (i.e. Hz/MHz) for fat.

### 31.4.3.3 Magnetic Resonance Correction of Image Distortion

The effect of MR distortions needs to be considered prior to utilising MR images for treatment planning. At the Royal Marsden Hospital, a protocol has been developed to correct for MR-related distortions (Finnigan et al. 1997; Tanner et al. 2000). Furthermore, this protocol incorporates measures to maintain the quality, accuracy, and safety of the imaging and correction procedures. System-related distortions may be corrected using dedicated MR phantoms of known geometry (Tanner et al. 2000). Studies using these phantoms have provided comprehensive maps of system distortions in three orthogonal planes, and by applying these measurements, observed distortions of up to 9 mm may be reduced to 1 mm or less (Finnigan et al. 1997). However, object- or patient-induced distortions cannot be corrected simply by phantom measurements. A procedure based on gradient reversals has been shown to be effective in correcting for object-induced distortions that include effects caused by the chemical shift (Finnigan et al. 1997). This correction procedure requires acquisition of one additional image for each slice acquired, and although this increases the overall patient scanning time, such correction is needed for accurate definition of target volumes, image correlation, and data registration for treatment planning. This distortion correction methodology has been further refined to improve the correction process for larger MR images that may allow imaging at extra-cranial sites and larger fields-of-view to be used (Doran et al. 2005; Reinsberg et al. 2005).

## 31.5 OTHER CONSIDERATIONS AFFECTING UTILISATION OF MAGNETIC RESONANCE IMAGING FOR TREATMENT PLANNING

### 31.5.1 GENERAL CONSIDERATIONS

MRI using closed MR systems that resemble narrow tunnels can be a formidable procedure for patients because of the noise and enclosed space of the magnet bore. Current generation closed MR systems have now been designed with flanged openings at either end of the magnet to create a better sense of space for the patient if he or she can be positioned toward the end of the magnet bore. Newer, open, C-shaped MRI systems may overcome the patient's claustrophobia to some extent, but are not as widely available as closed MRI systems. Alternatively, patient sedation may be provided, or it is possible to accompany and reassure the patient during MRI as ionising radiation is not used.

A small proportion of patients will be unsuitable for MRI by virtue of:

- Claustrophobia
- Presence of a cardiac pacemaker
- Previous history of metallic particle eye injury.

The latter two scenarios are excluded by careful screening with a questionnaire prior to patients entering the room housing the scanner. If doubt does exist regarding metallic foreign bodies in the eyes, plain radiographs of the orbits can help exclude the possibility of a very small ferro-magnetic object within the eye.

The reason for not allowing patients with ferro-magnetic objects close to critical structures to be scanned is that these objects may be moved by strong magnetic fields. External objects such as hair clips, scissors, and the like must also be excluded because of the potential danger from impact injuries as well as the introduction of distortions secondary to these objects within the system.

The MR scanning table must reproduce the flat bed design of the radiotherapy simulator and treatment couch. Any immobilisation device used in planning needs to be assessed for its magnetic safety as well as being able to fit into the patient tunnel and not interfere with the MR examination coils. Where this is not practical, e.g. for patients in stereotactic head frames, MR scans can be registered to planning CT scans.

### 31.5.2 MOTION

Any patient or organ motion will give rise to image blurring and artefacts, potentially masking pathology. Prolonged scan times will increase the potential for both patient and internal organ movement. Physiological movements such as cardiac and respiratory movements have a greater effect on the imaging of the thorax, abdomen, and pelvis compared to the limbs or the brain. Blood vessel motion can be significant and can result in severe artefacts that propagate through the images. Blood flow and motion of abdominal fat because of respiration can result in *phase mismapping* during data acquisition. This mismapping will give rise to image ghosting on image reconstruction (White et al. 1992). Peristaltic bowel movements and rectal and bladder filling are more subtle but can still alter the position of the target volumes within the pelvis during imaging.

Diagnostic methods exist to compensate for the problems of motion. However, it remains to be seen if these compensatory methods such as ECG gating, blood flow

compensation techniques, presaturation methods, and respiratory gating methods will be applicable for treatment planning. Some methods such as respiratory gating have been less successful because the imaging times have substantially increased (Wood 1988). Techniques such as scan averaging and breath-holding imaging, using fast *turbo* sequences for example, considerably reduce artefacts because of respiration (Miowitz et al. 1990; Flentje et al. 1993). Anti-muscarinic agents such as hyoscine butylbromide can be used to decrease gastrointestinal motility. Ultra-fast MR sequences such as Magnetisation Prepared Rapid Acquisition Gradient Echo (MP-RAGE), fast Spin-Echo, and Echo Planar Imaging (EPI) have much shorter scanning times and may produce acceptable image quality. Echo planar images have been obtained in under 100 ms, effectively freezing some physiological motion (Edelman et al. 1994). The possible distortion effects associated with these newer sequences need to be assessed before use.

---

## 31.6 METHODS TO ALLOW THE USE OF MAGNETIC RESONANCE IMAGING IN TREATMENT PLANNING

The lack of electron density information and the presence of MR distortion have meant that image processing methods must be employed if MRI is to be utilised for treatment planning. Once MR distortion and radiofrequency non-uniformity effects have been quantified and corrected, image segmentation and image registration or correlation techniques can be used to overcome the lack of electron density data from MR images. These procedures are not mutually exclusive as segmentation methods can be used to preprocess data for multimodality image registration. These concepts will only be briefly outlined.

### 31.6.1 IMAGE SEGMENTATION

One method of performing dose calculations on MR images is to segment the relevant tissues in order to assign the appropriate attenuation factors to these tissues. Manual segmentation methods are labour-intensive and time-consuming. Fully automatic segmentation methods can be more efficient, but the segmentation process needs to be accurate. Often these algorithms do not have adequate intelligence to distinguish reliably between subtle differences in soft tissue structures. Semi-supervised automatic methods are needed to ensure quality control for these procedures. A review of the many segmentation methods is not within the scope of this chapter, and further information may be obtained for instance from the review by Clarke et al. (1995).

In general, parameters such as MR pixel intensities can be used to threshold regions of interest and to define other features such as the edges and texture of anatomical organs to augment the segmentation process. However, there can be difficulty in determining the maximum contrast difference for the different soft tissues in order to select the optimum threshold for segmentation. Furthermore, non-uniformities of the radiofrequency field can vary the pixel intensities of a given tissue type within different regions of the same MR image, reducing the effectiveness of automatic pixel-based techniques. These issues may often require substantial operator input to provide reliable segmentation and may also result in both inter- and intra-observer variations. Attention needs to be paid to the increased noise associated with the use of faster modern MRI sequences that may result in reduced image quality and an increase in the variability of image grey scale shading that may result from radiofrequency non-uniformities and patient-induced distortion effects. MR segmentation methods appear to be successful for normal brain images (Clarke et al. 1993). The greater soft tissue contrast obtainable with MRI for regions such as the abdomen and pelvis may permit more reliable segmentation compared to CT (Khoo et al. 1999) as segmentation in

these anatomical regions remains time-consuming (Neal et al. 1994). Segmentation algorithms for MRI need to minimise the level of experienced operator supervision and provide reliable accurate results before they can be adopted as standard procedure.

### 31.6.2 IMAGE REGISTRATION

The registration of MR images with CT images allows the use of CT-calculated isodose contours with the superior tumour definition of MR for improved treatment planning. Manual registration methods are time consuming and require a high level of skill and regular practice. Automated approaches may allow more efficient registration, but without the developed skill, errors in automatic registration may go unnoticed.

Simple 2D registration procedures include the use of a projection system with an appropriate magnification that allows MR images to be superimposed over simulation films or isodose plans. Bony landmarks such as vertebrae and pelvic bones are used as correlation points. Registration methods in 3D are more complex, and a multitude of parameters need to be considered in the matching procedure such as the reproducibility of the patient position, the angle of the imaging plane, the image contrast and resolution, and the volume of the image set, including the width and gap distance of each slice. Registration techniques may be applied either prospectively or retrospectively, and they may include point or line matching, iterative matching, principal axes, and surface matching. A review of current techniques has been published by van den Elsen et al. (1993).

There are a number of algorithms for 3D image registration, but generally, they fall into one of several categories:

- In *surface matching* (e.g. Levin et al. 1988), one or more 3D contours are outlined (e.g. the external contour and specific anatomical structures that are well visualised on the two image sets) and then brought together in 3D space until the best mathematical match is made. The acquisition of contiguous and narrow CT images ensures good spatial definition and optimises outcome. However, the boundaries of structures may not be identical in MR and CT and there is likely to be more distortion of the external contour in the MR image.
- In *point matching* (e.g. Hill et al. 1991), a number of (usually at least five) 3D anatomical reference points are nominated on each of the two image sets. These points are preferably easily identified, small, and immobile, e.g. bony landmarks. The more points nominated, the more accurate the final match of the images is likely to be. An alternative is to use external fiducial markers applied to the patient for each of the imaging sessions. Although it is easier to use a large number of points with this method compared with internal landmarks (which can be surprisingly difficult to identify), reproducibility of marker position between different imaging sessions on different days presents a challenge. Ideally the CT and MR should be carried out on the same day without removing the markers. If this is not possible, the marker positions must be documented with photographs, diagrams, and measurements of their position relative to reproducible anatomical landmarks. It is important that the points used for registration are well-separated in 3D, and it is advisable that when using external fiducials, some internal points are used as well. A well-designed registration algorithm will provide information on the mean and individual point errors so that the operator can concentrate on those points with the greatest uncertainty. The problems associated with external fiducial markers are eliminated for brain imaging by using a stereotactic frame (see [Section 45.5](#)) that is firmly and reproducibly located on the patient's head although this may restrict the MR coils that can be used. The frame is usually fixed by surgical pins that ensure that it does not move relative to the skull, but relocatable frames have been devised for treatment planning (Kooy et al. 1994).
- *Mutual-information-based registration* (e.g. Studholme et al. 1999) of several image series is becoming more frequently used. It is a completely automated process that makes use of the internal 3D distribution of the information (i.e. grey levels) within MR and CT images, respectively.

For a more detailed description of the various methodologies and issues, the reader is referred to Kessler et al. (1991). Whatever method is used, it is important that a careful visual check is carried out once the registration is complete to verify that it has been satisfactorily performed. For this purpose, it is useful to have access to specific tools designed for accurate comparison of several image sets. A moving window that allows one modality to be viewed on top of the other is a useful example.

Image registration does have limitations:

- It is time consuming.
- Patient positioning can be difficult to reproduce during acquisition of different types of image at different scanning sessions. For example, the degree of neck flexion can be very different for CT compared to MR and may present difficulties in registering images of the head and neck region when the body surfaces are used for matching the images to each other.
- There may be a problem with reproducibility of the position of different internal organs to each other between imaging sessions. This is a particular problem with the prostate, which may shift position, depending on differential filling of the bladder and rectum (see below). This may compromise the position of internal reference points.
- External fiducial markers (if used) must be large enough to be visualised but small enough to give a precise 3D reference point.
- An adequate number of common points must be identified to provide the registration algorithm with enough spatial information to perform an accurate geometric match between image sets. This can be difficult when internal anatomical reference points are used, as insufficient points may be identifiable as being common to the two sets of imaging data. Differences in slice orientation between CT and MR data sets can make it difficult to identify consistent internal reference points.

Assuming MR distortions have been corrected, brain registration methods have reported a mean correlative value of between 1 mm and 3 mm for CT–MR matching (Schad et al. 1987b; Pelizzari et al. 1989; Hill et al. 1994; Van Herk and Kooy 1994; Veninga et al. 2004). More difficulty can be expected for imaging of the thorax, abdomen, and pelvis where movement and distortion effects are greater.

---

## 31.7 CLINICAL SITES OF MAGNETIC RESONANCE IMAGING APPLICATIONS IN TREATMENT PLANNING

Magnetic resonance imaging has been extensively used for the brain, and it is the modality of choice for this site. Intracranial movement is minimal, the skull can be rigidly immobilised, and the head is easily imaged in the centre of the magnetic field; therefore, MR distortions are generally smaller compared to larger body regions. These factors coupled with effective head registration methods have allowed easier integration of MR and CT for treatment planning. MRI has been shown to improve target volume definition in between 62% and 82% of CT-based brain treatment plans (Pötter et al. 1992; Gademann et al. 1993; Heester et al. 1993) as well as providing complementary information not visualised by CT imaging (Khoo et al. 2000). MRI has been used alone for treatment planning by assuming a homogenous attenuation value inside the brain with an error of less than 2 percent compared to CT-based dosimetry (Schad et al. 1994). Co-registered MR and CT images have also been used for brain brachytherapy planning to reconstruct catheter or radioisotope seed arrays in 3D to enable calculation of the dose distribution (Hardy et al. 1992). High resolution 3D vascular and neuro-anatomical information for stereotactic radiotherapy of cerebral arterio-venous malformations can be obtained using flow compensated gradient echo and fast 3D MR sequences. This avoids the invasiveness of angiography and allows frequent follow-up scans to assess the occlusion of the treated feeding blood vessels (Ehricke and Schad 1992).

MR has provided improved delineation of target volumes for radiotherapy of nasopharyngeal and head and neck cancers (Curren et al. 1986; Kovacs et al. 1992). Fast breath-held MR sequences and coronal MR angiography techniques have provided similar improvements in supradiaphragmatic lymphoma treatment planning with better localisation and avoidance of partial volume imaging effects (Müller-Schimpfle et al. 1992). MRI has also been shown to provide improved definition of target volumes in prostate radiotherapy, especially in the localisation of the prostatic apex, compared to CT (Kagawa et al. 1997; Khoo et al. 1999). For further radiotherapy applications of MR, the reader is referred to reviews by Khoo et al. (1997) or Khoo and Joon (2006).

---

## 31.8 CONCLUSIONS

Magnetic resonance imaging has considerable potential for treatment planning. The superior soft tissue contrast provided by MR and the ability to vary contrast by manipulation of the imaging parameters facilitate optimal tumour evaluation. Together with its 3D multi-planar imaging capability, MR can provide advantages over reconstructed CT images. Used in conjunction with CT, MRI can provide both complementary and supplementary information for the localisation and characterisation of tumours and surrounding normal tissues.

MR distortions can be geometrically corrected to provide accurate spatial information. For distortion correction, it is important that both patient images and distortion data are acquired using the same set of imaging conditions since MR distortion is strongly influenced by the parameters of the imaging sequence.

The appropriate MRI parameters for optimum tumour visualisation and treatment planning need to be identified, and faster MR sequences will reduce the effect of motion artefacts. Non-operator dependent segmentation and image registration methods that are accurate and reliable are required so that MR can be either used alone or integrated with CT for dose calculations. Although the full potential of MR in treatment planning remains to be realised, these methods will greatly enhance the utilisation and integration of MR applications in treatment planning.

## 32.1 INTRODUCTION

The Planning Target Volume (PTV, see [Section 29.2](#)) must receive a dose large enough to reach the therapeutic goal. Therefore, it must be covered by the beams that are used for treating that volume. For skin tumours, the beam definition is straightforward; only one beam is used, and the beam shape directly reflects the tumour lesion plus a margin. Treating tumours not visible from the exterior of the patient requires the use of x-ray equipment or other medical

imaging devices to define the location of the PTV (see [Section 30.3](#)). Treatment simulators (see [Chapter 13](#)) provide a diagnostic x-ray tube mounted in the same isocentric geometry as a treatment machine. Using a simulator, the bony anatomy is easy to identify and beam definition can be made relative to that. However, to obtain a precise match between the field shape and the shape of the PTV, a projection of the PTV (together with an appropriate margin) onto a plane perpendicular to the beam direction is required. This may be achieved in one of three ways.

- The PTV and its margin may be implicitly estimated or explicitly drawn on radiographic images taken from the appropriate beam direction on the simulator. This is referred to as the *anatomical* approach.
- Planning may be based on a few transverse cross sections where the desired PTV is marked. The information about the position of the PTV may be derived from a number of sources (including planar radiographs). This is referred to as the *traditional* approach.
- Simulation may be performed on the computer using a full 3D data set usually from a CT scanner. The positioning of the beams is carried out on a computer simulation of the patient, and this is referred to as *virtual simulation*.

In the following discussion, these three methods of simulation will be covered.

---

## 32.2 BEAM DEFINITION USING ANATOMICAL SET-UP

### 32.2.1 DIRECT SIMULATION OF THE BEAM ARRANGEMENT

In cases where the precise shape of the PTV is not considered, the beam arrangement will be decided according to the diagnostic information that exists. This may be in the form of x-rays (possibly with contrast), CT scans, radionuclide imaging, ultrasound, MR scans, and possibly biological tests to determine the stage of the disease. The beam geometry is then defined during simulation on the basis of the anatomy that is identified using the fluoroscopic image.

A number of points need to be considered during simulation:

- Beam modality
- Beam energy
- Beam direction
- Beam divergence or the arrangements to avoid or compensate for beam divergence at one beam edge
- Beam shape or lead shielding

Some of these may have been decided prior to simulation, either on the basis of the specific patient or on the basis of protocols for the given tumour site.

In most radiotherapy departments, the available beam modalities are photons and electrons. Electron planning will be discussed in [Chapter 34](#). In most departments, photons are available with different energies ranging from 4 MV up to about 20 MV. The choice of energy is dependent on patient separation (i.e. the distance between the beam entry and exit points) and the depth of tumour. If the skin or superficial tissue less than 0.5 cm deep is part of the target, bolus may be used to increase the dose to this region. The preferred energy range for targets close to and involving the skin is 4 MV to 6 MV. If, however, the target is deeply situated, higher energies offer better dose distributions. In some cases, a combination of, e.g. 20 MV and 6 MV will yield the best plan. Beam direction, shape, and blocking are site specific and will be briefly discussed for a limited number of sites in [Section 32.2.2](#).

Finally, at simulation, all physical parameters required to calculate the dose need to be acquired. The field size and any associated shielding will be decided. It is also necessary to define the dose prescription point and any additional dose calculation points. For each of these, it is necessary to establish the depth and patient separation and the source to skin distances (SSD) for each beam. Some of these parameters may be indirectly acquired by taking a patient outline on which the beam axes are indicated. From the outline, the SSD and depth to the point of interest can be measured.

Outlines can be obtained in a number of ways, e.g. an outline may be manually acquired using the SSD indicator and polar graph paper, by using a pantograph, or with one of a number of commercial optical outlining devices. At least one outline should be taken in a transverse plane through the centre of the treated area. Further outlines are recommended if there is a significant change in the patient shape within the treatment area.

Optical devices generally make use of laser projections on the patient skin. The images are acquired by two (or more) fixed cameras (Wilks 1993) or by a single camera mounted on the simulator gantry and operated at different gantry angles. These images are converted into outlines that may be scaled and printed, or exported to a treatment planning computer. Because of patient curvature, several images from different angles need to be acquired and merged to obtain a surface outline. Further parallel outlines may be obtained by moving the couch. Satisfactory outlines of the patient's anterior surface, which is visible by the camera, can be obtained in this way. However, the delineation of the posterior surface of the patient is inaccurate because it is not visible by the camera, and it is often approximated by a straight line. Therefore, care must be taken if beams are to enter the patient from posterior angles. Measurements of the patient separation can be taken using callipers to check points on the contour. Systems for measuring surface shapes lack information on internal structures. One exception is the system described by Wilks (1993) that uses an algorithm to draw lungs on breast contours by using the depth of the lung seen on the radiograph of the simulated field. Alternatively systems can be based on stereo-video acquisition of light patterns projected on the patient skin (Bert et al. 2005).

If one has access to a simulator equipped with a CT option (see Chapter 13), the external outlines as well as the outlines of internal structures can be directly extracted from CT images transferred to the treatment planning computer.

### 32.2.2 SPECIFIC EXAMPLES OF ANATOMICAL SET-UP

Anatomical set-ups should be restricted to cases where it is considered acceptable to define the PTV on the basis of general diagnostic information without strict delineation of this volume on a series of axial slices. It must also be realised that such an approach is possible only if the beam arrangement is simple enough to be able to anticipate what the dose distribution will look like. Some typical examples are listed below. For a more comprehensive overview of radiotherapy treatment set-ups, see, for instance, Dobbs et al. (1999).

#### 32.2.2.1 *Parallel Opposed Simple Fields*

A pair of parallel opposed fields with relatively simple shapes is frequently used, e.g. for palliative treatment of vertebral or brain metastases. In such cases, the field area will be defined at simulation according to bony landmarks. In some cases, contrast will be used to indicate the location of organs such as the bladder or rectum more clearly. For the location of the vagina, a radio-opaque tampon can be used.

#### 32.2.2.2 *Mantle Fields*

It has been the practice to treat Hodgkins and non-Hodgkins lymphoma with large anterior and posterior fields covering the whole chest and neck. Because the aim is to treat the tumour and lymphatic drainage while avoiding critical structures such as the lung and heart,

these fields need carefully designed shaping. Knowledge of the pre-chemotherapy extent of the solid tumour (generally in the form of a diagnostic CT scan of the patient) and information on the position of the lymph nodes (for which an anatomical atlas may be helpful) will enable the shielding to be determined. The field size required could be larger than the maximum size available on the linear accelerator at the standard SSD, so these treatments can be planned at an extended SSD that is typically between 120 cm and 140 cm. Extending the SSD has the added advantage of reducing the size and weight of the lung blocks. However, it requires that, for the posterior field, the table can be elevated to a distance of between 20 cm and 40 cm above the isocentre and this is not always possible. It also requires that the table top has an opening large enough to let the beam through or is made of a material, such as carbon fibre, that attenuates the beam minimally. If the required field length cannot be achieved with the gantry beneath the couch, it will be necessary to treat the patient prone, but this should be avoided if possible, because the relative positions of internal organs differ.

### 32.2.2.3 *Tangential Breast Beams*

To simulate tangential breast treatments, the gantry angle that covers the breast volume while minimising the amount of underlying lung tissue in the fields can be found by real-time fluoroscopic adjustment of the beam position. Lead markers can be placed on the skin at the margin of the palpable breast to facilitate the radiological set-up. The opposing beams should be angled such that their internal beam edges are non-divergent and include a minimal amount of lung. The relative gantry angles can be worked out by fluoroscopy or through trigonometry by using the field width.

For tangential breast beams, it is also advantageous to keep a non-divergent or vertical beam edge at the superior border in order to allow for the addition of an axillary field (even if that is not prescribed as primary treatment). This can be achieved either by using trigonometry to compensate by adjusting the couch angle and the collimator angle of the tangential fields, or one can use half beam blocks (asymmetric diaphragms) provided the field length is not restricted (see [Section 33.9.3](#)).

In most situations, an anatomical set-up does not dispense with the need to confirm the plan by computation of the dose distribution, using the data acquired during the simulation process. Small adjustments of the plan (i.e. beam weights, beam modifiers, shielded area) might be performed without resuming the simulation. However, large changes (i.e. beam directions) could necessitate a repeated simulation.

---

## 32.3 COMPUTER-BASED BEAM DEFINITION—THE TRADITIONAL APPROACH

Computerised planning based on one or more transverse sections of the patient is recommended when the choice of beam arrangement is too difficult to make an anatomical set-up practical. Beam characteristics will be defined during the dose planning process. In these cases, the simulation process is split into two parts:

- The acquisition of anatomical data (before dose planning)
- The verification simulation of the selected plan (after dose planning).

Information about the position of the tumour and organs at risk (OARs) can be obtained from any of the data acquisition methods that have been explained in [Chapter 30](#) and [Chapter 31](#). From a combination of these data sources, a set of external outlines, reference skin marks, and information on internal structures are obtained.

After transferring these data to the treatment planning system and indicating the limits of the PTV, the beams are graphically defined on transverse sections in order to cover the PTV and to avoid the OARs. Their characteristics (number, energy, incidence, position, field size, etc.) are interactively edited until a satisfactory dose distribution is obtained.

The beam parameters are finally transferred back to the simulator in order to check the plan's feasibility and consistency on the patient before progressing with treatment. At this stage, the beam entry points can be marked on the patient's skin (e.g. tattooed markers) and radiological images taken to serve as a reference.

This traditional approach is appropriate for a plan that makes use of a limited number of cross-sections (e.g. less than 10). When a large series of thin adjacent slices is acquired, a full 3D reconstruction can take place, and the beam definition can be made with the virtual simulation approach.

---

## 32.4 COMPUTER-BASED BEAM DEFINITION—VIRTUAL SIMULATION

### 32.4.1 PRINCIPLE OF VIRTUAL SIMULATION

When a full CT data set is available for a patient in the radiotherapy treatment position, the CT data serves as a 3D anatomical model of the patient. The CT data provides the basic electron density or physical density map that allows correction for tissue heterogeneities to be made in the dose calculation. In 3D planning systems (Goitein et al. 1983; Mohan et al. 1988; Galvin et al. 1995), the CT data can be viewed not only in transaxial (i.e. the original CT slices) but also in sagittal and coronal views. Generally, the sagittal and coronal views show a coarser resolution in the crano-caudal direction; however, they allow a better appreciation of the basic anatomy and the 3D extent of the various anatomical structures.

The target and OARs should, as a minimum, be outlined on all slices. The projections of these outlines are shown on the transverse planes (where they were defined) and on the sagittal and coronal plans, either as contours or as colour wash. In many 3D planning systems, the user can toggle any structures on or off, which can be very helpful, as overlying structures can obscure each other and the underlying greyscale CT data. In addition to the three orthogonal 2D views, it is helpful to have a 3D surface rendered view of the structures outlined. In particular, it is useful to view the 3D volumes from different angles to decide on the beam directions.

The planning process for computer-based set-up is taken away from the simulator and performed at the planning computer. Presently, however, it is still common, as for the traditional approach, to send the patient to the simulator for a plan check, i.e. to get reference images of the planned fields and sometimes to mark the patient up for treatment, limiting the set-up time for the first treatment. In some departments, the simulator is interfaced to the record and verify system of the treatment machine. In this case the set-up parameters (except the monitor units) can be transferred automatically from the simulator to the accelerator. This saves time and reduces the risk of errors incurred by manual data entry (see [Chapter 41](#)). However, the definitive source of beam parameter data is the treatment planning system and it is better to transfer these data, including the monitor units, to the linear accelerator record and verify system. Where there is couch angulation, the simulation also checks for collision risks\* as these are not usually considered in planning systems. Some groups have developed graphical simulation that enables collision situations between the gantry and couch to be

---

\* In principle, ensuring that there will be no collision in the treatment room requires that the geometrical characteristics of the simulator, table, and accessories are the same as for the treatment equipment.

predicted (Kessler et al. 1995; Muthuswamy 1999; Nioutsikou et al. 2003). However, unless the patient anatomy is included in the graphical simulation, it does not allow for the risk of collision between patient and gantry. Assessing the collision risk is less difficult for coplanar beams.

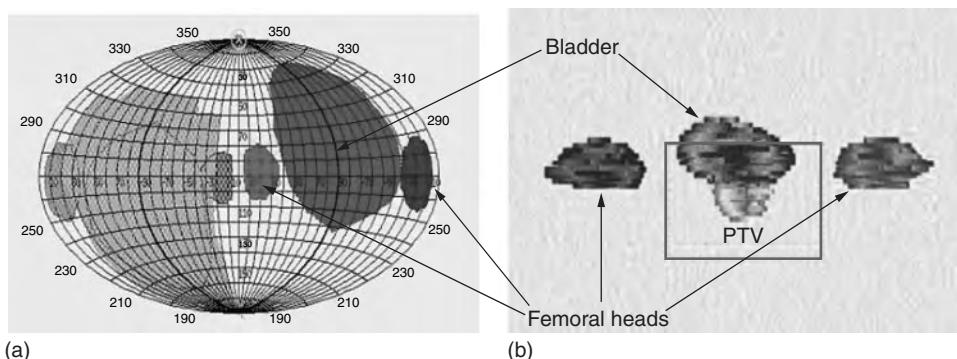

### 32.4.2 BEAM AXIS DIRECTION

In some cases, standard beam angles can be used (e.g. the treatment of prostate tumours with between 3 and 6 coplanar fields), but in others, the incident directions for the beams are selected for individual patients by the treatment planner. The planner needs to find the beam direction that treats the PTV while best avoiding irradiation of the OAR. This may be done through the use of various computer visualisations.

A very useful representation, complementary to the visualisation of the transverse sections as used in the traditional approach, is the *beam's-eye-view* (BEV) (Goitein et al. 1983). It is generated by taking a plane perpendicular to the beam direction and showing the projected PTV and OARs relative to the beam edges (the rectangle on Figure 32.1b). As the beam direction and couch angle are interactively changed, the projections of the structures are shifted with respect to the beam edges until the best compromise between PTV coverage and OAR avoidance is achieved.

Another example of a helpful tool is the *spherical view* (Figure 32.1a). This represents a flattened globe with the geometric centre of the PTV, coincident with the treatment isocentre, at its centre and the OARs projected onto its surface. The colours of the OARs are as in the BEV shown in Figure 32.1b. The grey shaded areas represent forbidden angles for couch (latitude) and gantry (longitude) combinations. Beams with couch and gantry angles that are in the clear regions will not pass through an OAR in order to reach the PTV. The main restriction of the spherical view is that it only shows the projection of the central axis, and this shortcoming is illustrated in Figure 32.1b where part of the beam passes through the (green) bladder even though this is not apparent from the spherical view. The spherical view is not currently implemented in standard commercial planning systems.

Individual centres have developed software which semi-automatically optimises the beam direction and such software is now available in some commercial systems. However, as has been discussed in the literature, such optimisation will always be limited (Rowbottom et al. 1999a, 1999b; Bedford and Webb 2003).

**FIGURE 32.1**  
**(See colour insert following page 590.)** (a) A spherical view produced from Voxelplan. The gantry angle is depicted as meridians and the couch angle as latitudes. (b) The 3D Beam's eye view (BEV) (or Observer's Eye View) of the same patient showing planning target volume (PTV) (lighter region within the field rectangle), bladder (darker central region above PTV), right, and left femoral head. This view is from 0° gantry and 0° couch. The cross at the top of the spherical view (a) indicates the couch and gantry angle for this BEV.

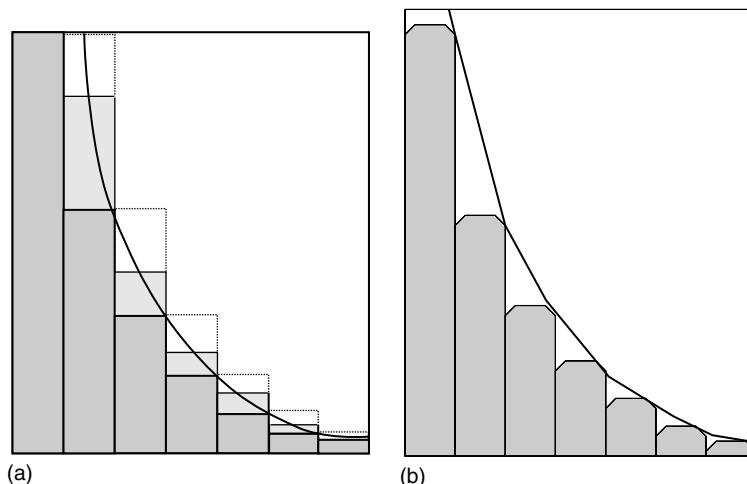

### 32.4.3 FIELD SHAPING

Having determined the incident beam axes, a BEV can be generated, showing the projected extent of the PTV and the OAR in a plane perpendicular to the beam axis. The field shape is then generated from the projection of the PTV by adding a margin to allow for the penumbra of the beam (Brewster et al. 1993). The ideal width of this margin depends on the field size and depth and whether the fields are coplanar or not. In a coplanar situation, the margin will need to be between 4 mm and 6 mm greater in the directions where all the field edges coincide. The shielding can either be a custom-made low-melting-point alloy block (see Section 22.5.3.2), or it can be achieved with a multi-leaf collimator (see Section 32.4.4). A custom-made block conforms to the field shape and is made either by sending the shape from the treatment planning system to a block cutter or having the blocks manually made using a printed template.

### 32.4.4 FITTING MLC LEAVES IN BEAM'S-EYE-VIEWS

Multileaf collimators (MLC) do not produce smoothly rounded isodose distributions as discussed in Section 22.5.4. The geometric projection of the MLC leaves approximately defines the 50% isodose; hence, a margin to account for penumbra (~6mm) must first be applied to the PTV to establish the required field shape. It is this field shape that is fitted by the MLC, using one of several shape fitting algorithms. Generally, treatment planning systems support fitting leaves to the outside, the inside, or to the middle of the MLC leaf (see Figure 32.2a and Section 22.5.4). In practice, the corners of the MLC leaves may be considered to be cut off as shown in Figure 32.2b (Heisig et al. 1994) and this concept provides a good fit to the 50% isodose line.

In practice, the choice of model to use for fitting the MLCs will be restricted by what is available on the planning computer, and, for the sake of consistency, there should be a departmental policy on the margin size and fitting mode for different sites of treatment. How well the MLC conforms to the target shape will also depend on the collimator angle. Most planning systems provide the planner with a graph of either the total volume or the normal tissue volume irradiated plotted against collimator angle. This enables the planner to choose a collimator angle that results in the best fit of the MLCs to the PTV. If, however, a wedge is used, the collimator

**FIGURE 32.2**

Multileaf collimators (MLC) fitting to the field shape. Here, a schematic corner of an elliptical PTV is shown. (a) Solid bold line-shaded dark grey: MLC fitting outside the field shape; light grey shaded: MLC fitting to middle of leaf; Dotted line: fitting to shield all outside of field shape. In (b) the fitting method of Heisig et al. (1994) is shown.

angle and the MLC orientation are determined by the wedge direction. In such cases, the MLC fit may be improved by shifting the isocentre for that beam (Fernandez et al. 1995).

The most usual MLC leaf width is 10 mm at the isocentre. However, standard or micro MLCs have also been designed with smaller leaf widths (see [Section 11.4.3.2](#)). The micro MLCs were originally designed for brain tumour treatment but are also shown to give a closer fit for prostate treatments (Kubo et al. 1999) sparing significantly more bladder and rectum. In all cases the conformity of the dose distribution to the PTV is the principal criterion in determining the optimal positions of the leaves.

### 32.4.5 DIGITALLY RECONSTRUCTED RADIOGRAPHS

Just as anatomical simulation uses fluoroscopic or conventional radiographs, so virtual simulation uses *digitally reconstructed radiographs* (DRRs) to enable treatment fields to be visualised in relation to the patient's anatomy. The advantage of a DRR produced from a therapy CT data set with the patient in the treatment position is that the data used for target localisation are derived from the same data set as that used for verification of the treatment beam direction. This means that the DRR can be used as the reference image so eliminating the simulation process. In addition, the PTV outlines can be directly projected onto the DRR (see [Figure 32.3](#)). However, in order to be useful tools in the clinic, DRRs must be of comparable quality to conventional radiographs. An understanding of how DRRs are produced will enable the physicist to ensure that best use is made of the software used to create and enhance DRRs.

DRRs are generated by summing the radiological thicknesses along each ray line from the virtual source of the beam through the 3D patient model to a point in the plane of the DRR. The geometry used to make the DRRs and the mathematical transformations required are described by Siddon (1981, 1985). The attenuation along the ray lines can be derived from the definition of the Hounsfield Unit (HU), as follows (Killoran et al. 2001):

$$HU = 1000 \frac{\mu - \mu_w}{\mu_w} \quad (32.1)$$

Which can be rearranged in the form:

$$\mu = \mu_w \left( \frac{HU}{1000} + 1 \right) \quad (32.2)$$

where  $\mu$  and  $\mu_w$  are the linear attenuation coefficients of the tissue and water, at the energy used to produce the CT, respectively.

The linear attenuation along a ray line will be the sum of the attenuation in the voxels in the path of the ray line. It is important to note that CT scans are acquired at about twice the energy used for conventional radiographs so that the ratio of the photoelectric effect to the Compton effect is much reduced. Consequently, bone contrast is inherently much lower in DRRs.

Using the relationship of linear attenuation coefficient with energy, it is possible to generate DRRs that resemble simulator images (photoelectric) and megavoltage images (Compton) by recalculating radiological thickness maps according to the beam quality. Modifications can also be made to the mapping between CT scanner Hounsfield Units and relative electron density to emphasise different anatomical features. For more details, see Sherouse et al. 1990; Cheng et al. 1987; Cullip et al. 1993; and Killoran et al. 2001.

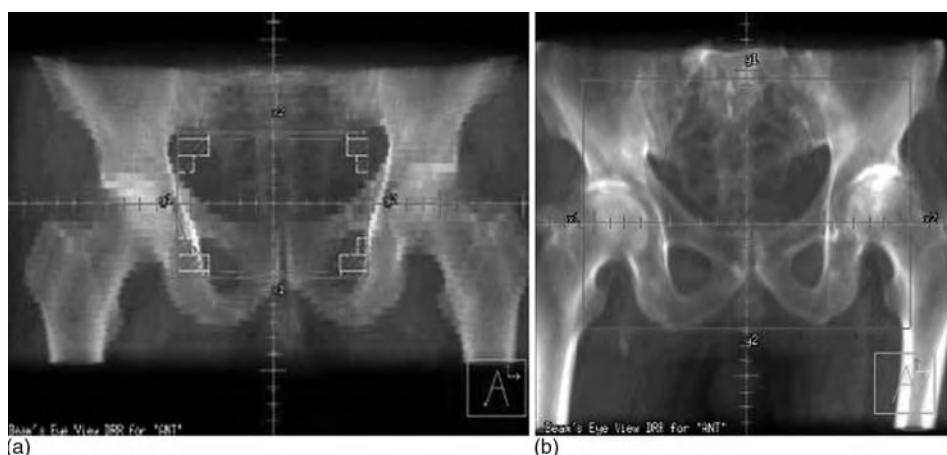

For reference images, the photoelectric effect is most often used as that gives the highest contrast and best visualisation of bony landmarks. It is debatable if Compton images are of any

use as treatment verification becomes a comparison of two low contrast images (Killoran et al. 2001). Radiological thickness maps contain the information required to make dose compensators (see [Section 22.6.3](#)) in situations where fields are opposed (e.g. tangential breast treatments).

DRR quality is influenced by a number of factors, related to both data acquisition and reconstruction algorithms.

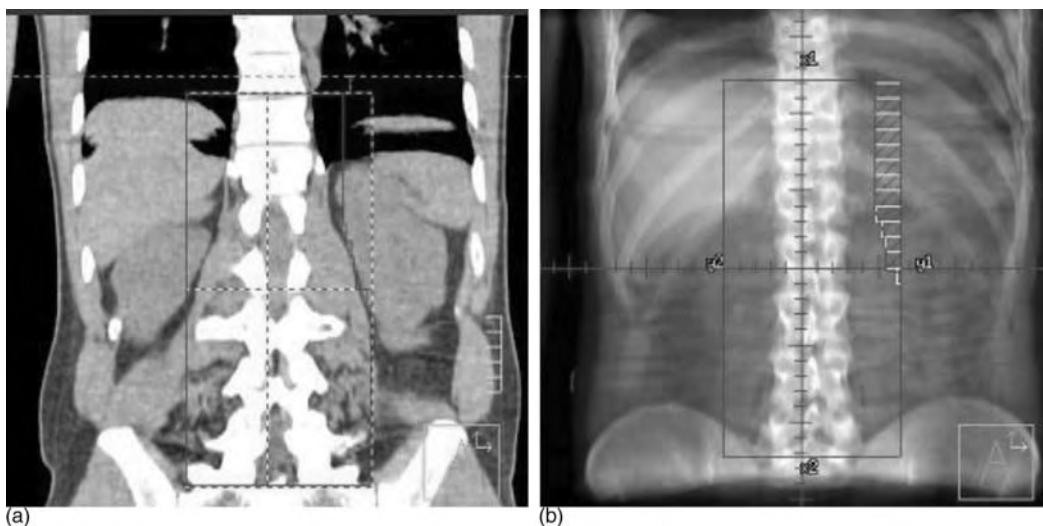

- *The separation of the CT slices.* This determines the resolution in the longitudinal plane and provides an objective limit to DRR quality. Slice separations of 10 mm will result in poor DRRs. Images that are suitable for verification in the pelvic region can be produced with 5 mm slice separations (see Figure 32.3a) although a smaller separation gives a better image (see Figure 32.3b). In the chest, head, and neck region, a separation of 2 mm to 3 mm is always recommended (Dong et al. 1995; Gilhuijs et al. 1996). It is also important that the CT data set extends to the whole treatment area, which can be some distance beyond the tumour especially if non-coplanar beam arrangements are used.
- *The ray tracing mode.* This refers to the way the summation is performed. It either uses the nearest CT pixel only for a fast reconstruction, interpolates between the CT pixels of adjacent slices, or uses a full interpolation of all eight nearest pixels.
- *The step size.* This is the size of the increment used when summing up the DRR.
- *The number of pixels.* This is the number (rows  $\times$  columns) that is in the output DRR.
- *The magnification of the DRR.* If print-outs are requested, DRRs will need to be rescaled to be the same size as the simulator verification image or the portal image. However, this increases the pixel size and reduces the spatial resolution.
- *The manipulation of the relative contrast of the structures in the DRR.* It is possible to enhance DRRs by selectively altering the visibility of different structures according to their relative densities. It is also possible to generate a DRR based exclusively on the voxels encountered within a given depth range and therefore to reinforce the contrast of the structures lying within this range. Several planning computers incorporate these features which, in principle, enable for instance airways and bones to be simultaneously enhanced, something which is impossible with conventional radiographs.

With the increased number of CT scanners available in radiotherapy departments, the use of CT scans for simple treatments such as parallel pairs is increasing as CT based planning offers

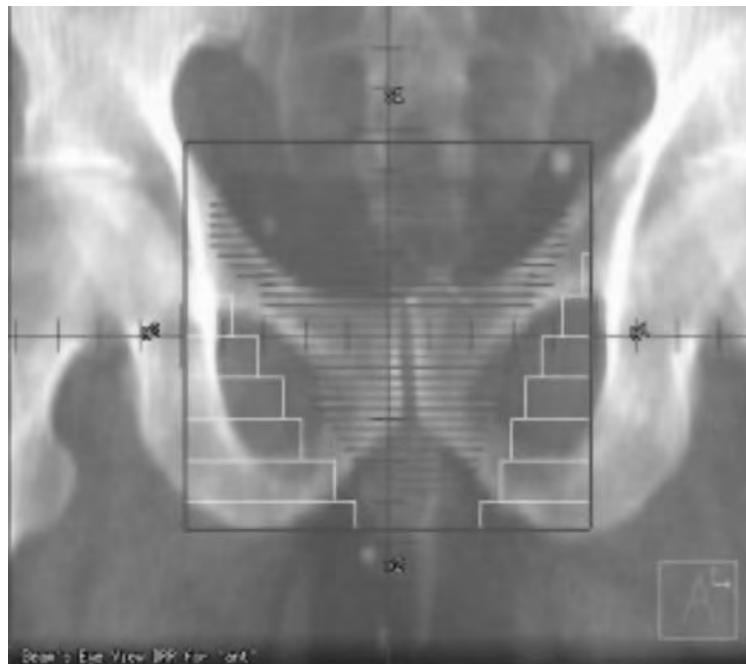

**FIGURE 32.3**

(See colour insert following page 590.) Examples of digitally reconstructed radiographs (DRRs) generated by the Pinnacle planning system; in (a) the CT data set had 5 mm slice separation and a coarse reconstruction was used, whereas in (b) the CT data set had 2.5 mm slice separation and the DRR algorithm was smooth; therefore, the DRR looks very much like a simulator radiograph.

**FIGURE 32.4**

(See colour insert following page 590.) (a) A coronal view, showing the position of the kidneys relative to the field borders, and (b) a DRR on which the field size and the individual MLC leaves can be positioned.

increased accuracy to the treatment and often reduces the time the patient needs to spend in the radiotherapy planning department. For example, palliative lung cancer treatments where the lung tumour is medial, i.e. the tumour is partially in the shadow of the mediastinum, are often very difficult to simulate as the full extent cannot be seen using a conventional x-ray simulator. In these cases, a CT scan will reveal the extent of the tumour, and a combination of transverse and coronal views can be used to define the beams for the parallel pair.

**FIGURE 32.5**

(See colour insert following page 590.) The DRR shown in Figure 32.3b with the prostate PTV contours (horizontal lines) and MLC projection overlaid.

CT scans can also be used to reduce the use of contrast agents administered to patients. One particular site is the treatment of the para-aortic nodes where the position of the kidneys relative to the treatment fields is crucial. Here, the patient benefits from the CT scan by avoiding the intravenous contrast that would be administered to show the extent of the kidneys. The planning is then performed by simultaneously looking at a coronal reconstruction (see [Figure 32.4](#)) and the DRR. This combination will give a full appreciation of the position of the kidneys (by scrolling through the coronal reconstructions) relative to the para-aortic nodes and allow for manual positioning of the MLC leaves to shield them.

If the PTV and other structures have been outlined on the CT data set, they can be overlaid on the DRR. The beam shape and conformal blocks or MLCs may also be added as overlays as shown in [Figure 32.5](#). Using DRRs as the reference images for treatment verification eliminates the need to use the simulator to verify a computer plan and reduces one source of error. It is important that the patient has the same position at treatment as at CT scanning. This is facilitated in purpose-designed CT simulators that have rigid flat couch tops.

With the use of multislice CT scanners, slice separations of 1 mm are readily achieved. With such small slice separations, DRRs can almost match the spatial resolution of conventional radiographs with the additional possibility to enhance and manipulate the digital images and to benefit from the automatic overlay of the structures which were delineated in the transverse sections. It is important that DRRs are produced by skilled and experienced staff that have had the time to test the enhancing tools available and liaise with the clinicians who will use the images. Care must be taken to achieve an image quality that allows satisfactory delineation of the structures\* that will be seen on the verification portal images which will be acquired during the course of the treatment.

\* There are therefore two possibilities to obtain structures overlaid on a DRR: either drawn directly or projected from transverse contours. Then, the decision must be taken, for each anatomical site, about which method to use for which organ in order to achieve an optimal result.

## 33.1 INTRODUCTION

The goal of radiotherapy treatment planning is to design a beam configuration which will deliver a homogeneous dose to the specified planning target volume (PTV), ensuring that normal tissue receives a reasonably low dose and that critical organs receive less than their tolerance doses. ICRU 50 (ICRU 1993) suggests an acceptable dose variation of +7%/-5% of the reference dose, the reference dose point being the centre of the PTV, the isocentre, mid-plane or some other suitable point (see [Section 37.6](#)). This is achieved by choice of treatment modality (photons or electrons), beam energy, beam arrangement, use of wedges, compensators or blocks, and methods such as conformal planning (see [Section 43.1](#)) as appropriate. The ICRU objectives are not always met and sometimes compromise may be necessary, depending on the aims of radiotherapy. For example, if the treatment is palliative, long-term radiation effects may not be a consideration and a simple beam arrangement will suffice. On the other hand, if the treatment is radical, i.e. aiming at local control of the tumour, long-term effects need to be taken into account and this may result in a more complex radiotherapy regime. Centres may also be limited in the choice of photon beam energy or the availability of electron therapy.

Single beams are easily visualised with the use of isodose curves, sets of which may be produced for a range of field sizes for each available treatment energy. This is particularly true for electron and kilovoltage treatments. In the past, when beams were combined, isodose curves were amalgamated manually by superposition of standard isodose curves with the help of tracing paper. This was a slow process and placed limits on the optimisation of treatment plans. Modern treatment planning computers provide a fast way of viewing dose distributions. The effect of adding and repositioning beams, changing beam weights and adding wedges can be seen almost instantaneously, thus facilitating the planning process and allowing the planner to investigate various options before deciding on the final plan. The ability to view dose distributions in three dimensions also adds to the armoury of the radiotherapy treatment planner, as does the use of dose volume histograms (see [Section 35.3](#)).

In this chapter, we will address the basic principles of photon-based treatment techniques that are currently used in radiation therapy to treat the most common types of cancer. Electron beam techniques will be dealt with in [Chapter 34](#). Although the conformal approach is becoming the standard for a majority of curative treatments (see [Chapter 43](#)), it is still necessary, for safe and efficient treatment planning, to have a good knowledge of the more conventional techniques discussed below.

---

## 33.2 SINGLE BEAM TREATMENTS

### 33.2.1 KILOVOLTAGE BEAMS

Kilovoltage beams are mostly used to treat superficial disease, normally with single fields. With these energies, there is a large dose fall off with depth and the maximum dose is at or very near the surface. Typical doses at 1 cm depth are 80% for 120 kV, 90% for 150 kV and 95% for 300 kV. There is differential absorption of the dose in bone due to the photoelectric effect and lesions over bone or calcified cartilage should therefore be treated with electrons rather than with kilovoltage beams. (The exception is in the region of the eye because of the need for a corneal shield (see [Section 21.5](#))).

### 33.2.2 MEGAVOLTAGE BEAMS

Single, high-energy photon fields provide skin sparing compared to kilovoltage beams due to the build-up effect (see [Section 22.3.1](#)) and increased dose with depth. Both the build-up

**TABLE 33.1**

Typical Beam Parameters for a 10 cm×10 cm Field at 100 cm SSD

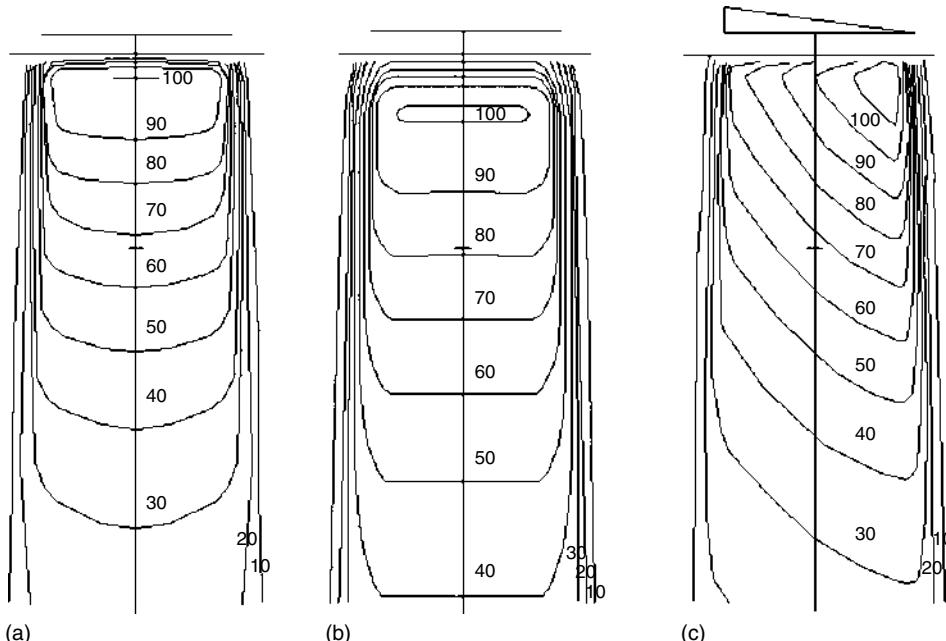

Nominal Energy (MV)	$d_{\max}$ (cm)	% Depth Dose at 5 cm	% Depth Dose at 10 cm
Cobalt-60	0.5	80.4	58.7
4	1.0	83.9	63.0
6	1.5	86.9	67.5
8	2.0	89.6	71.0
10	2.3	91.4	73.0
15	2.9	94.5	77.0
25	3.8	98.5	83.0

effect and the depth dose increase with energy. Energies available range from  $^{60}\text{Co}$  sources to 50 MV linear accelerator beams, although more typical megavoltage energies would be between 4 MV and 25 MV (see Table 33.1 for typical beam parameters). Combinations of high- and low-energy photon beams can produce an equivalent intermediate energy if required.

The dose gradient across the PTV for a single photon beam is large, the fall off for a 6 MV beam being approximately 4% per cm. Therefore, dose homogeneity will probably fall short of the recommendations in ICRU 50. Single fields are therefore not suitable for treating deep-seated tumours.

The prescription may be made to a point at the required treatment depth, but this will result in a high dose at the point of dose maximum,  $d_{\max}$ , and any normal tissue in the beam

**FIGURE 33.1**

Dose distributions from single photon beams (a) 6 MV photon beam, (b) 25 MV beam, (c) 6 MV 45° wedged beam. 100% is at  $d_{\max}$  on the beam axis. 10 cm depth is indicated by a mark on the beam axis. The general shape of the isodose lines for a given energy may vary significantly depending on the design of the flattening filter (see [Section 22.3.3.2](#)).

overlying the PTV. The use of a higher energy will make the distribution more uniform (see Figure 33.1a and b). For volumes near the surface, bolus can be added to ensure that none of the PTV lies within the build up region.

The field size is normally defined by the 50% dose relative to the central axis, and a margin must therefore be added to the PTV when designing a beam to fit a target volume so that it does not lie within the beam's penumbral region. For x-rays (i.e. excluding cobalt) this margin will increase with energy, but a typical value is 6 mm at the isocentre.

Single fields provide a simple mode of treatment which may suit the clinical needs of the patient in particular cases. They are used to treat breast nodes (in combination with tangential fields to the breast, see below) and the lower neck and supraclavicular nodes (in combination with an opposed pair to the upper cervical nodes).

One example of the use of single beams is that of a long, narrow, posterior field in the treatment of the spine, with the anterior limit of the spinal cord being at approximately 5 cm deep. The variation in dose to the cord along the treatment field, due to the change in source surface distance (SSD) and depth, can be greater than 10%. It is possible to obtain a uniform dose by using purpose-built compensators: shaped blocks of aluminium or other suitable material, placed in the beam accessory tray, below the treatment head. Alternatively, this compensation of the single field may be achieved with smaller *top up* fields overlaid on the single field, using asymmetric collimator settings or with intensity modulation obtained with multileaf collimators.

---

## 33.3 TWO BEAM ARRANGEMENTS

### 33.3.1 PARALLEL OPPOSED PAIR

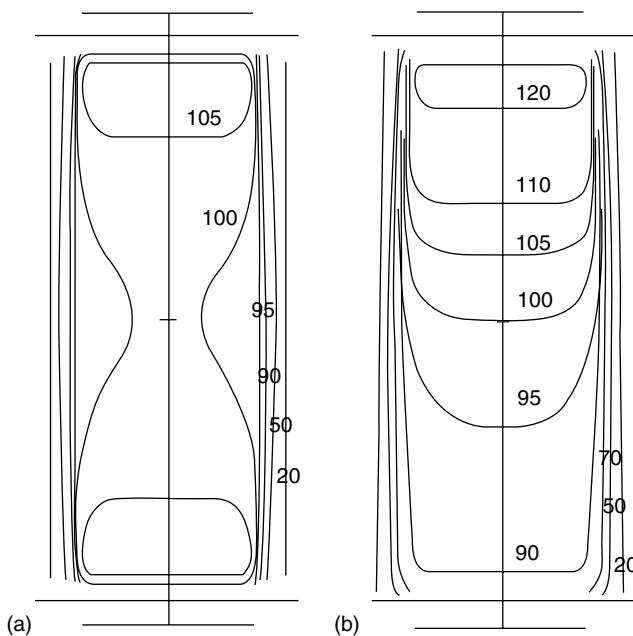

For deeper volumes, two opposed beams may be used, a *parallel opposed pair*. This will produce a more uniform dose in the PTV but will also give a high dose to overlying normal tissue in the path of the beam, the region of highest dose being near the surface. The shape of the isodoses in a parallel pair setup is that of an hourglass (see Figure 33.2a). For an antero-posterior pair, this is the case in both the transverse and sagittal planes. Parallel pair treatments are used widely in all areas of the body. The parallel pair may be used for the entire treatment course, especially when the intent is mainly palliative, or may form the first phase of a two-phase radical treatment. As the separation of the patient increases, the uniformity of the dose distribution decreases, with an increase in dose close to the surface compared to the mid-plane. This may lead to higher normal tissue doses or to an unacceptable dose inhomogeneity within the PTV. The non-uniformity can be reduced if a higher energy is chosen for treatment.

### 33.3.2 BEAM WEIGHTING

If the centre of the PTV is not at the centre of the patient's cross-section, i.e. in the mid-plane of the patient, then the opposed beams can be given different weightings (see Figure 33.2b). The definition of beam weights depends on the planning system or calculation technique used. It can be proportional to the *beam-on* time (i.e. set monitor units<sup>\*</sup> for linear accelerators or time for cobalt-60 units), or proportional to the dose contribution of that beam to a specific point, usually the isocentre<sup>†</sup>. For a parallel pair with the isocentre at mid-plane, weighting to *set MU* is the same as weighting the dose to the isocentre (in the absence

\* See Section 20.1.2 for a definition of monitor units (MU).

† In some planning systems the weight may be based on the calculated dose in a water medium or in conditions which may differ from the actual ones (e.g. without shielding blocks).

**FIGURE 33.2**

6 MV parallel pair distributions normalised to 100 at mid-plane, showing the effect of beam weighting; separation is 20 cm (a) equal weighting, (b) 2:1 weighting.

of inhomogeneities), so a 2:1 weighting will give the ratio of beam-on time and of contributions to the isocentre. However, weighting to a different point will result in different values of the beam weight, depending on which weighting system is in use. Increasing the weighting of the beam entering the side of the patient nearest the PTV will always increase the PTV dose relative to the normal tissue lying on the opposing side. Equal weights defined in terms of the dose administered to the centre of a PTV which is not at mid-plane would result in an overdosage of healthy tissues on the opposing side. With this definition of beam weight it is necessary to compensate by significantly increasing the weight of the beam entering the side nearest the PTV.

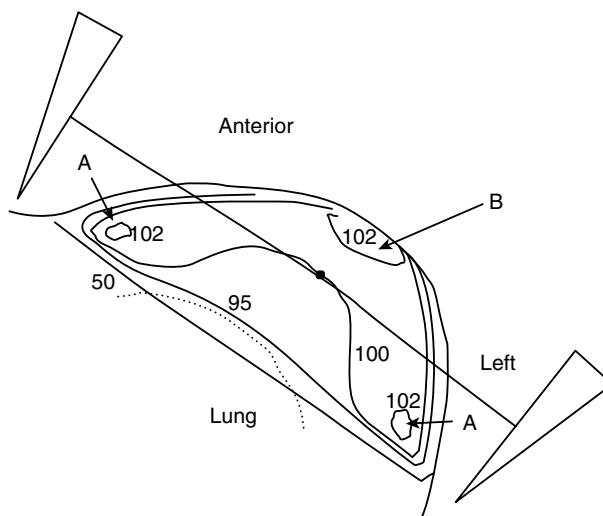

### 33.3.3 WEDGE FILTERS

Where opposed beams are applied to sloping surfaces, for example in larynx or breast treatments, it is necessary to use wedge filters to maintain a uniform dose distribution perpendicular to the beam direction. The effect of the wedge is to tilt the isodoses; in these situations it compensates for missing tissue. A detailed discussion of wedge filters can be found in [Section 22.6.1](#) and [Section 22.6.2](#).

For breast and larynx treatments the wedged direction is in the transverse plane, but in principle a wedge can be used for compensation in any orientation. An example of the use of the wedged direction in the sagittal plane is to compensate for the sloping surface of the chest in the upper thorax.

### 33.3.4 TANGENTIAL BEAMS

Radiotherapy of the breast and chest wall (post mastectomy) is usually carried out using two tangential fields. These may be set up so that the posterior borders of the two fields are aligned. This ensures that the beams do not diverge into the lung, which would result in an

**FIGURE 33.3**

6 MV tangential breast fields, normalised to 100 at the isocentre. Note the indications of patient orientation (Anterior and Left) which should always be present on any treatment plan.

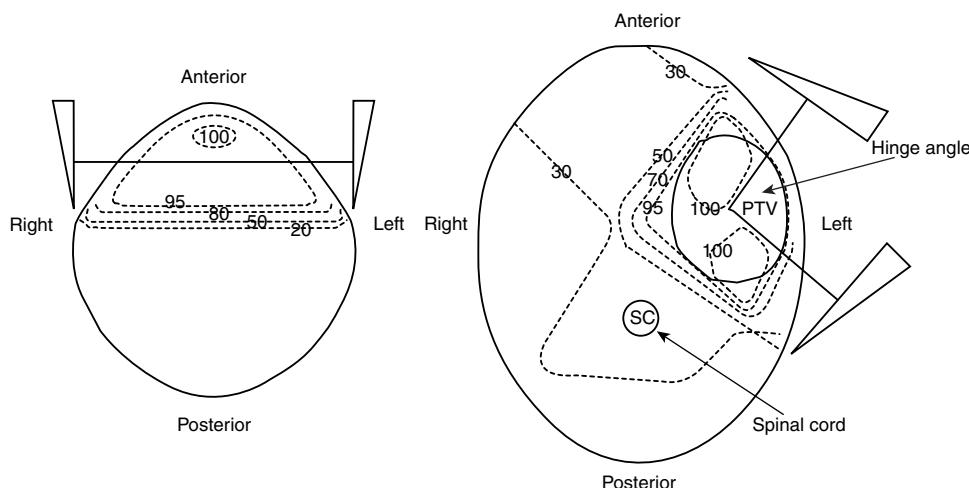

increase in lung dose. Alignment of the field edges may be achieved either by using half-blocked beams and placing the isocentre at the posterior edge of the field or by angling the gantry to make the posterior borders of the fields parallel. Wedges are added to achieve a more uniform dose distribution by compensating for the differential tissue thickness across the beam width (see Figure 33.3). The amount of lung in the beam also needs to be considered, both because of the sensitivity of lung tissue to radiation and because the lower density of lung tissue can lead to hot spots at points A in Figure 33.3. Not all treatment planning systems account for the lack of scatter in air, a further consideration when beams enter the patient obliquely. This may result in an overestimation of the dose at point B\*. Normally equal weight is given to the two beams, but it may be necessary to vary beam weights to account for asymmetry of the breast or positioning of the isocentre to optimise the dose distribution.

Breast radiotherapy may involve node irradiation using an anterior field with a possible posterior boost field. Suitable collimator angles and couch twists can be set up on the tangential beams so that a vertical match plane is produced for the node fields. Alternatively, asymmetric fields can be matched by placing the isocentre at the superior border of the tangential fields to achieve a vertical match plane with no divergence into adjacent fields.

### 33.3.5 WEDGED PAIR BEAMS

Wedged pair beam arrangements are common in head and neck radiotherapy, e.g. parotid, oral cavity and maxillary antrum, with the angle between the beams, often referred to as the *hinge angle*, being less than 180°. In this case the wedge is used to compensate not only for missing tissue but also because the beam entry points are close together on one side of the patient. As a result the open field isodose lines would not be parallel to each other resulting in hot spots close to the surface between the beam entry points. The smaller the hinge angle, the

\* Calculation of breast plans with older planning systems that did not allow for either the decreased attenuation of lung or the decrease in dose at point B would lead to a requirement for a thicker wedge to achieve a homogeneous dose distribution. With a modern planning system it is usually found that a wedge angle between 15° and 20° is the maximum that is ever needed, whereas with older systems it was common to find 30° or even 45° wedges being used.

**FIGURE 33.4**

6 MV dose distributions normalised to 100 at the isocentre from two wedged fields. (a) A parallel opposed larynx treatment. (b) A typical beam arrangement for treatment of the parotid gland (labelled PTV).

larger the required wedge angles needed to obtain a uniform dose across the PTV. In an ideal case where no missing tissue compensation is required, the wedge angle should be ( $90^\circ - 1/2$  hinge angle). An example is shown in Figure 33.4. This is a good beam arrangement for volumes near the surface, as it minimises the dose to normal tissue.

### 33.3.6 PHOTON AND ELECTRON BEAMS

Photon and electron beams can be overlaid to treat the same site. The result of this arrangement is an increase in skin sparing compared to an electron-only treatment, and a lower dose at depth than that obtained from a photon-only treatment. Examples include treatment of the parotid gland (thus reducing the dose to the contralateral parotid and spinal cord) and the intra-mammary chain in the mediastinum.

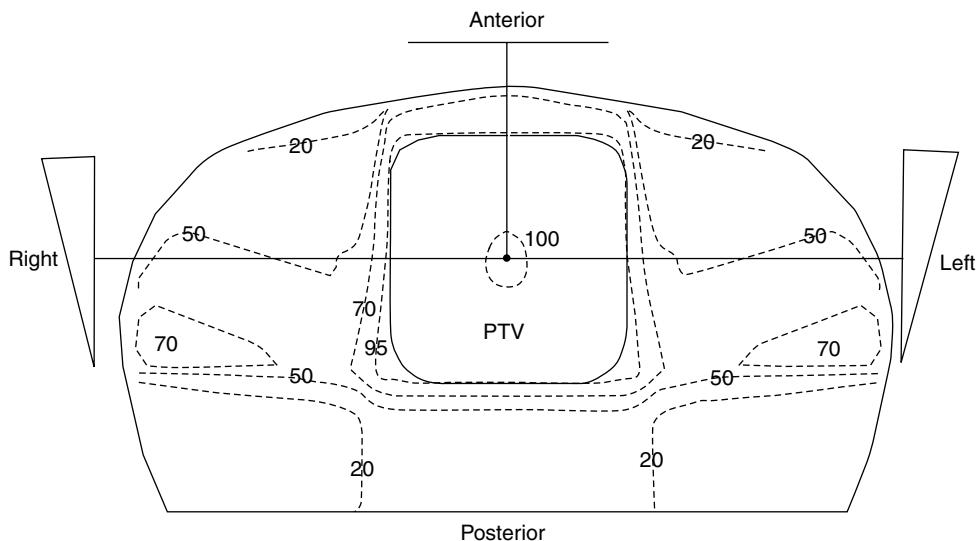

---

## 33.4 MULTIPLE COPLANAR BEAMS

The use of three or more beams reduces the dose level to normal tissue within the irradiated volume compared with a parallel pair arrangement, as the entrance and exit doses do not coincide. This is important when the beam traverses a sensitive structure such as the bladder or rectum or a dose-limiting structure such as the spinal cord or lung. Beams converge on the PTV and, with the use of suitable beam angles, weights and wedges, produce a uniform dose within the PTV that is higher than in surrounding tissue. Beam weights and wedges can be chosen so that the dose to normal tissue in the path of the beams is spread equally, or to spare particular sensitive structures at the expense of giving a higher dose to other normal tissues. Selection of the best field arrangement for a specific site therefore depends upon many factors with varying degrees of clinical importance (Bedford et al. 1999).

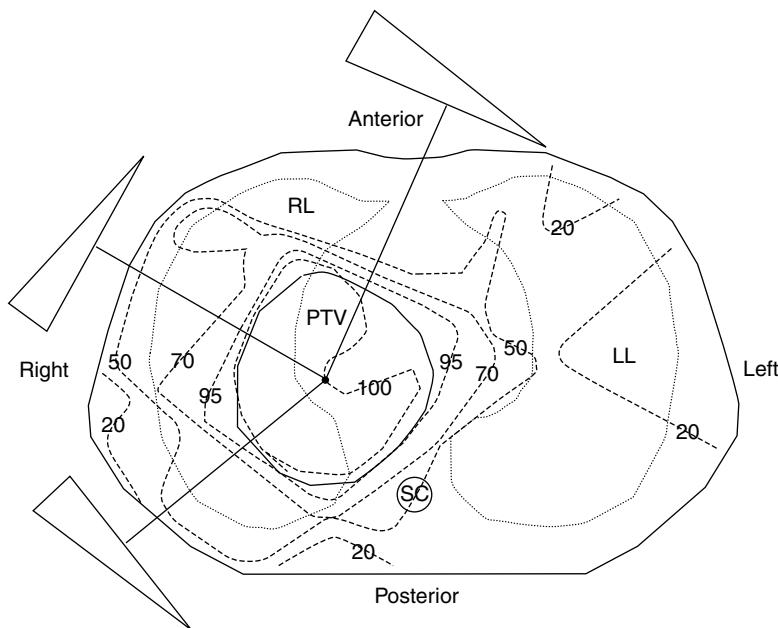

### 33.4.1 THREE-BEAM ARRANGEMENTS

Three-beam treatments are used in the pelvis (prostate and bladder), abdomen and thorax as well as the brain.

**FIGURE 33.5**

6 MV three-beam dose distribution normalised to 100 at the isocentre to treat the bladder (PTV).

The beam arrangement depends on the treatment site, but a typical configuration in the pelvic area is an anterior or posterior beam plus two lateral or lateral oblique fields (see Figure 33.5). In the pelvis (treatment of the prostate or bladder), the three-beam arrangement ensures that no beam enters through the rectum. Wedges on the lateral or lateral oblique beams ensure a uniform dose to the PTV, compensating for the uneven spacing of the beams around

**FIGURE 33.6**

6 MV three-beam dose distribution normalised to 100 at the isocentre, for the treatment of a right bronchial tumour (PTV). The beams are arranged to avoid the contra-lateral lung and to keep dose to the spinal cord (SC) below tolerance. RL indicates the right lung and LL the left lung.

the patient. [Figure 33.6](#) illustrates a three-beam bronchus treatment, with the beams arranged to avoid the spinal cord and the contralateral lung.

Oesophagus treatments may be delivered as two-phase treatments, with an anterior and posterior parallel pair as the first phase, followed by an anterior and two posterior oblique beams with wedges as the second phase. The first phase delivers minimum dose to the lungs, the second phase minimum dose to the spinal cord. The number of fractions for each phase is chosen so that the dose to the lungs and spinal cord is kept below tolerance.

It is possible to use different beam energies in multi-beam plans. A lower beam energy may be chosen for one beam to reduce the exit dose (e.g. the anterior beam which exits through the rectum in prostate treatments) at the expense of an increase in the surface and entrance doses.

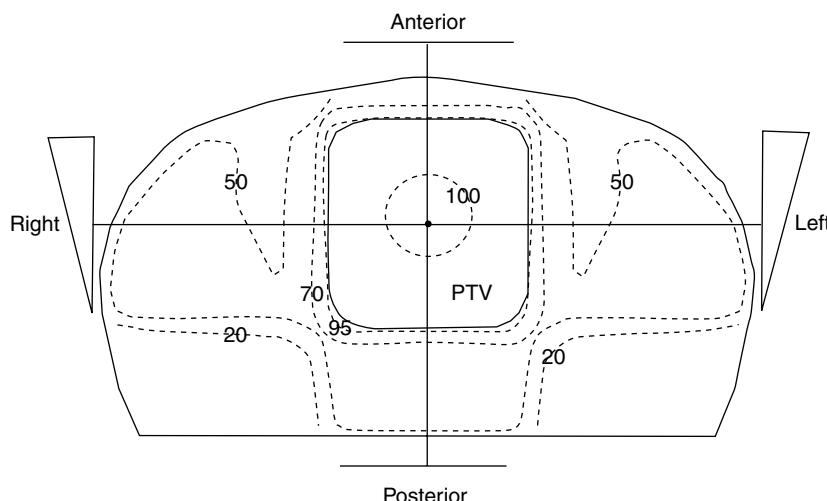

### 33.4.2 FOUR-BEAM ARRANGEMENTS

Four-beam arrangements can be used in the pelvic area, consisting of an anterior, posterior and two lateral beams (see [Figure 33.7](#)). Wedges can be used to compensate for missing tissue. The beam weights may be different depending on the beam direction.

### 33.4.3 ARRANGEMENTS WITH MORE THAN FOUR BEAMS

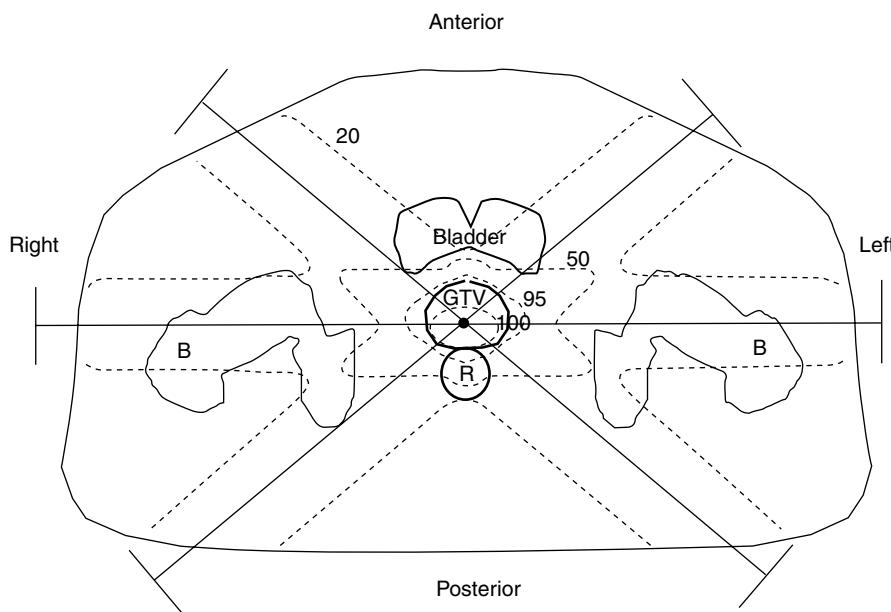

Arrangements using more than four beams are less common. As the number of fields increases, the mean dose to normal tissue within the irradiated volume decreases, but the volume of normal tissue that is irradiated increases. Whilst there may be some advantages to using a large number of beams for specific cases, overall treatment time will be greater due to increased set up and delivery time.

Rotational or arc therapy is the ultimate endpoint for large numbers of beams, but this is seldom practised in conventional radiotherapy today. The main reason is that in conventional rotational therapy (i.e. with no dynamic conformal shielding), it is not possible to produce conformal dose distributions, so the technique is limited to cylindrical or spherical PTVs.

**FIGURE 33.7**

Dose distribution normalised to 100 at the isocentre for a 6 MV *four-beam brick* arrangement (also called *box* technique) in the pelvic area, treating the same patient and PTV as in [Figure 33.6](#).

**FIGURE 33.8**

Dose distribution normalised to 100 at the isocentre for a Phase 2 boost treatment to the prostate (GTV) using six beams; R indicates the rectum and B the pelvic bones (and femoral heads). Note the lower dose to normal tissue relative to that in [Figure 33.5](#) and [Figure 33.7](#), but the consequent increase in the amount of normal tissue irradiated.

One example of a six-field treatment is that of prostate boost treatments, one of the arms of the RT01 trial (Sydes et al. 2004) (see Figure 33.8). This was the second phase of a two-phase prostate treatment. The first phase was a conventional three-field technique to the PTV with a prescribed dose of 64 Gy. The second phase consisted of two lateral beams with right and left anterior and posterior oblique fields to treat the GTV only to 10 Gy. Both phases included conformal blocking.

### 33.5 NON-COPLANAR BEAMS

In all of the above examples, the beam axes are contained in the transverse plane and are therefore coplanar. Even in relatively simple treatments such as treatment of carcinoma of the larynx by a wedged pair of anterior oblique beams, non-coplanar fields may be required. The couch may need to be rotated by 5° or 10° in order to avoid the beams passing through the shoulders. Such beams are non-coplanar. In traditional planning, where only a single slice was considered, these small angles were often ignored, as the error involved was minimal. However, modern 3D planning systems can easily model the angulation correctly, provided that they have multislice patient data. A 3D plan using the correct angles is essential if data are to be transferred electronically between the planning system and the treatment machine.

Although the use of multiple beams can significantly reduce the dose to normal tissue, it is often difficult to avoid the exit dose of one beam contributing to the entrance dose of another, opposing beam. More importantly, it may be impossible to direct several treatment beams at the PTV whilst avoiding critical structures if all the beam axes are in one plane (normally the transverse plane). To overcome these problems, non-coplanar beam arrangements can be employed. Below the neck, the possibilities of non-coplanar beams are limited by potential collisions between the gantry and either the patient or the patient support system. Any beams entering out of the transverse plane may have increased path lengths to reach the PTV,

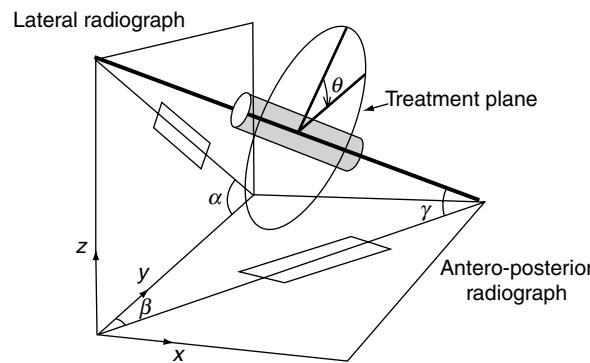

resulting in an increased irradiated volume. However, non-coplanar beams can be useful in treating small lung tumours, as they facilitate the avoidance of normal lung tissue.

The problem of access is reduced in the head, which can be seen as approximately spherical, although constraints such as the patient support system, be it a shell or stereotactic frame, can restrict the choice of beam arrangements. Because the critical organs can now potentially be irradiated from any direction, the ability to visualise these structures in three dimensions during the planning process rather than viewing single dose planes is essential. Analysis of the dose distribution must also be performed in three dimensions. As simply considering a transverse, sagittal and coronal dose plane through the isocentre may miss important information outside these planes, the use of tools such as dose volume histograms and 3D graphics are important in the planning process. The ideal four-beam arrangement, minimising field overlap, would be a tetrahedron. Constraints, for example not exiting into radiosensitive structures such as the thyroid and the eyes, can limit the freedom of beam orientations, while for conformally shaped beams, the beam configuration may be influenced as much by the optimum shielding of adjacent critical structures as by achieving a homogeneous dose distribution. It has been found that, when using cerrobend blocks to shape the field, increasing the number of static beams beyond four only marginally improves normal brain sparing (Perks et al. 1999) for lesions such as the pituitary. Larger numbers of conformal beams may be needed to further reduce the dose to specific adjacent normal tissues. Arcing non-coplanar fields have a role in treating spherical brain lesions (using circular fields), but where the PTV is of irregular shape, fixed conformal fields offer the best solution for normal tissue sparing (Laing et al. 1993). Stereotactic treatments of brain lesions are considered further in [Chapter 45](#).

## 33.6 TREATMENTS IN INCLINED PLANES

Treatments of inclined cylindrical volumes, such as the oesophagus and some head and neck volumes, may be best planned with fields that are in the plane perpendicular to the longitudinal axis of the volume. By selecting the appropriate table, collimator and gantry angles, it is possible to arrange for beams from any angle to be coplanar in an inclined treatment plane. This method was originally described by Fleming and Orchard (1974) and further developed by Casebow (1976) and Siddon (1981).

In the general case, the long axis of the PTV is inclined to the horizontal and rotated with respect to the longitudinal axis of the patient. The projections of the two angles are measured

**FIGURE 33.9**

Illustration of a PTV inclined at an angle  $\gamma$  to the horizontal and showing the projection of  $\gamma$  onto lateral and AP radiographs,  $\alpha$  and  $\beta$ . The treatment plane is normal to the axis of the PTV. The frame of reference of the linear accelerator is given by coordinates  $x$ ,  $y$ ,  $z$ , as defined by the IEC (see [Figure 11.31](#)). The angle  $\theta$  represents the planned gantry angle in the treatment plane. (From Casebow, M. P., *Br. J. Radiol.*, 49, 278–280, 1976.)

on lateral and anterior radiographs.  $\alpha$  is the projection of the PTV axis to the horizontal and  $\beta$  is the projection to the longitudinal axis. The true angle,  $\gamma$ , to the horizontal is given by:  $\tan \gamma = \tan \alpha \tan \beta$ . The sign of  $\gamma$  is important: viewed from the patient's left side (patient supine) clockwise rotations are positive. Let  $\theta$  be the planned beam angle in the treatment plane (i.e. what would be the gantry angle if the plan were being performed in that plane). [Figure 33.9](#), based on Casebow (1976), illustrates these angles. The gantry (GA), table (TA), and collimator (CA) angles of the treatment machine are given by:

$$\cos \text{GA} = \cos \gamma \cos \theta \quad (33.1)$$

$$\tan \text{TA} = (\sin \gamma / \tan \theta) - \beta \quad (33.2)$$

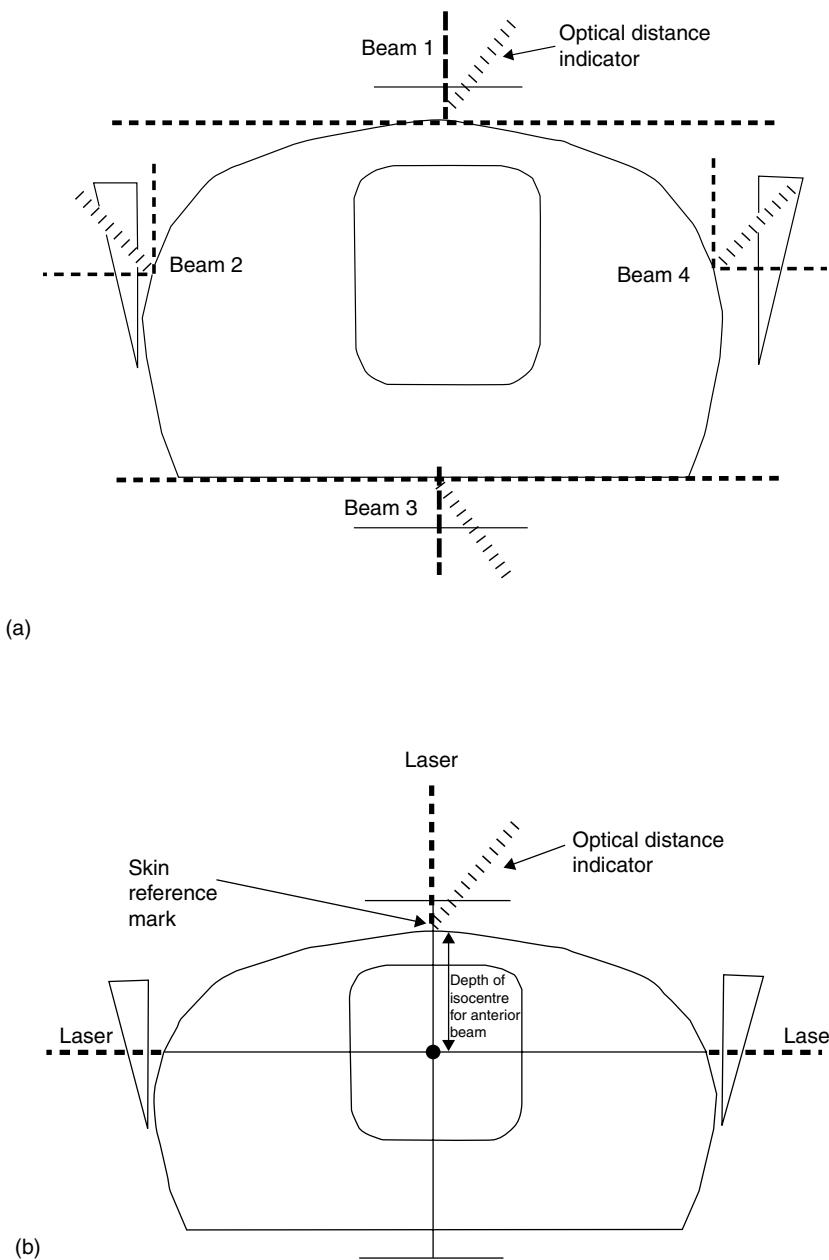

$$\tan \text{CA} = (\tan \gamma / \sin \theta) \quad (33.3)$$

If the PTV is in the sagittal plane, as is frequently the case,  $\beta=0$  and  $\gamma=\alpha$ .

### 33.7 FIXED SOURCE SURFACE DISTANCE BEAMS VS. ISOCENTRIC TREATMENTS

An essential component of any treatment plan is the set-up instructions that relate the dose distribution and field arrangement to the external reference marks of the patient. For multiple field arrangements, it is preferable to be able to set up the treatment at the outset, and to move only the gantry and collimator between fields, rather than adjusting the patient position and couch movements. This is illustrated in [Figure 33.10](#) for a four-beam treatment in which the isocentric arrangement has been set up to the skin reference mark using the isocentre lasers and the optical distance indicator (ODI). The treatment unit lasers are centred on the isocentre and therefore intersect with the patient, enabling lateral marks to be used to ensure that the patient is not rotated prior to setting up the remaining fields. Although the ODI would not be necessary for setting up the remaining fields, it is useful as a secondary check, as the SSD for each beam can be obtained from the treatment plan. For the fixed-SSD set-up, the ODI and lasers must be set up to each beam entry point by moving the couch laterally and vertically, and separate measurements are required to ensure that the patient is not rotated. Isocentric plans are therefore easier to set up, as the isocentre only has to be set once, and this patient position then applies to all fields. In addition, the dose to the PTV is expected to be more accurate because (i) with isocentric set-up of opposing beams, an inaccurate patient positioning will have the opposite effect on the dose contributions of both beams; (ii) a change in patient thickness will have consequences on the tissue attenuation but not on the distance to the PTV, which remains unchanged.

It may be argued that maintaining a constant source-to-surface distance, SSD, in a multiple beam treatment simplifies the dose calculation, as the inverse square dependence of the beam output is constant and may be looked up directly from depth dose tables. However, using tissue phantom ratio or tissue maximum ratio tables for isocentric treatments is no more complex (see [Section 23.3.3.2](#)). With modern treatment planning computers, which can perform calculations accurately for any SSD, the need for non-isocentric setups for multiple convergent beam treatments is limited, and isocentric treatment is recommended for most situations. However, for 80 cm source axis distance (SAD) cobalt-60 machines, for thick patients, or when using lead shielding on a shadow tray, there may be difficulties with potential collisions or increase of surface dose due to electron contamination from the close perspex tray. This can be solved by the use of an SSD set-up.

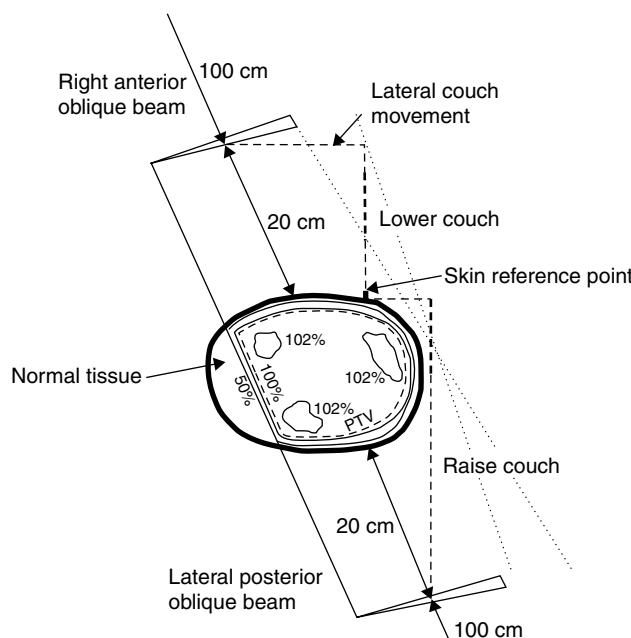

**FIGURE 33.10**

A comparison between a four-beam fixed SSD set-up and a four-beam isocentric set-up. For the fixed SSD set-up (a) the optical distance indicator (ODI) must be used for each of the four beams; for any of them and for the frequent situation where the SSD is taken equal to the SAD, the projection of the central axis on the skin coincides with the intersections or the projections of the wall mounted lasers (represented by thick dashed lines). For the isocentric set-up (b), the ODI could be used for the anterior beam to adjust or check the table vertical position; it could also be used to check the isocentre depth for any beam direction, but the set-up relies mostly on the laser projections and the table is not moved when rotating the gantry.

### 33.8 EXTENDED SSD

It may not be possible to cover larger PTVs with a field at the standard SSD, and an extended SSD is therefore required to increase the available field size on a particular treatment machine. Examples of long volumes include the spine in treatments of the whole central nervous system, and sarcomas, some of which extend from the pelvis to the knee and may be in excess of 50 cm long. Increasing the SSD increases the field size geometrically, with a dose output that falls by inverse square dependence. For example, a 40 cm long field will become 52 cm long at 130 cm SSD. Appropriate corrections should be made for the change in percentage depth dose, as described in [Section 23.3.4.3](#). The option to treat at extended SSD depends upon the flexibility of the treatment unit itself, in that a large range of couch movements are required. Raising and lowering the couch will facilitate increased field sizes for vertical beams, but, for horizontal beams, the range of lateral couch movements available will usually be more restricted. As patients are generally treated while lying either supine or prone (to obtain a reproducible set-up), the possibilities for using extended SSD fields will be greater for antero-posterior beams.

Extended SSD fields can be set at oblique gantry angles, which by combining both couch lateral and vertical movements, provides the greatest SSD available for a given treatment machine. When oblique fields at extended SSD are employed, the machine isocentre is located considerably distant from the patient surface, and detailed set-up instructions are required to move the couch both vertically and laterally from a skin reference point. Figure 33.11 shows a beam configuration to treat a sarcoma in the thigh. The extent of the lesion in the transverse plane shown means that only a small volume of the normal tissue of the leg is spared from irradiation. The preservation of this small volume is essential in preventing amputation of the lower limb, so the beams are angled to achieve a non-diverging edge of the beam and therefore a sharp dose gradient from the PTV to the normal tissue. However, this means that the accuracy of the set-up is critical and demonstrates

**FIGURE 33.11**

An extended SSD treatment of the thigh, showing the couch lateral and vertical movements required to set up each field individually from a skin reference point.

the importance of accurate and reproducible lateral and vertical couch movements and display scales over a range perhaps exceeding 80 cm.

## 33.9 MATCHING FIELDS

The need to match adjacent fields can arise when treating a volume greater in length than can be covered by a single field even at extended SSD. Another common need for beam matching is during treatment of an area abutting a previously treated volume. Perfect matching at all depths is usually difficult to achieve and it is important to establish whether overdosing or underdosing normal tissue is the deciding clinical factor when determining gaps between fields.

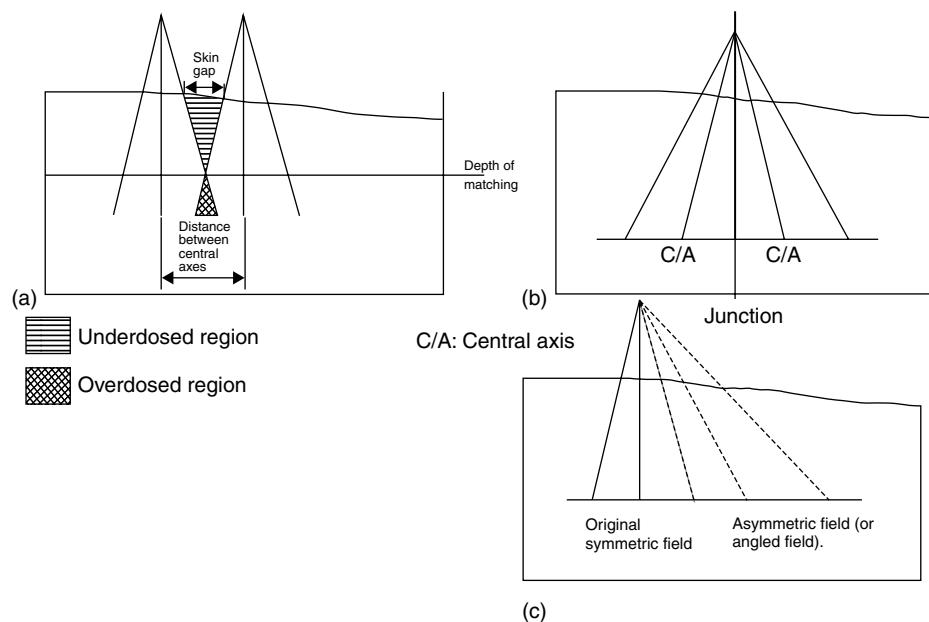

### 33.9.1 ABUTTING FIELDS WITH PARALLEL AXES

Where symmetric fields with parallel central axes (C/A) are to be abutted, it is necessary to calculate the separation required between the field edges at the skin surface to prevent an overdose or an underdose of the underlying tissue. Due to the divergence of the beam, exact matching can only occur at one depth (see [Figure 33.12](#)). Therefore when calculating gaps, a depth must be specified at which the fields will be matched. Frequently, the fields are matched at the midplane depth. Alternatively, matching may be to a critical structure (e.g. the spinal cord) and the gap calculated to ensure that no part of the structure receives more than 50% of dose from each field. The distance between the fields may be defined as a gap at the skin surface between the field edges, or by the distance between the central axes of the beams ([Figure 33.12](#)). The depth at which the field is defined must be known, i.e. how deep the isocentre is for each beam. Calculation of the gap is based on the use of similar triangles using the geometrical divergence of the field edge.

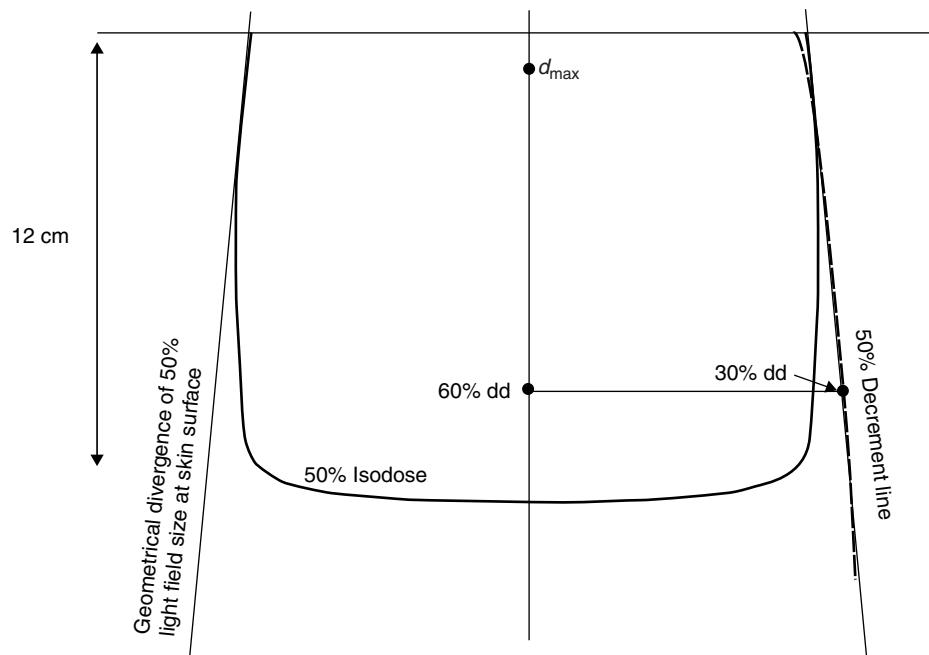

If a parallel opposed pair is to be matched to an adjacent opposed pair, all beam axes being parallel (e.g. at the junction of a supra- and infra-diaphragmatic treatment of lymph nodes) a compensation occurs between antero-posterior and postero-anterior divergences resulting in a fairly uniform depth dose, provided that the matching is at midplane depth and that the field sizes are not too different. When small fields are to be matched, it is possible to achieve almost perfect matching using asymmetric collimators to eliminate beam divergence at the junction and to enable the two fields to provide a uniform dose at all depths ([Figure 33.12b](#))\*. It may also be possible to match diverging field edges with asymmetric fields, as shown in [Figure 33.12c](#), but this could be restricted by the limitations of the collimator travel and the maximum field size available on the treatment unit. The risk with matching fields is that a small error in the set-up can result in a large overlap volume in which dose is contributed from both fields. Another drawback in matching fields asymmetrically with no divergence at the junction is that the field edge not being abutted will diverge more and consequently irradiate more normal tissue. This effect is illustrated in [Figure 33.11](#), in which the non-diverging field edge in this case is producing a sharp dose fall-off into the normal tissue region. However, in this treatment, the excess divergence arises in air, so there is no penalty. A non-diverging field edge is often used for breast treatments as shown in [Figure 33.3](#). It is also used for matching neck irradiation with a single vertical beam to head irradiation with parallel opposed horizontal beams.

It should be understood that matching is usually to 50% of the central axis dose at the chosen depth. This is not the same as the 50% isodose line, as can be clearly seen in

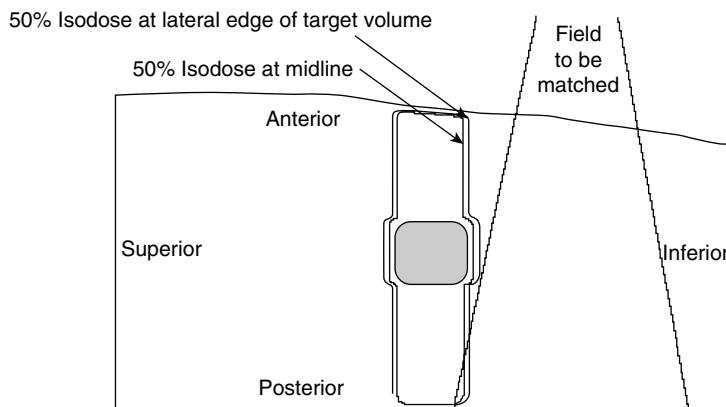

\* On [Figure 33.12b](#), the lines indicated as central axes (C/A) are different from the collimator rotation axis. They represent a virtual axis defined from the centre of the asymmetric fields. Similar edge matching would be obtained with symmetric fields by rotating the gantry, but this would be restricted to the transverse plane.

**FIGURE 33.12**

Matching fields, (a) at a specified depth, using skin gap or C/A separation, (b) using asymmetric collimators to eliminate divergence at the junction, or (c) using asymmetric collimators to match the divergence at the junction.

**FIGURE 33.13**

$^{60}\text{Co}$  beam (80 cm SSD) showing 50% isodose and 50% decrement lines. The depth dose values (dd) are normalised at  $d_{\max}$  on the beam axis.

**FIGURE 33.14**  
Matching a single field to a previously treated isocentric plan.

Figure 33.13, in which the 50% isodose of an 80 cm SSD Cobalt beam is shown. The line representing 50% of the central axis dose is called 50% decrement line\*. The 50% decrement line follows the divergence of the beam almost exactly for all megavoltage beams.

### 33.9.2 MATCHING SINGLE FIELDS TO PARALLEL OPPOSED PAIRS

It is not possible to provide a satisfactory 50% match between a parallel opposed pair and a single abutting field due to the contradictory divergences of the opposed beams. The clinician must decide where the tissue may be over-dosed or must be under-dosed before a gap can be determined. Figure 33.14 shows a field abutting the 50% level at the tumour but overdosing at the posterior field entry point.

### 33.9.3 MATCHING ADJACENT BEAMS IN INCLINED PLANES

When an inclined PTV is to be treated together with adjacent nodal regions, as in breast and head and neck treatments, it is important not to have a gap or an overlap between the field edges even though different field arrangements are used for the two volumes. If asymmetric jaws are available, it is often possible to match adjacent beams by using a single isocentre, but this reduces the field length available or may place the isocentre where it is difficult to set up. In these cases, it is possible to abut the field edges with the use of appropriate angulation (Siddon 1981; Casebow 1984). This methodology is widely used for matching tangential breast fields to supraclavicular and axilla nodal fields.

The fields to be matched are illustrated in Figure 33.15, in which the beam axes of the medial and lateral tangential fields are oblique in the crano-caudal direction, rather than lying in a transverse section. The beam divergence,  $\epsilon$ , is given by:

$$\epsilon = \arctan\left(\frac{L}{2\text{SAD}}\right)$$

\* It used to be the practice to define the field size as the width of the 80% isodose line, and this is still sometimes done for cobalt units. In that case, geometric beam matching must take into consideration the distance between the optical field edge and the 50% point.

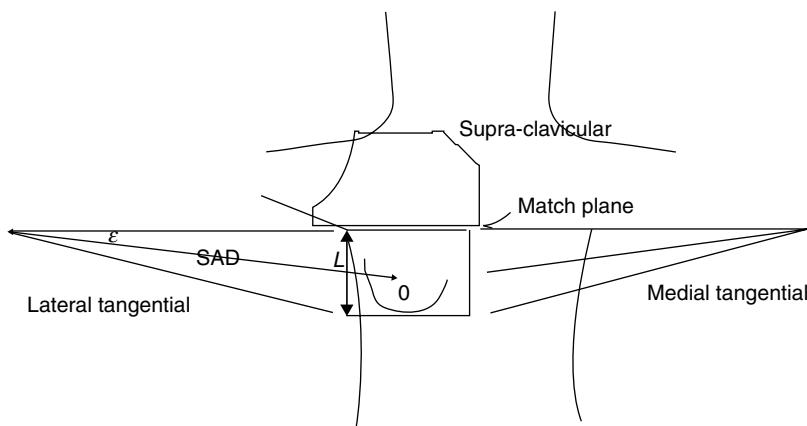

**FIGURE 33.15**

Diagram of a typical arrangement for a breast treatment where the tangential beams are angled superiorly and rotated so that their superior edges are parallel to each other and align with the inferior edge of the supraclavicular field. The distance from the target to the isocentre, SAD, is usually 100 cm.

where  $L$  is the beam length, and SAD is the source axis distance.  $\varepsilon$  is taken as positive for the edge of the beam nearest the gantry (i.e. it is positive for the superior edge of the beam and negative for the inferior edge). It is important that the tangential fields do not diverge into the supraclavicular field and that their posterior borders are aligned and do not diverge into the lung. To achieve this, the patient's back may be raised on a *breast board* so as to make the sternum horizontal and the plane of the tangential fields vertical. However, most CT scanners cannot accommodate a breast board and an alternative arrangement is that the patient lies flat and the tangential fields are in an inclined plane to which the supraclavicular field is matched. The following equations derived by Casebow (1984) (with the nomenclature adapted to be the same as in [Section 33.6](#)) ensure that the superior borders of the tangential fields are non-diverging and lie in a plane inclined at  $\gamma$  to the vertical, to which the inferior border of the supraclavicular field is matched.

$$\text{GA} = \arccos(\cos \theta \cos \gamma \cos \varepsilon - \sin \gamma \sin \varepsilon) \quad (33.4)$$

$$\text{CA} = -\arcsin\left(\frac{\sin \varepsilon \cos \text{GA} + \sin \gamma}{\cos \varepsilon \sin \text{GA}}\right) \quad (33.5)$$

$$\text{TA} = -\arcsin\left(\frac{\sin \gamma \cos \text{GA} + \sin \varepsilon}{\cos \gamma \sin \text{GA}}\right) \quad (33.6)$$

Using the IEC1217 convention,  $360^\circ$  is added to negative gantry angles. The angle CA is added to the unrotated value of the collimator angle, which is defined by the wedge direction for the tangential fields. If the patient is on a breast board such that the match plane is vertical,  $\gamma$  becomes zero and the equations are simplified.

### 33.9.4 MATCHING ELECTRON TO PHOTON FIELDS

The shape of the electron beam isodoses makes exact matching impossible, although the 50% decrement line (i.e. the field size defined) will not be as bowed as the lower value decrement lines. A small gap of typically 2 mm offers the best compromise for most clinical

electron energies, but depending on whether overdosing or under-dosing is the main clinical concern, no gap or up to a 5 mm gap at the skin surface may be employed. As with photon beam matching, concerns arising over the beam junctions may be alleviated by considering that modest doses may be involved, for example when a 20 Gy neck node electron field contributes to a total dose of 60 Gy. Matching of electron fields is discussed in [Section 34.5](#).

## 34.1 INTRODUCTION

The feature that makes electron beams very useful for a range of clinical applications is the shape of the depth dose curve. This allows for relatively uniform dose delivery to reasonably well-defined regions from the surface to the therapeutic range, with sparing of underlying tissue due to the rapid reduction of the dose towards the practical range. At about 20 MeV and above, the gradient of the depth dose curve begins to lose the characteristic steepness seen at lower energies and the separation of the high-dose and spared regions becomes increasingly blurred. Energies higher than this can be used for deep-seated tumours, but the techniques begin to approach those used for megavoltage photons. However, the majority of linear accelerators that provide clinical electron beams produce energies within the range 4 MeV to 20 MeV; this section concentrates primarily on their use. Electron beams of these energies deliver high doses (greater than about 90% depth dose) to depths of around 1cm to 6 cm. Common applications include skin and lip cancers, chest wall and peripheral lymphatic areas in breast cancer, additional boost doses to limited volumes such as scar areas and nodes, various head and neck cancers and other sites lying within these depths of the surface. The most commonly used beams are those of medium energy.

The basic physics of electron beams used in clinical practice has been described in [Chapter 24](#). This section discusses how these principles may be applied to techniques and problem-solving in electron treatment planning. In the following discussion, the term *treatment planning* is taken to include treatment using single fields; indeed, such treatments constitute the bulk of electron therapy in clinical practice.

When presented with an electron treatment planning problem, it is helpful to use a checklist as an aid, and the following list contains items which should be considered.

---

## 34.2 CHECKLIST FOR ELECTRON TREATMENT PLANNING

*Special Techniques.* Does the problem warrant special techniques such as electron arcing?
